hypocalcaemia is given in **Table 5**. The so called 'idiopathic hypoparathyroidism' is probably autoimmune in origin, and autoantibodies to the calcium sensing receptor have been demonstrated in patients, including Indians.

Table 5: Causes of Hypocalcaemia

PTH absent

- Hereditary hypoparathyroidism
  Idiopathic hypoparathyroidism
  Syndromes associated with hypoparathyroidism
  – DiGeorge syndrome, Kenney Caffey syndrome, etc.
  Polyglandular autoimmune type 1 deficiency
  Autosomal dominant hypocalcaemia hypercalciuria (ADHH)
- Acquired hypoparathyroidism
  Surgery
  Radiation
- Hypomagnesemia

PTH ineffective

- Chronic renal failure
- Active vitamin D lacking
  Decreased dietary intake or sunlight exposure
  Defective metabolism
  – Anticonvulsant therapy
  – Vitamin D dependent rickets type 1
  Active vitamin D ineffective
  – Intestinal malabsorption
  – Vitamin D dependent rickets type II
  Pseudohypoparathyroidism

PTH overwhelmed

- Severe acute hyperphosphatemia
  Tumour lysis
  Acute renal failure
  Rhabdomyolysis

Osteitis fibrosa after parathyroidectomy

Clinical Features of Hypoparathyroidism

Symptoms include muscle spasms including the classic carpopedal spasms, facial grimacing and in extreme cases, laryngeal spasm, convulsions and respiratory arrest. Increased intracranial pressure occurs in some patients with long standing hypocalcaemia, often in association with papilloedema. Mental changes include irritability, depression and psychosis. The QT interval on electrocardiogram may be prolonged. Arrhythmias occur and effect of digitalis may be reduced. Intestinal cramps and chronic malabsorption may occur. Chvostek's and Trousseau's signs may be positive. *Trousseau's sign* is the development of carpal spasm when sphygmomanometer cuff is kept inflated at a pressure 30 mmHg above systolic blood pressure for 2 minutes. *Chvostek's sign* manifests as twitching of facial muscles when the facial nerve is tapped anterior to the ear.

Basal ganglia calcification is common and extrapyramidal syndromes are seen occasionally. Brittle hair and nails and lenticular cataracts can also be present. Alopaecia and candidiasis are associated with autoimmune polyglandular failure.

Treatment

Treatment involves replacement with vitamin D or $1,25(OH)_2D_3$ (calcitriol) combined with calcium supplementation. For most patients, 0.5 to 1 µg calcitriol combined with 1g elemental calcium is satisfactory. The wide dosage range reflects the variation encountered from patient-to-patient; precise regulation of dose is required. Since the urinary calcium excretion is high in these patients, care must be taken to avoid excessive urinary calcium excretion after calcium and vitamin D therapy; otherwise, kidney stones can develop. A thiazide diuretic especially along with a low sodium diet is beneficial in mitigating hypercalciuria and easing the daily management of these patients.

PSEUDOHYPOPARATHYROIDISM

Pseudohypoparathyroidism (PHP) is a hereditary disorder characterised by symptoms and signs of hypoparathyroidism, typically in association with distinctive skeletal and developmental defects. The hypoparathyroidism is due to deficient end organ response to PTH. Hyperplasia of the parathyroids, a response to hormone resistance, causes elevation of PTH levels. Four types of PHP exist; PHP I, subdivided into a and b, PHP II and pseudoPHP (PPHP). PHP Ia, PHP Ib and PHP II have hypocalcaemia and hyperphosphataemia. Pseudo-pseudohypoparathyroidism (PPHP) has normal calcium and phosphorus levels.

Albright's hereditary osteodystrophy (AHO) phenotype is present in PHP Ia and PPHP. AHO phenotype consists of short stature, round face, skeletal anomalies (brachydactyly - short fourth and fifth metacarpals and metatarsals) and heterotopic calcification. Basal ganglia calcification is seen in half of these patients.

Treatment of PHP is similar to that of hypoparathyroidism, except that the doses of vitamin D and calcium are usually lower than those required in true hypoparathyroidism.

10.8 Disorders of Adrenal Glands

Eesh Bhatia, Vijayalakshmi Bhatia

INTRODUCTION

The adrenal glands are divided into two major parts: the cortex and medulla. In this chapter only function and disorders of the adrenal cortex will be considered.

The adrenal cortex secretes three main sets of hormones: the glucocorticoids (cortisol), mineralocorticoids (aldosterone) and androgens (dehydroepiandrosterone, DHEA). The steroid hormones are synthesised from cholesterol through a series of enzymatically catalysed steps. The enzymes are differentially expressed in differing zones of the cortex. Thus, the outermost zona glomerula secretes mineralocorticoids, while the remaining zones (fasiculata and reticularis) secrete cortisol and androgens. A simplified diagram showing the synthesis of the adrenal hormones is shown in **Figure 1**. Cortisol is required for an adequate stress response, intermediary metabolism and immune functions. Aldosterone regulates plasma volume, blood pressure and electrolytes. The adrenal androgens are important for secondary sexual characteristics in females.

Glucocorticoids

The synthesis of cortisol is regulated by adrenocorticotrophin hormone (ACTH), which is synthesised and stored in corticotrophes of the anterior pituitary. The secretion of ACTH is regulated by three influences: positive signals [from hypothalamic hormones, corticotrophin releasing hormone (CRH) and arginine vasopressin (AVP)], extrinsic signals (e.g. stress) and negative feedback by cortisol (**Figure 2**). Through signals from the hypothalamus, ACTH (and hence cortisol) is secreted with a circadian rhythm, being highest in the early morning and lowest at midnight. Cortisol exerts a feedback effect both at the level of the pituitary and the hypothalamus. Thus, a deficiency of cortisol resulting from an enzyme block or destruction of the adrenal gland leads to an elevation of ACTH.

Aldosterone

While aldosterone secretion is increased by ACTH in the short-term, its regulation is predominantly under the effect of the renin-

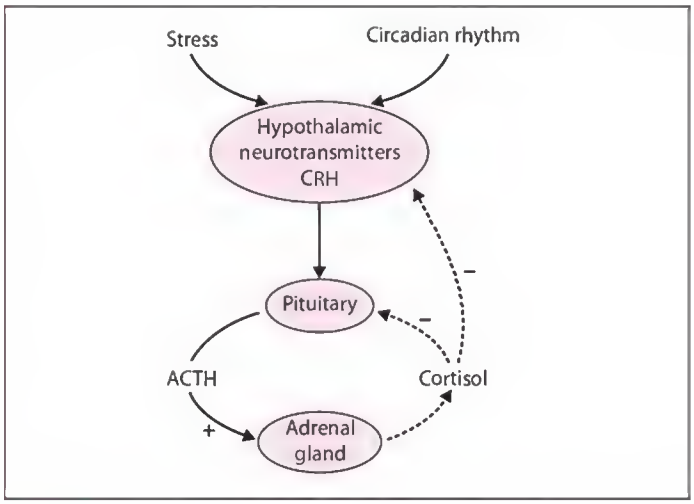

Figure 2: Regulation of hypothalamic-pituitary-adrenal axis.

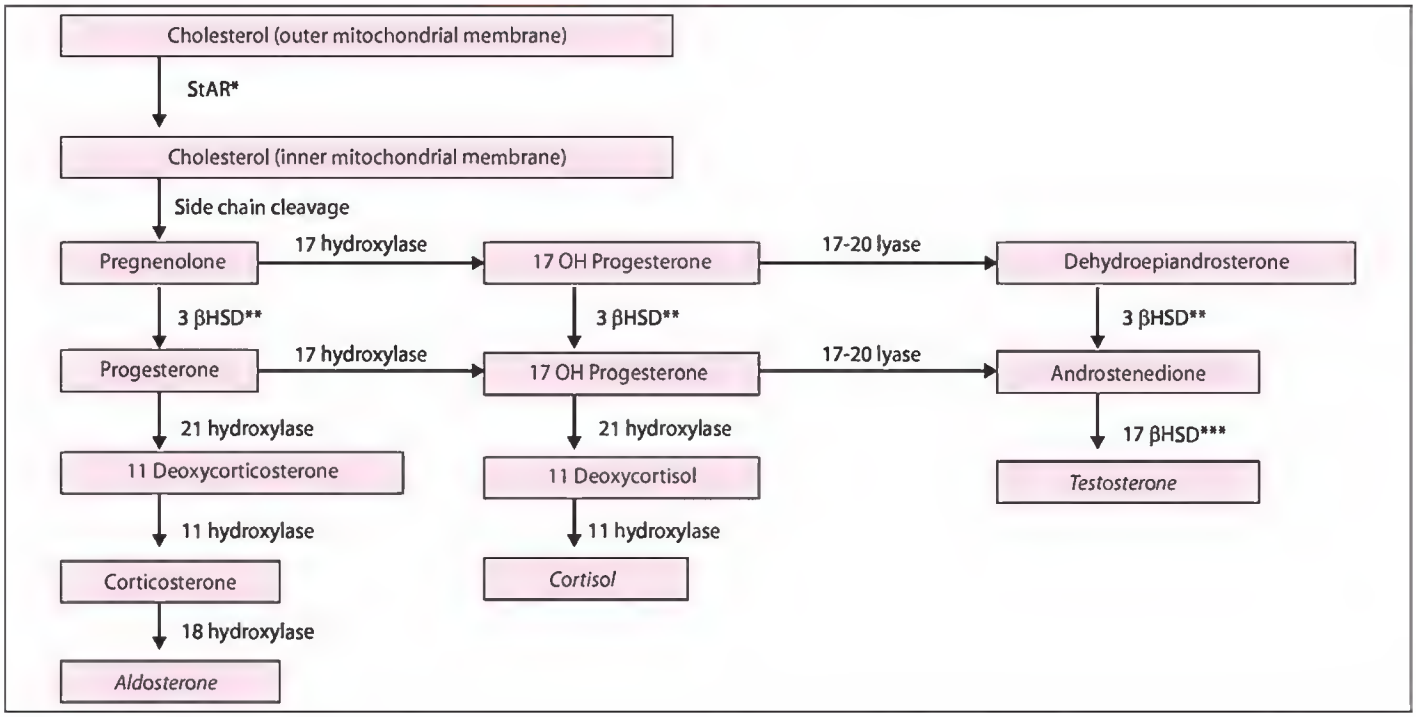

Figure 1: Adrenal steroid hormone synthetic pathways.
(*StAR: steroidogenic acute response protein; **3 βHSD: 3 β-hydroxysteroid dehydrogenase; ***17 βHSD: 17 β-hydroxysteroid dehydrogenase).

angiotensin system (**Figure 3**). A decrease in plasma volume stimulates the secretion of renin from the juxtaglomerulus apparatus cells surrounding the afferent arterioles in the kidney. Renin cleaves angiotensinogen to angiotensin I, which is then converted by the angiotensin converting enzyme (ACE) to angiotensin II. The latter then stimulates aldosterone release, sodium retention and increase in plasma volume. In addition, potassium ions directly stimulate the secretion of aldosterone.

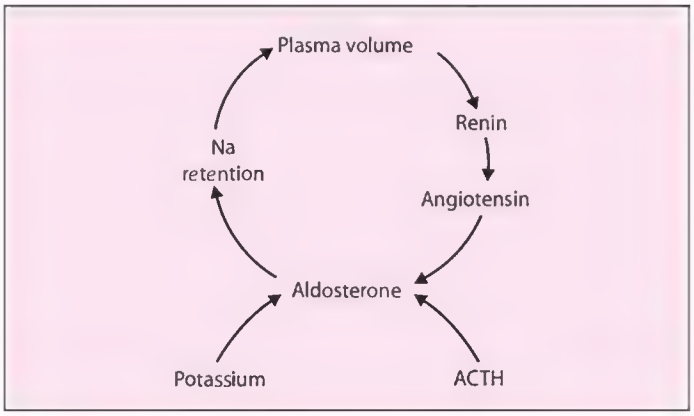

Figure 3: Regulation of aldosterone secretion.

Adrenal Androgens

These include predominantly androstenedione and DHEA. They are relatively weak androgens in comparison to the end product, testosterone and consequently have minimal effects in males. In contrast, in females, over-secretion can lead to virilisation. Adrenal androgens are regulated by ACTH.

HYPERFUNCTION OF THE ADRENAL CORTEX

Cushing's Syndrome

Cushing's syndrome (CS) was named after Sir Harvey Cushing who described the syndrome in 1912. Excessive production of adrenal glucocorticoids results in a characteristic combination of clinical features. Though CS is an uncommon illness, it has a high morbidity and mortality if untreated. This is mainly due to an increased risk of cardiovascular disease as well as infections. Therefore, early diagnosis and treatment is essential.

Aetiology

CS results from an excess of corticosteroids, either endogenous or exogenous. The various causes for CS are shown in **Table 1**. In clinical practice, the excessive use of steroids with glucocorticoid activity is the most common aetiology of CS (exogenous CS). In contrast, CS due to endogenous causes is relatively uncommon.

Certain medical conditions, such as depression, alcoholism, severe obesity and pregnancy may closely mimic clinical features of CS ('pseudo-Cushing's'). This occurs as a result of activation of the hypothalamic-pituitary-adrenal axis and increased secretion of CRH. In such conditions, the levels of cortisol are elevated and other diagnostic tests may also be falsely positive. The features of CS remit with the resolution of the basic medical problem.

Clinical features

The clinical features of CS result from the effects of excessive levels of glucocorticoids on the body. There is an increased body fat, mainly in a truncal distribution: marked central obesity with abdominal fat, rounding of face (moon face) and fat deposition in the neck (buffalo hump). Protein catabolism results in reduced muscle mass of the limbs, thinning of the skin, broad (>1cm) and reddish-violet striae (**Figure 4A**), easy bruising without trauma and proximal muscle weakness. These features are important in distinguishing CS from exogenous obesity. Growth retardation is an important sign in children. Other frequent features, though not specific for CS, include hypertension, glucose intolerance or diabetes, depression and other changes in mood, and hirsutism, oligomenorrhoea or amenorrhoea in women. Fungal skin infections are common. Osteoporosis, most severely affecting the lumbar spine, is frequent and may result in pathological fractures.

Table 1: Aetiology of Cushing's Syndrome

Aetiology	Comment
ACTH-dependent	***80%***
Pituitary adenoma	Most common aetiology of endogenous Cushing's syndrome; mostly microadenomas (<10 mm diameter)
Ectopic ACTH	Small cell carcinoma lung (most common), bronchial adenoma, bronchial and thymic carcinoids, medullary thyroid carcinoma, pheochromocytoma
Ectopic CRH	Rare
ACTH-independent	***20%***
Adrenal adenoma	Small, homogeneous tumour
Adrenal carcinoma	Large adrenal mass, rapid course, poor prognosis
Primary adrenal hyperplasia	May be micronodular or macronodular
Oral or parenteral steroids	Most common aetiology of Cushing's syndrome; cortisol and ACTH are undetectable (in case of most synthetic steroids)

CRH = Corticotrophin releosing hormone; ACTH = Adrenocorticotrophin hormone. The common oetiologies of endogenous Cushing's syndrome ore pituitory odenomo, ectopic Cushing's syndrome ond odrenol tumours.

Specific aetiologies of CS have characteristic clinical features. Cushing's disease (CD) is more common in females of the age groups 20 to 40 years and the course is often slowly progressive. Hyperpigmentation may be noted. Ectopic ACTH syndrome, due to a slow growing malignant tumours, such as small cell carcinoma lung present with weight loss, marked hyperpigmentation, hypokalaemia and muscle weakness. In contrast, ectopic ACTH syndrome due to a slow growing tumours such as bronchial carcinoid or cortisol-secreting adrenal adenoma may be indistinguishable from CD. In contrast, adrenal carcinomas have a rapid course, palpable abdominal mass and, in case of females, may lead to virilisation.

Diagnostic evaluation

The diagnostic evaluation of CS is done in two parts. First, the diagnosis is confirmed and then the aetiology determined (**Figure 5**). To confirm the diagnosis of CS, cortisol levels in serum, urine or saliva are measured. Alternatively, testing for the lack of suppression of serum or urine cortisol after supraphysiological doses of dexamethasone is utilised. Unfortunately, no single test is more than 95% sensitive, and hence a battery of tests needs to be conducted. Screening tests include the overnight 1 mg dexamethasone suppression test, 24-hour urine cortisol and midnight salivary cortisol (not commonly available in India) (**Figure 5**). The 2-day low-dose dexamethasone

Figures 4A to C: Clinical features of adrenocortical disorders. (A) Broad violaceous striae in a patient with Cushing's disease; (B) Addison's disease: hyperpigmentation of the hands; (C) Addison's disease: hyperpigmentation of gums and buccal mucosa).

suppression test (0.5 mg 6 hourly over 48 hours followed by serum cortisol measurement) is often used as a confirmatory test. Recent guidelines suggest that at least 2 of the above 4 tests need to be positive to diagnose CS.

To determine the aetiology of CS, plasma ACTH levels are measured. In case plasma ACTH is undetectable (<10 pg/mL) a CT scan of the adrenal glands is performed for an adrenal tumour (**Figures 6A to C**). If ACTH is elevated or normal, the most likely aetiologies are a pituitary adenoma or ectopic ACTH syndrome. In this case, an MRI of the pituitary with contrast is performed. In case a pituitary adenoma is clearly visible no further tests are required (**Figure 6**). However, if no tumour is seen, the best option is to proceed to inferior petrosal sinus sampling to directly measure ACTH secretion from the pituitary, preferably after injecting CRH intravenously. If ACTH is higher in either petrosal sinus compared to a peripheral vein, this suggests a pituitary aetiology. On the other hand, if there is no gradient it indicates an ectopic ACTH source. A CT of the chest and abdomen can then be performed to visualise any tumour. Alternatively, since petrosal sinus sampling can only be performed in advanced referral centres, in many centres if a

pituitary MRI does not show an adenoma, a CT scan of the chest/abdomen is directly performed. Detailed evaluation of CS is a specialised task and is best carried out by an experienced endocrinologist in a referral hospital.

Management

Cushing's disease

Different modes of treatment include trans-sphenoidal resection of the tumour, bilateral adrenalectomy, focused radiotherapy and medical treatment with drugs which block adrenal steroidogenesis. The primary treatment modality is trans-sphenoidal surgery with an operating microscope using a sub-labial or transnasal approach. This should always be performed by a neurosurgeon experienced in this technique so as to obtain optimum results. Since most patients harbour microadenomas (size <10 mm), a complete resection is feasible without damaging the normal pituitary. Immediate remission rates are close to 70% to 90% while long-term remission is 60% to 70% in most centres. Undetectable postoperative cortisol (< 1.8 µg/dL) shortly after surgery suggests greater chance of long-term remission. Patients need to be on life-long follow-up since relapses of the disease (15% to 20% over 10 years), as well as new pituitary hormone deficiencies, may occur at any time point. In case of failure of initial surgery or relapse, a repeat trans-sphenoidal surgery is attempted or bilateral adrenalectomy or pituitary radiotherapy can be utilised.

Bilateral adrenalectomy is nearly always successful in the treatment of CD. However, the morbidity and mortality of the surgery is significant and life-long replacement with glucocorticoids and mineralocorticoids is necessary. In addition, the pituitary tumour may increase in size after surgery and lead to elevated ACTH, hyperpigmentation and local tumour invasion (Nelson's syndrome) in nearly 15% to 20%. Fractionated external beam radiotherapy or stereotactic radiosurgery is effective in reducing ACTH levels but the effect is slow. Control can be achieved in approximately 50% to 60% within 5 years. Side effects such as hypopituitarism are frequent and occasionally damage to adjoining structures can occur. Finally, medical therapy with drugs such as ketoconazole or metyrapone (not available in India) can be utilised to block adrenal steroidogenesis. While the drugs are effective, they have numerous side-effects and are frequently used for only for short-term control, such a prior to surgery or awaiting the results of radiotherapy.

Other Aetiologies

The treatment for ectopic ACTH syndrome involves surgical removal of the neoplasm or, if not feasible, chemotherapy or radiotherapy of the primary tumour. Adrenal adenomas are cured after unilateral adrenalectomy. In contrast, the prognosis of adrenal carcinoma is poor. Treatment involves resection of the tumour and then treatment with mitotane (o,p'-DDD), an adrenolytic agent.

PRIMARY ALDOSTERONISM

Excessive aldosterone production by the adrenal cortex results in a syndrome characterised by hypertension, hypokalaemia and metabolic alkalosis, known as primary aldosteronism (PA). This needs to be differentiated from the more common secondary aldosteronism, where the stimulus to aldosterone production is an increased rennin secretion due to causes such renal artery stenosis or malignant hypertension.

Prevalence

Earlier studies reported that less than 1% of patients with hypertension who were screened by presence of hypokalaemia had PA. More recently, studies in certain series of hypertensive patients, suggest that more than 10% are secondary to PA.

Aetiology

Causes of PA are shown in **Table 2**. An important treatable cause of PA is a unilateral aldosterone-producing adenoma (Conn's

Table 2: Aetiology of Aldosteronism

Aetiology	Comment
Primary	
Adenoma	Small homogeneous tumour
Carcinoma	Very uncommon
Hyperplasia	Common; may be unilateral or bilateral
Familial hyperaldosteronism (types I and II)	Autosomal dominant; type I is also known as glucocorticoid remediable aldosteronism
Miscellaneous (ingestion of licorice)	Both aldosterone and PRA are low
Secondary	
Malignant hypertension, renal artery stenosis	Both PRA and aldosterone elevated

PRA = Plasma rennin activity; aldosterone secreting adenoma and adrenal hyperplasia are most frequent causes. All other aetiologies are rare.

syndrome). Such adenomas are commonly unilateral, benign and less than 2 cm in diameter. Aldosterone secreting carcinomas are very rare. Cortical nodular hyperplasia of the adrenal gland is far more common than an adenoma. The hyperplasia may be unilateral or bilateral. Hereditary forms of hyperaldosteronism (familial aldosteronism types I and II) are autosomal dominant disorders. The former is also known as glucocorticoid-remediable aldosteronism and can be ameliorated by small doses of glucocorticoids.

Clinical Features

Patients present with sustained hypertension, which may be severe. The hypertension may require two or more drugs for its control. Hypokalaemia and/or increased urine potassium excretion is found in one-third of patients with PA (more commonly in adenomas). Hypokalaemia may be associated with muscle weakness (and in severe cases can lead to periodic paralysis), polyuria and mild hyperglycaemia. The frequency of cardiovascular accidents and hypertensive cardiomyopathy are higher in PA when compared to essential hypertension, probably due to the adverse effects of high aldosterone on target tissue.

Diagnosis

The diagnosis should be suspected in patients with severe hypertension, poor control with 2 or more drugs, onset <30 years, family history of early-onset hypertension, associated hypokalaemia or association with early cardiovascular events. A flow chart for confirming the diagnosis is shown in **Figure 7**. The best screening test is the ratio of plasma aldosterone (in ng/mL)/plasma renin activity (in ng/mL/hour). Before performing this test drugs such as diuretics, angiotensin converting enzyme inhibitors and angiotensin receptor blockers should be stopped for four weeks. An elevated value (>30) is highly suggestive of PA. A high ratio should be followed a confirmatory test for PA, which aims to assess non-suppression of aldosterone after salt loading and increasing plasma volume. Once PA is confirmed, a CT scan of the adrenals is performed. In case a single adenoma is visualised, and the patient is <40 years of age, surgery can be advised. In all other cases (bilateral adenomas, hyperplasia) if surgery is desired, it is recommended that bilateral adrenal venous sampling for aldosterone should be performed to determine the side of aldosterone production. This last test carries some risk of haemorrhage into the adrenal gland and requires special expertise.

Management

In case of adenoma or unilateral hyperplasia, a unilateral adrenalectomy, performed laparoscopically, improves both hypokalaemia and hypertension. However, hypertension which is long-standing, or requiring more than 2 drugs for control prior to surgery, may persist though control will improve. If medical

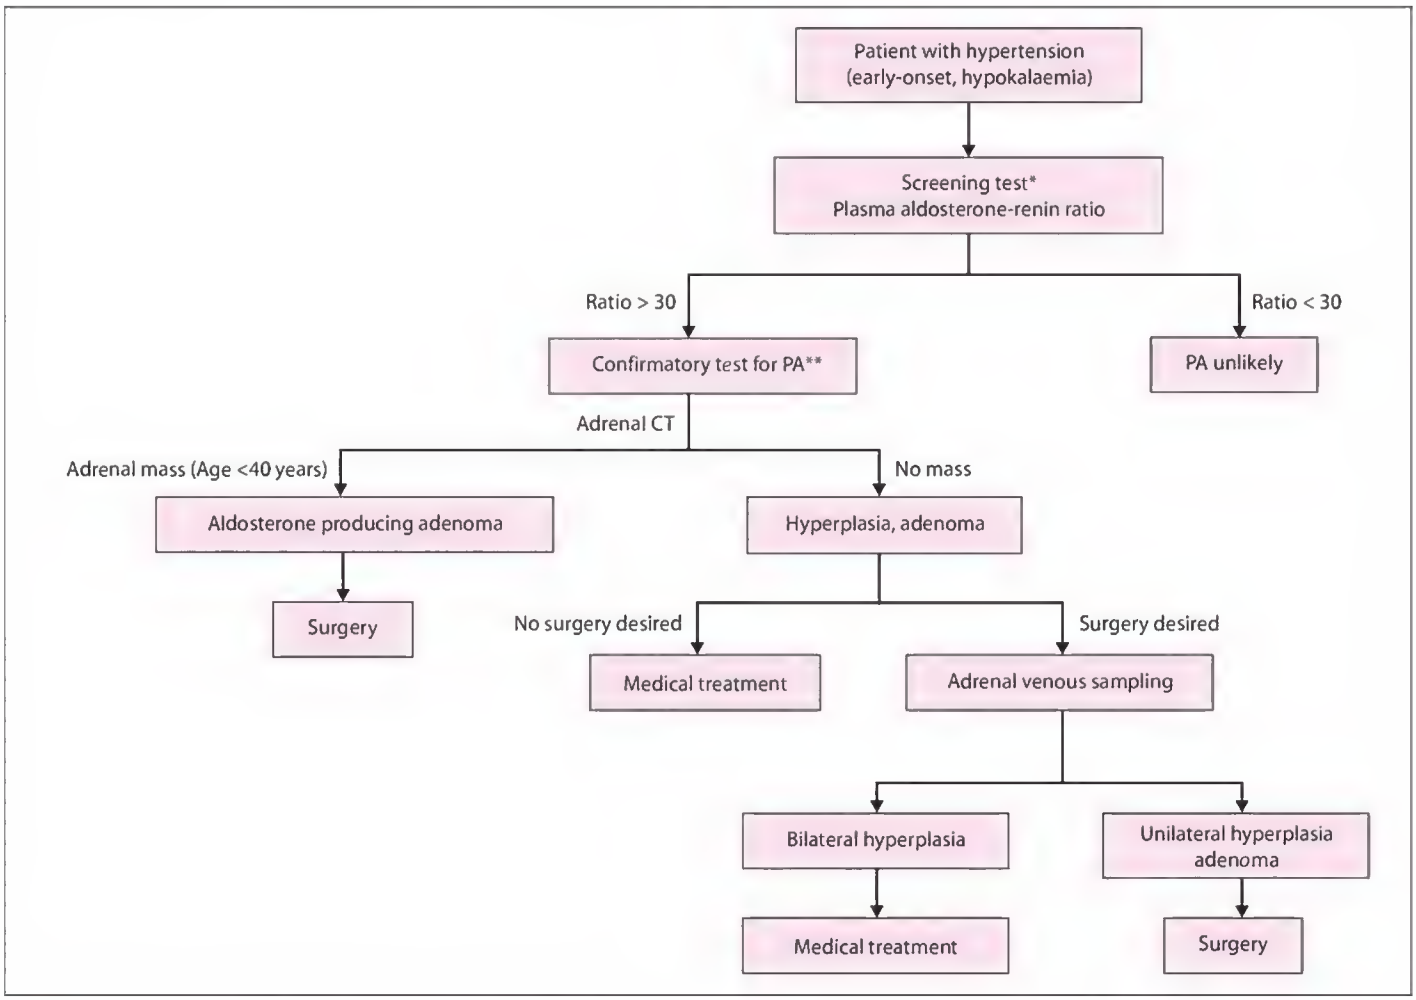

Figure 7: Approach to a patient with suspected primary aldosteronism.

**Screening test: Morning plasma aldosterone (measured in ng/mL) and plasma renin activity (measured in ng/mg/hour) ratio >30; **Confirmatory test: Infusion of 2 litres of 0.9% saline over 4 hours; serum aldosterone >10 ng/dL. (not to be performed in uncontrolled hypertension or cardiac impairment).*

therapy (bilateral lesions, patient preference) is opted for, mineralocorticoids receptor blockers (spironolactone, eplerenone) and potassium-sparing diuretics (triamterene, amiloride) are effective.

ASYMPTOMATIC ADRENAL MASSES

In recent years, due to the easy availability of ultrasound and CT imaging, adrenal masses are often detected incidentally ('incidentaloma'). In autopsy studies, the frequency of adrenal adenomas is 6%, with an increasing prevalence with age. The prevalence of adrenal carcinoma, however, is low. The management of such masses depends upon the evidence of malignancy at other sites, the functional activity of the tumours and their size and radiological characteristics (**Figure 8**).

For the evaluation of such masses, screening for functional tumours (urine or plasma metanephrines, overnight 1 mg dexamethasone suppression test for cortisol) should be performed. In addition, in case the patient is hypertensive, the ratio of plasma aldosterone to plasma renin should be measured. If the mass is found to be functionally active, it should be undergo resection. In case it is non-functional, in subjects with evidence of malignancy elsewhere, fine needle aspiration cytology (FNAC) to rule out a metastatic lesion should be performed. In addition, if an infective aetiology (tuberculosis, histoplasmosis) is suspected, FNAC and other relevant tests should be undertaken. In other cases the radiological characteristics of the mass should be considered. Masses >4 cm in diameter, having an irregular margin, heterogeneity or non-enhanced CT scan attenuation >10 Hounsfield units have a greater chance of malignancy and should be removed. Other tumours can be followed up by CT scan and by functional assays after six months and then annually for 4 to 5 years for any change in size. If their size increases they should undergo surgery.

ADRENAL INSUFFICIENCY

Adrenal insufficiency (AI) can result from either destruction of both adrenal cortices (primary AI) or from a deficiency of ACTH (secondary AI). Patients with primary AI (Addison's disease) may present acutely in shock (adrenal crises) or more indolently, with increased pigmentation, weakness and postural hypotension. Once diagnosed, the disease has an excellent prognosis with appropriate replacement of steroids and most patients have a normal life-expectancy.

Prevalence

The overall prevalence of AI (primary, secondary due to hypothalamic and pituitary tumours, and congenital adrenal hyperplasia) is approximately 5 per 10,000. The prevalence of Addison's disease in Western countries, primarily of autoimmune aetiology, is 125 to 280 per million. However, its prevalence in India is not known.

Aetiology

AI develops after approximately 90% of the adrenal cortex is destroyed. In Western countries the most common aetiology is an autoimmune destruction of the adrenal cortex (**Table 3**). However, in developing countries such as India, infectious disorders such as tuberculosis constitute nearly half the cases. Less frequently encountered are fungal infections, mainly histoplasmosis.

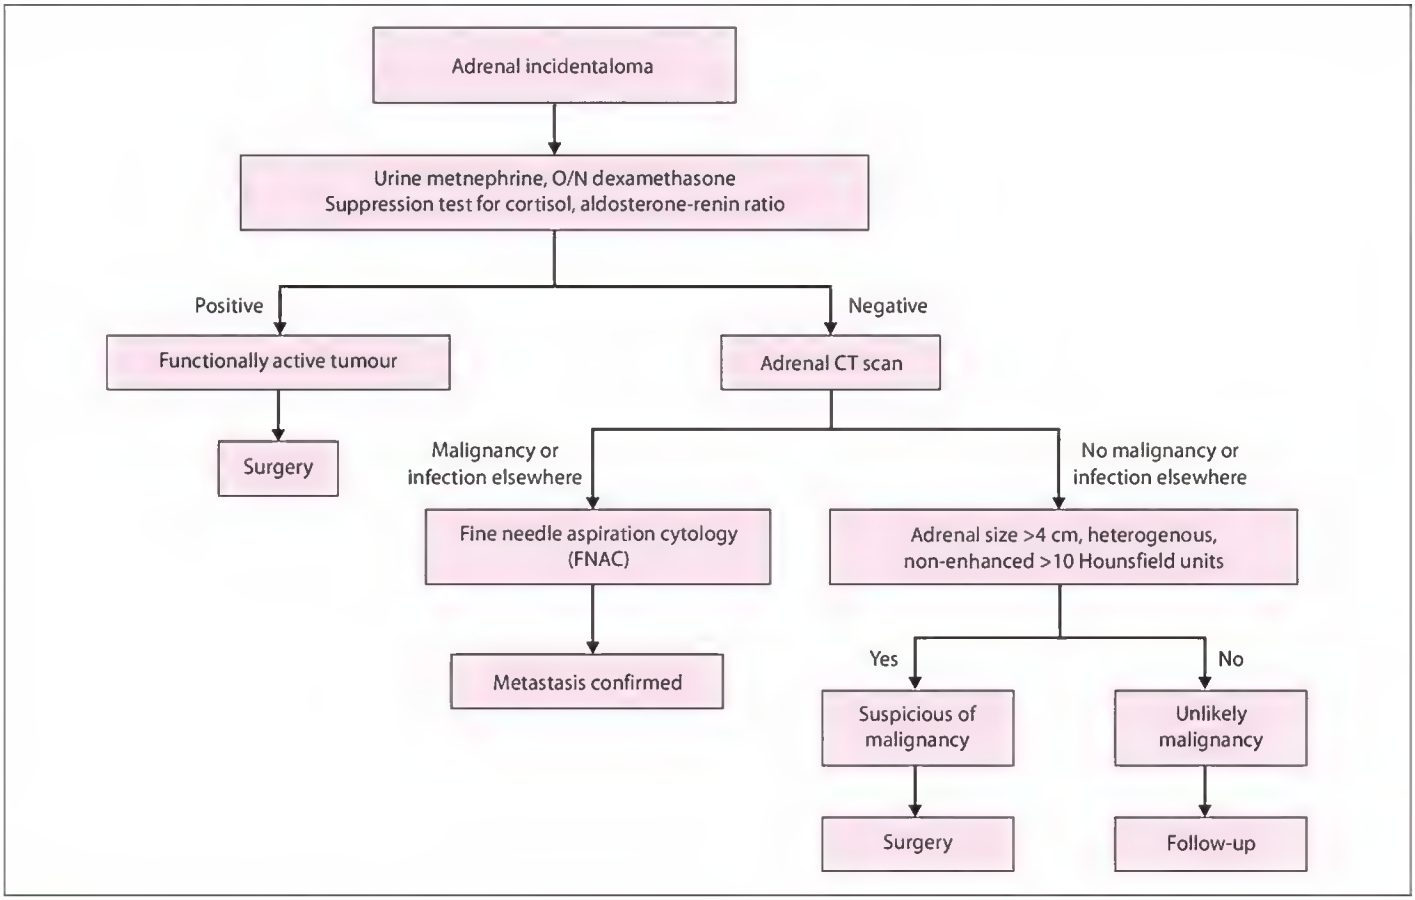

Figure 8: Approach to a patient with incidentally detected adrenal mass.

Table 3: Aetiology of Adrenal Insufficiency

Aetiology	Comment
Primary	
Autoimmune	Frequency 80-90% in industrialised nations, approximately 50% in Indians
Infections	
Tuberculosis	Frequency 50% in Indians
Fungal	Histoplasmosis
Viral (HIV-AIDS)	Cytomegalovirus
Adrenomyeloleucodystrophy and adrenoleukodystrophy	X-linked, males involved, associated neurological degeneration, accumulation of very long chain fatty acids
Malignancy	Lymphoma, metastases
Infiltration	Haemochromatosis, amyloidosis, sarcoidosis
Haemorrhage	Septicaemia, antiphospholipid syndrome
Secondary	
Pituitary and hypothalamic tumours, infiltration, surgery, radiation, haemorrhage	–
Steroid withdrawal	Common after prolonged supra-physiological steroids usage

Autoimmune and tubercular aetiologies are equally common in Indians; all other aetiologies of primary adrenal insufficiency are uncommon.

Autoimmune AI may occur independently or be associated with other disorders of organ-specific autoimmunity, (known as autoimmune polyglandular syndromes, APS). APS type 1 consists of mucocutaneous candidiasis, hypoparathyroidism and AI. Multiple other autoimmune disorders are frequent. APS type 1 results from recessive mutations in the autoimmune regulator gene (AIRE) which codes for a transcription factor important for central tolerance. APS type 2 consists of AI, autoimmune thyroid disease and/or type 1 diabetes. It is far more frequent than APS 1.

Clinical Features

Acute AI can result from overwhelming sepsis, most commonly due to *Neisseria meningitides* (Waterhouse-Friderichsen syndrome), oral anti-coagulants, bilateral thrombosis of the adrenal veins or the phospholipid syndrome. Patients present with abdominal pain and unexplained shock which is unresponsive to fluids or vasoconstrictors, hyperkalaemia, hyponatraemia and metabolic acidosis.

Chronic AI is far more common than acute adrenal failure. Patients present with lassitude, weakness, weight loss and postural hypotension of variable duration. Abdominal complaints (vomiting, pain) may be prominent. Hyperpigmentation of the skin (palm creases, nipples, and nails) and oral mucosa (gums, buccal mucosa, and tongue) is characteristic (**Figures 4B and C**). In patients with an autoimmune aetiology, skin pigmentation and vitiligo may coexist. Evidence of other autoimmune disorders (hypothyroidism, Graves' disease, premature ovarian failure, coeliac disease) may be present or develop subsequently. Androgen deficiency may be apparent in females leading to loss of pubic and axillary hair and decrease in libido. Some patients may present in acute adrenal crises after a predisposing illness or stress.

Diagnosis

Routine tests reveal hyponatraemia, hyperkalaemia and mild metabolic acidosis. The diagnosis is confirmed by the measurement of serum cortisol after stimulation with 250 ug of intramuscular synthetic aqueous 1 to 24 ACTH (Synacthen®) (**Figure 9**). A serum cortisol <18 µg/dL, measured 30 or 60 minutes after ACTH injection, indicates inadequate adrenal

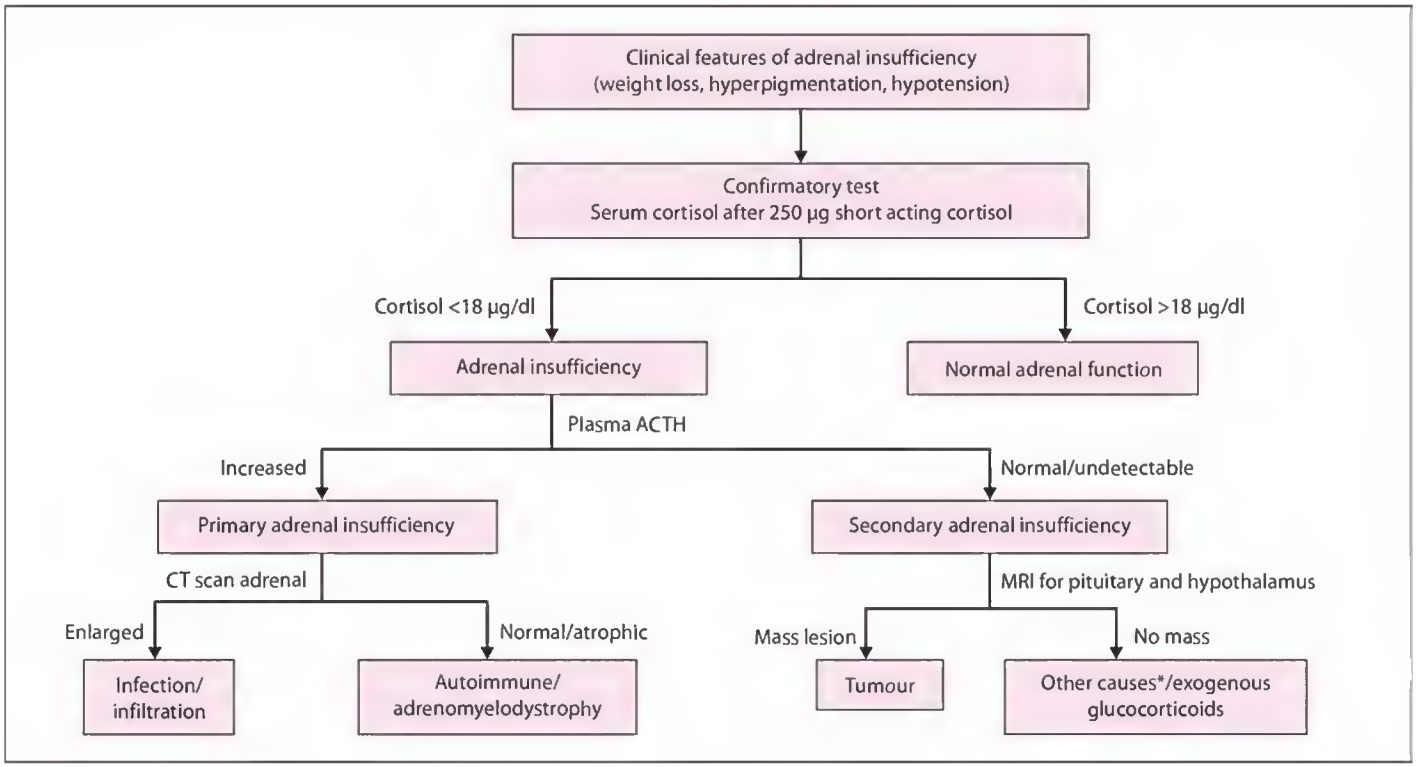

Figure 9: Approach to a patient with adrenal insufficiency.

** Other causes: see **Table 3***

function. A simultaneous plasma ACTH sample is elevated, usually >100 pg/mL. To determine the aetiology of Addison's disease, a CT scan or MRI of the adrenal glands is performed. In the case of infections such as tuberculosis and histoplasmosis, one or both adrenal glands are usually enlarged, heterogeneous and with calcifications. In case of normal or atrophic glands, adrenal antibodies may be measured, but this test is not available in India. Thyroid function should be tested at onset in patients suspected to have an autoimmune aetiology.

Management

Acute AI

If strongly suspected, it is not necessary to confirm the diagnosis of the illness prior to starting treatment when the patient is critically ill. A random sample for cortisol can be obtained and parenteral fluids and steroids are immediately started. Replacement with normal saline or dextrose-saline should be started at a fast rate, and monitored closely. Parenteral hydrocortisone 100 mg intravenously and should be followed by 8 to 10 mg/hour hydrocortisone by continuous intravenous infusion. In case it is not feasible to give intravenous steroids by infusion, intravenous or intramuscular hydrocortisone should be given in a dose of 50 mg 6 hourly. The precipitating cause must be sought and appropriate treatment, e.g. antibiotics should be instituted. Once the patient is recovering the dose of hydrocortisone can be gradually tapered and oral hydrocortisone or prednisolone can be substituted. Once the dose of hydrocortisone is <50 mg/day, fludrocortisone in a daily dose of 0.1 mg should be added.

Chronic AI

Patients with long-standing AI require replacement with both glucocorticoids and mineralocorticoids. The glucocorticoids commonly used are hydrocortisone (12 to 15 mg/m^2 in two or three divided doses) or prednisolone (2.5 to 5 mg/day in two divided doses). The larger portion of the steroid is taken as early in the morning as feasible and second dose at 2 to 4 pm. Hydrocortisone tablets may be difficult to procure in some cities. The dose of steroids should be adjusted depending upon features of under-replacement (weight loss, lack of energy and increasing pigmentation) or over-treatment (weight gain, striae, and hypertension). The dose of fludrocortisone is 0.05 to 2.5 mg/day taken as a single morning dose. The dose can be adjusted depending upon blood pressure, oedema and electrolytes. A normal salt intake is advised, but salt and fludrocortisone dose may need to be increased in summer months. Replacement with adrenal androgen, DHEA, may be useful in some women with features of androgen deficiency such as dry itchy skin and loss of libido.

The aetiology of AI should be sought and treated. While there is no specific treatment known to reverse features in patients with an autoimmune (idiopathic) aetiology, these patients need to be tested at onset and subsequently at yearly intervals for development of autoimmune thyroid disorders (hypothyroidism or Graves' disease). Other organ-specific autoimmune disorders develop less frequently, but should be kept in mind. Infectious causes (tuberculosis, histoplasmosis) should be appropriately treated, though recovery of adrenal function after treatment is unlikely.

Stress doses: Stress doses should be emphasised in all patients with AI. In less severe forms of stress (fever, infections and surgery under local anaesthesia) the dose of the glucocorticoid should be increased to 2 to 3 times of daily dose for the duration of the stress. In case of severe stress (e.g. surgery under general anaesthesia, severe infections, major accident) higher doses of glucocorticoids should be provided parenterally. A dose of hydrocortisone 150 to 200 mg/day in four equal doses intramuscular or intravenous should be given initially, and gradually tapered when the stress subsides. All patients should be provided an identification card to keep, which provides information on their disease and emergency measures in case of crises. Their family members should be taught to inject hydrocortisone or dexamethasone if required.

Glucocorticoid-Induced Adrenocortical Deficiency

Prolonged glucocorticoid use, whether for therapeutic reasons, intention abuse, or inadvertently due to spurious admixture with other drugs, leads to suppression of the hypothalamo-pituitary-adrenal (HPA) axis and adrenal cortex. This is most likely to occur with use of more potent glucocorticoids which have longer duration of action, e.g. dexamethasone, high doses, prolonged use and oral/parenteral administration. It is unlikely after inhalational or topical steroids, though rare instances of adrenal insufficiency have been noted. The use of prednisolone in doses of more thant 20 to 30 mg/day for more thant 1 week, or in lower doses for less thant 1 month, is likely to lead to significant suppression. However, glucocorticoids in physiological amounts (prednisolone ≤5 mg/day, hydro-cortisone 15 to 20 mg/day), especially if given early morning, are unlikely to lead to adrenal cortical suppression.

A small proportion of patients who receive prolonged high doses of glucocorticoids may develop clinically apparent secondary AI if the steroids are withdrawn abruptly. This is most likely to occur in the setting of acute stress such as infection, serious injury or major surgery. The AI occurs due to suppressed levels of ACTH, as well as due to an inability of the atrophied adrenal gland to respond to ACTH (**Figure 2**). Such patients, despite having certain physical features of CS due to chronic steroid excess, present with many of the signs and symptoms seen in primary AI. However, they are not hyperpigmented. Serum cortisol is low or undetectable (except if the patient is ingesting hydrocortisone or prednisolone) and plasma ACTH is also suppressed. The response of serum cortisol after injecting 250 ug soluble 1 to 24 ACTH (rapid ACTH stimulation test), or after insulin hypoglycaemia, is subnormal. The former test can be used to monitor the recovery of the HPA axis.

As a general principle, the smallest dose of glucocorticoids should be used for the shortest period of time to obtain a required therapeutic effect. The steroid should be given as a single dose in the morning or on alternate days, if feasible. It should be tapered to physiological doses (≤5 mg/day prednisolone or 10 to 12.5 mg/m^2 hydrocortisone/day) as soon as feasible to allow the HPA axis to recover and then stopped. The problems which may arise on tapering glucocorticoids include flare up of the original illness and adrenal insufficiency. Overall recovery of the HPA axis may take weeks to >1 year and is longer with a higher dose and

longer duration of treatment. For higher doses given for prolonged periods, it is recommended that glucocorticoid be withdrawn over weeks or months. The dose can be reduced weekly or two weekly by 10 mg if the daily dose of prednisolone is >30 mg, and 5 mg once the daily dose is <30 mg. After a dose of <20 mg/day is reached slower reduction, e.g. by 2.5 mg every 2 to 4 weeks, can be done. After reaching physiological doses, the glucocorticoid can be given on alternate days, thus allowing the HPA axis to recover faster. At this time, the adrenal recovery should be studied by measuring the basal cortisol or more accurately by using the short ACTH stimulation test (described earlier). An 8 am serum cortisol or stimulated cortisol of >20 ug/dL, suggests normal adrenal function and glucocorticoids can be discontinued. Testing may have to be done on more than one occasion until recovery is documented.

CONGENITAL ADRENAL HYPERPLASIA

As discussed earlier, the production of adrenal steroids requires numerous enzymes, several belonging to the cytochrome P450 family (**see Figure 1**). When any of these enzymes is deficient (e.g. due to a genetic mutation), cortisol production is decreased and there is release of the negative feedback on the corticotrophs of the pituitary. The resulting elevated ACTH drives growth of the adrenal glands (causing hyperplasia) as well as hyperfunction of several enzymes in steroid synthesis. Biochemical precursors proximal to the enzymatic block are massively elevated and shunted into the pathways which may have a block, such as the mineralocorticoid or androgen pathways. This gives rise to typical clinical characteristics as well as a diagnostic steroid profiles in serum and urine.

21-Hydroxylase Deficiency

Deletions or mutations in the CYP 21A gene encoding the 21 hydroxylase enzyme are responsible for 95% of congenital adrenal hyperplasia (CAH). It is a relatively common genetic disorder, with a worldwide prevalence of approximately 1:15,000 births. It is characterised by deficiency of cortisol. Proximal to the block, the elevated serum precursor 17 hydroxyprogesterone (17 OHP), is shunted into the androgen pathway to produce excess of dehydroepiandrosterone, androstenedione and testosterone. The latter brings about virilisation of the female foetus *in utero*, and virilisation in both genders postnatally. Thus, the labia in a female newborn may resemble a scrotum, the clitoris may resemble a small penis, and the perineum may be partially or completely fused, obliterating the external vaginal opening. In the most severe degree of masculinisation, the genitalia will resemble those of a completely normal male baby but with apparent bilateral cryptorchidism. Pigmentation can be appreciated on the genitalia and nipples in addition to the skin. If the enzymatic block is severe, features of mineralocorticoid deficiency will also be present (salt-wasting variety). In contrast, the simple virilising type does not affect mineralocorticoid production much.

Newborn female babies can be diagnosed at birth, due to the abnormal genitalia. However, male babies will only come to light during salt wasting episodes which may start from about 1 week of age. These are characterised by diarrhoea, vomiting, lethargy and hypotension and may be mistaken for ordinary diarrhoeal episodes. The typical electrolyte pattern of hyponatraemia, hyperkalaemia and metabolic acidosis should alert the physician. Untreated, salt-wasting CAH is associated with morbidity and mortality. Further, in childhood, the effects of postnatal adrenal androgen production result in peripheral precocious puberty in boys and heterosexual precocity or virilisation in a girl. Certain mutations of the CYP 21A gene give rise to a mild variety of disease called late onset congenital adrenal hyperplasia (LOCAH). This presents in the peripuberted age with hirsutism, menstrual irregularity, anovulation and, less commonly, male pattern scalp hair loss, muscular habitus and clitoromegaly.

Diagnosis

The diagnosis of classic 21 hydroxylase deficiency is made by measurement of serum 17 OHP or its urinary metabolite pregnanetriol. Serum 17 OHP is >10,000 ng/dL and plasma renin activity is elevated. Supportive tests include electrolytes and blood gas analysis. LOCAH on the after hand, has lower levels of 17 OHP, necessitating stimulation by ACTH to establish a firm diagnosis. Basal 17 OHP (done at 8 to 9 AM) is usually > 200 ng/dL and stimulated 17 OHP ranges from 1500 to 2000 ng/dL.

Treatment

This is aimed at replacing cortisol, with hydrocortisone or prednisolone, which will also bring about the suppression of precursors and thereby androgen formation. Simultaneously, fludrocortisone is administered. Added salt must be provided in the first year of life, till the baby starts getting salt from table foods.

Treatment of LOCAH includes glucocorticoids for suppressing androgen and bringing about ovulation. Spironolactone may be added to give better relief of hirsutism and estrogen – progesterone pills may be needed for regularisation of menstrual cycles.

Other CAH

P450 oxido-reductase deficiency is the latest in the list of P450 enzyme mutations that can cause a disorder of sexual differentiation. Other enzyme deficiencies include 3 β hydroxysteroid dehydrogenase, 11 hydroxylase and 17 hydroxylase. The last two may cause hypertension as well cortisol deficiency.

10.9 Disorders of Puberty

AC Ammini

INTRODUCTION

Puberty is the transitional period between childhood and adulthood when rapid linear growth, sexual maturation and reproduction capacity are attained. It is an extremely important phase in the physical and psychosocial development for both girls and boys. Initiation of puberty is brought about by a complex series of inter-related endocrine events leading to activation of the hypothalamo-pituitary-gonadal axis (**Figures 1 and 2**).

There has been a positive secular trend in adult height since mid 19th century in most European countries. Adult height is increased by 1.5 to 2 cm per decade during this period up to 1960. This was believed to be due to improvements in nutrition, hygiene and health care. During this period, age at menarche decreased from 17 years to 13 years.

Energy balance exerts a critical influence on puberty and reproductive functions. The neuroendocrine mechanisms involved in the coupling between energy homeostasis and puberty onset are not clear. This possibly involves several metabolic hormones and neuropeptides, which involve/interact at the brain/hypothalamic centres regulating reproduction. Some of the metabolic hormones could be insulin, leptin and ghrelin. These may act as links between energy store, like adipose tissue and reproductive system, indicating if adequate energy stores are present for normal reproductive functions.

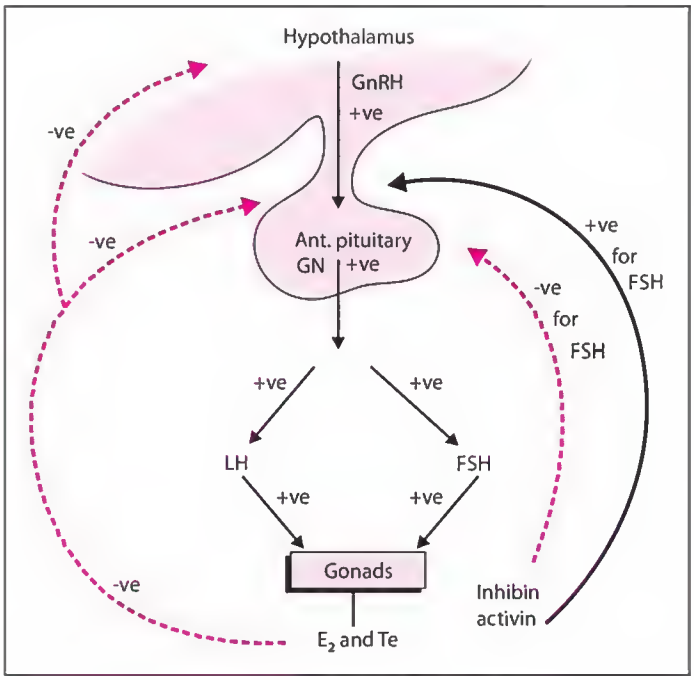

Figure 1: LH, FSH feedback mechanism.

E_2 = Oestradiol; Te = Testosterone; LH = Luteinising hormone; FSH = Follicle stimulating hormone; GN = Gonadotrophin.

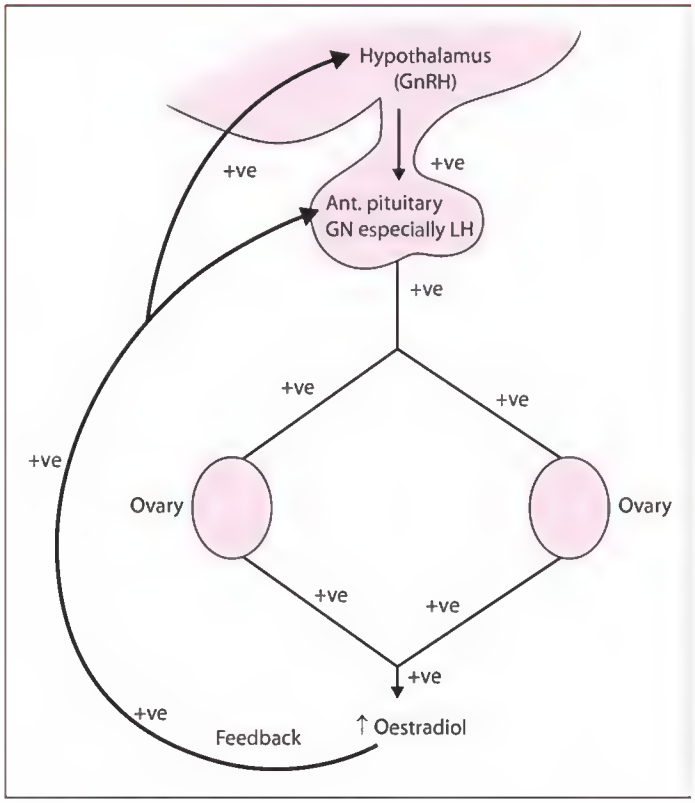

Figure 2: Midcycle positive feedback effect of oestradiol on hypothalamic-anterior pituitary axis.

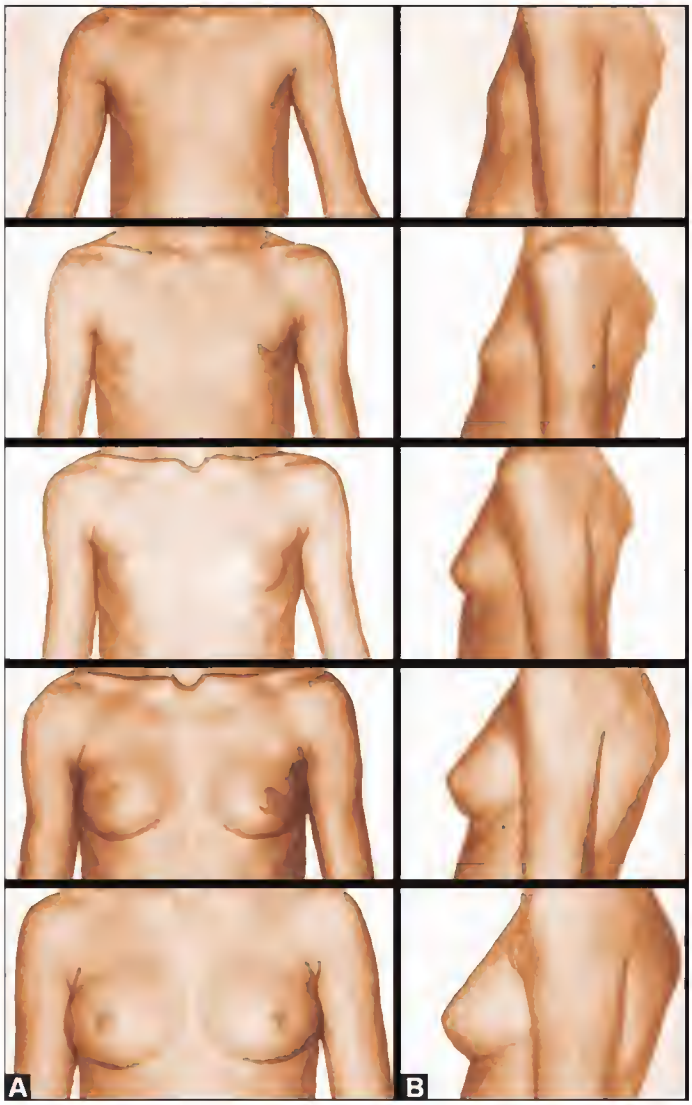
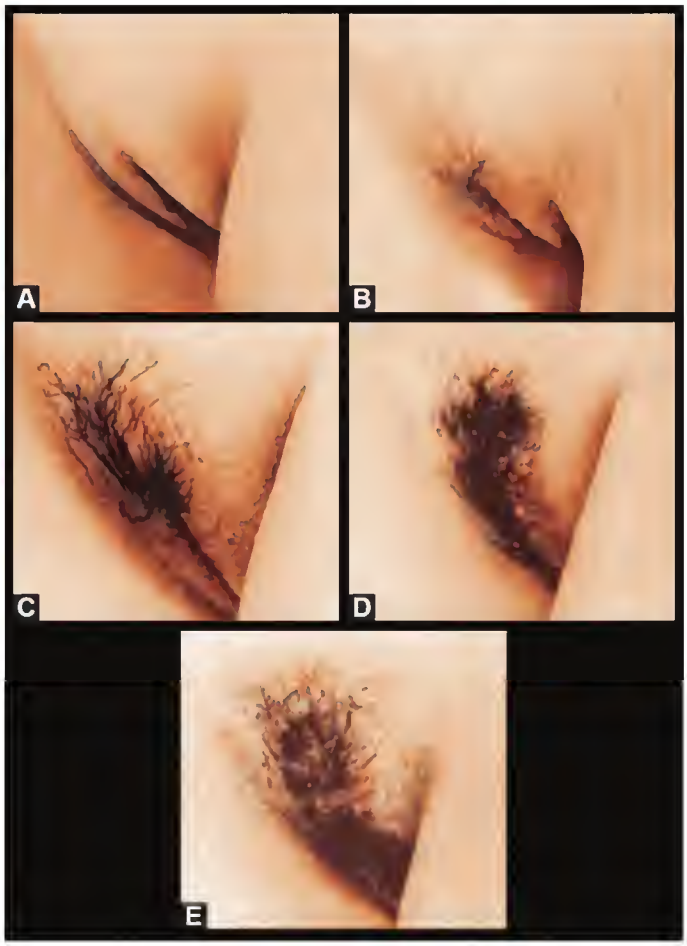
Kisspeptin (product of Kiss 1 gene) acting through its receptor (G protein coupled receptor 54) has been shown to have an important role in the regulation of the gonadotrophic axis and reproduction. Mutations (in human) and deletions (genetically targeted mutations in mice) of either Kiss 1 or Kiss 1 receptor (GPR54) cause hypogonadotrophic hypogonadism. Neurones that express Kiss 1/Kisspeptin are found in discrete nuclei in the hypothalamus and other brain areas. Kisspeptin neurones stimulate gonadotrophin-releasing hormone (GnRH) neurones, the final common pathway, through which brain regulates reproduction. Kisspeptin neurones express both oestrogen and androgen receptors, and these neurones are believed to be direct targets for the action of gonadal steroids. This may be involved in triggering and guiding tempo of sexual maturation at puberty, preovulatory GnRH/LH surge, seasonal control of reproduction, etc. It also has functions outside the realm of reproductive endocrinology like in vascular dynamics, metastasis, placental physiology, etc.



PINEAL GLAND

The status of the pineal gland has evolved from 'the seat of human soul' (Descartes, 17th century) to that of a neuroendocrine transducer with isolation of melatonin. It transforms the information about light received from retina to an endocrine response by synthesis and release of melatonin. Melatonin is a powerful neurotransmitter which makes the pineal gland, a



'biological clock'. Melatonin also has an antigonadotrophic effect in most animals. The seasonal changes in the number of hours per day that melatonin is secreted, mediate the temporal coupling of reproductive activity to seasonal changes in day length.

Increase in GnRH pulse frequency and amplitude triggers a cascade of events starting from increase in luteinising hormone (LH), follicle stimulating hormone (FSH) and sex steroids and this brings about the manifestations of puberty, both external (breast development, genital enlargement) and internal (uterus, ovaries, testes). Pubic hair develops largely through the effects of androgens secreted by the adrenal glands.

Sexual maturity scoring is used to describe different phases of puberty. The most widely used description of pubertal events in boys and girls is that of Marshall and Tanner who examined groups of English girls and boys as they went through puberty. The different phases of external pubertal development in girls are designated as Tanner stages, B1 through B5 for breast development (**Figures 3A and B**) and PH1 through PH6 for pubic hair growth (**Figures 4A to E**). It takes about 4 years from B2 (palpable breast bud under the nipple) to adult breast development. Breast development before the age of 8 years is considered precocious while no breast development till 13 years of age is considered delayed.

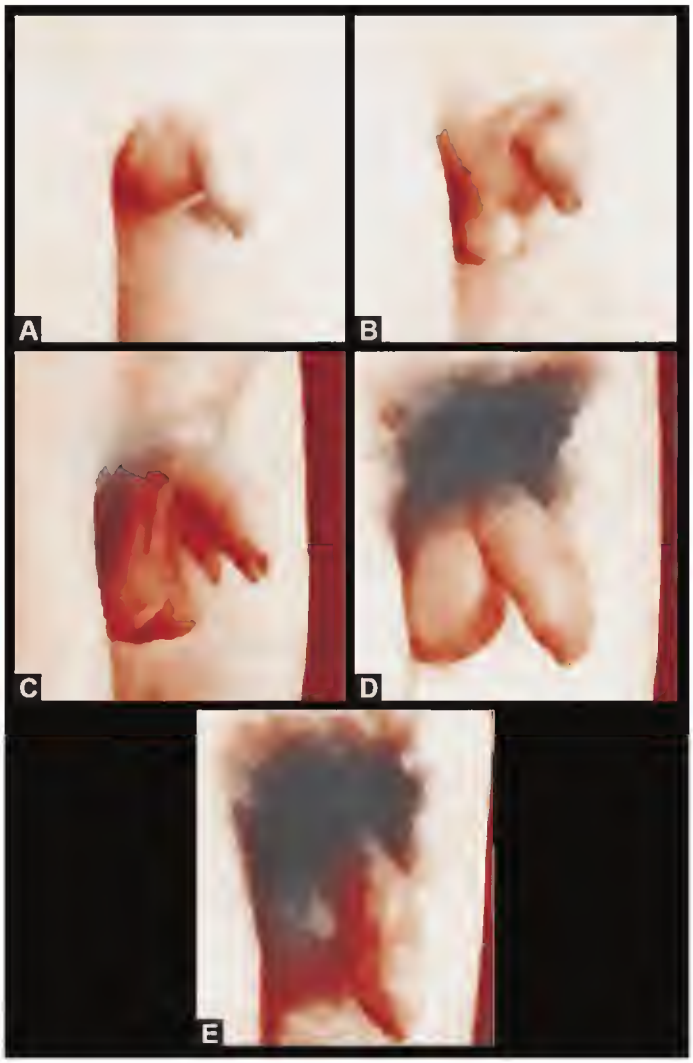
Figures 3A and B: Stages in normal breast development in female [front (A) and lateral view (A)].

Figures 4A to E: Stages of normal pubic hair development in female.

Pubertal development in boys begins with increase in testicular size (**Figures 5A to E**). Later pubic hair appears, penile size increases and voice breaks. Spermatozoa first become detectable around 13 to 14 years of age.

TIMING OF PUBERTY

Signs of puberty before the age of 8 years in girls and 9 years in boys are considered early or premature; while no signs of puberty till the age of 13 in girls and 14 in boys are defined as delayed puberty. Diagnostic evaluation is aimed at differentiating pathological conditions from normal variants. The normal variants include constitutional delay or acceleration of growth and development, premature thelarche, premature pubarche and pubertal gynaecomastia.



In constitutional delay of growth and development, there is spontaneous pubertal development, more than 2 SD, later than the mean age at onset of puberty. Growth is slower, but final adult height is often in the target range.

Premature Thelarche

Breast tissue develops early, sometimes during the first 2 years of life, occasionally in neonatal period and then persists till the time of puberty. It is an isolated event without signs of accelerated growth or skeletal maturation.

Premature Pubarche

It is the development of pubic or axillary hair (before age 8 in girls and 9 in boys). The adrenal androgen levels are normal, there is no increase in growth and skeletal age is comparable

Figures 5A to E: Stages in normal genital and pubic hair growth development in male.

to chronological age or slightly advanced. Premature pubarche is to be differentiated from premature adrenarche where adrenal androgens are elevated, like in congenital adrenal hyperplasia or androgen secreting tumour.

Pubertal Gynaecomastia

Some degree of gynaecomastia can be observed in over 50% of boys. In most cases, it is only a small induration under the nipple which regresses in 6 to 18 months. In some cases, it is more pronounced and persists longer. In such cases, medical/surgical intervention may be required. Rarely pubertal gynaecomastia can be due to increased oestrogen production or other conditions like Klinefelter's syndrome, partial androgen insensitivity syndrome, true hermaphroditism, etc.

Pathological conditions, which lead to early puberty, can be divided into gonadotrophin dependent (true precocious puberty) or gonadotrophin independent (precocious pseudopuberty) disorders.

GONADOTROPHIN DEPENDENT EARLY PUBERTY (TRUE PRECOCIOUS PUBERTY)

It is initiated by premature activation of hypothalamo-pituitary-gonadal (HPG) axis and is more common in girls. Prevalence is estimated to be 1 in 5000 to 1:10,000. It follows the normal sequence of events in pubertal development. The cause remains unidentified in 40% to 60% of cases, more so in girls. Lesions in pituitary hypothalamic area (hypothalamic hamartoma, glioma, astrocytoma, germinoma), internal hydrocephalus, earlier episodes of meningitis, radiotherapy, traumatic brain injury, etc. can cause true precocious puberty. The magnetic resonance imaging of brain is indicated in all cases of true precocious puberty.

GONADOTROPHIN INDEPENDENT PRECOCIOUS PUBERTY (PRECOCIOUS PSEUDOPUBERTY)

It starts before and independently of the HPG axis maturation. Appearance of secondary sexual characteristics is due to the increased production of sex steroids. HPG axis is suppressed due to the abnormally elevated sex steroids. Oestrogens produce isosexual puberty in girls and heterosexual puberty in boys. Similarly, androgens produce isosexual puberty in boys and heterosexual puberty in girls. There are several causes for precocious pseudopuberty including hormone secreting tumours of the central nervous system, adrenal gland, gonads and liver; testotoxicosis; McCune Albright syndrome; steroid biosynthetic disorders, like congenital adrenal hyperplasia.

Germ cell tumours secrete human chorionic gonadotrophin (hCG) which in turn stimulate LH receptors in testes which produce testosterone. These tumours can arise from the CNS (pituitary, pineal), liver, retroperitoneal or posterior mediastinum. Gonadal and adrenal tumours produce testosterone.

Familial Testotoxicosis

There is early Leydig cell maturation and testosterone production due to an activating mutation of the LH receptor. It is an autosomal dominant disorder, affecting only boys.

McCune Albright Syndrome

This syndrome manifests with café-au-lait spots, fibrous dysplasia and follicular cysts with precocious pseudopuberty. The cause is a somatic mutation in the alpha subunit of the G protein resulting in pathological over secretion of a variety of hormones. In addition to precocious pseudopuberty, patients may manifest with hyperthyroidism, Cushing's syndrome or increased growth hormone secretion.

Congenital adrenal hyperplasia is the most common cause for premature adrenarche. These patients may develop precocious true puberty after starting glucocorticoid therapy.

Absence of puberty could be due to disturbances in hypothalamus, pituitary or gonads (**Tables 1 and 2**). Plasma LH and FSH are low when it is pituitary or hypothalamus (hypogonadotrophic hypogonadism), while these are high when there is primary gonadal failure called hypergonadotrophic hypogonadism (**Table 3**). Sex steroids are low and follicular maturation or sperm production does not occur in both situations.

Table 1: Hypothalamic Causes for Absent Puberty

Migration disorder of the GnRH neurone (Kallman syndrome)
Disturbances of GnRH secretion
Mutations of GnRH receptor gene
Mutations in leptin/leptin receptor gene
Mutations in Kiss 1/GPR54 gene

Table 2: Pituitary Causes for Hypogonadism (Congenital or Acquired)

Congenital	
	Mutations in pituitary transcription factors
	Mutations of the gene for LH or FSH subunit
	Mutations of LH or FSH receptor gene
	Congenital midline defects
Acquired	
	Tumours of the hypothalamic pituitary region
	Pituitary surgery/radiation
	Hypophysitis and infiltrative disorders
	Post-traumatic

Table 3: Causes of Hypergonadotrophic Hypogonadism

Girls	Boys
Turner's syndrome and variants	Klinefelter's syndrome
Pure gonadal dysgenesis	Disorders of testosterone biosynthesis
Damage to ovaries	Testicular damage
– Oophoritis	– Radiation
– Radiation	– Chemotherapy
– Chemotherapy	– Torsion
– Surgical ablation	– Trauma

Absence of signs of puberty (breast development in girls or testicular volume less than 3 mL in boys) by 15 years requires evaluation. The major cause still will be constitutional delay in growth and development.

Functional hypothalamic hypogonadism refers to a reversible dysfunction usually associated with anorexia nervosa, severe emotional stress or participation in intense physical training.

Primary amenorrhoea in a girl with normal secondary sexual development should raise the possibility of congenital malformation of the genital tract (Müllerian duct). Cases of complete androgen insensitivity also present with primary amenorrhoea with normal breast development. Absence of pubic and axillary hair, and the presence of gonads in the labia are clues to diagnosis of this syndrome.

Children with disorders of sexual development also have problems of pubertal development. Congenital adrenal hyperplasia (CAH) is the most common cause for disordered sexual development in girls. Appropriately treated children enter puberty normally. However, some girls, especially those with simple virilising forms of CAH who did not receive medical attention during neonatal period, may present at puberty with masculinisation and primary amenorrhoea. 46 XY disorder of sexual differentiation (DSD), e.g. partial androgen insensitivity syndrome, disorders of testosterone biosynthesis, gonadal dysgenesis, etc. will also require appropriate treatment for proper pubertal development. It is a bigger challenge in our country as many of these may not have been diagnosed or treated during childhood.

10.10 Disorders of Growth and Development

Nalini S Shah

Growth is a unique and complex process that is affected by multiple factors. However, children normally grow in a remarkably predictable manner. Deviation from a normal growth pattern can be the first manifestation of a wide variety of disease processes, including endocrine and non-endocrine disorders.

Clinical assessment using parameters like height measurement, growth velocity, use of appropriate growth charts, mid-parental height, body proportions and stage of puberty can generate valuable clues for differential diagnosis of growth disorders.

MEASUREMENT OF HEIGHT

Accurate serial height measurements documented over time on a growth chart are important for the diagnosis of growth abnormalities. During first 2 to 3 years of life, length should be measured with an infantometer (**Figure 1A**). It contains a firm horizontal platform, an attached yardstick, a fixed head plate, and a movable foot plate. During measurement, one person supports the child's head and ensures that the head is positioned in the Frankfort horizontal plane (lower margin of the bony orbit and upper margin of the external auditory meatus in the same horizontal line). A second person can align the child's legs by placing one hand with gentle pressure over the knees. With the other hand, foot piece is slided to rest firmly against the soles of the feet which are flexed perpendicular against the foot piece (**Figure 1B**). After 2 to 3 years of age, height should be measured on a wall-mounted, well-calibrated ruler with an attached horizontal measuring bar fixed at 90 degrees [e.g. a stadiometer (**Figure 1C**)]. The child should stand erect with the back of the head, back, buttocks area and heels touching the vertical bar of the stadiometer; the horizontal measuring bar is lowered to the child's head to obtain the measurement (**Figure 1D**). The height can be expressed as standard deviation scores (SDS or Z scores). Z score is calculated using the formula: (Child's height – mean height for age from a reference chart) ÷ 1 SD of height for that age and sex in the reference chart. The Growth Monitoring Guidelines Consensus Meeting of the Indian Academy of Paediatrics recommends the use of Agarwal *et al*, growth charts as reference charts for Indian children.

In addition to height, weight measurement will provide clues towards the aetiology of short stature. Normal or elevated weight SDS points towards endocrine disorders like Cushing's syndrome or pseudohypoparathyroidism while low weight SDS points towards systemic illnesses.

Figures 1A to D: (A) Infantometer; (B) Method of measuring length with an infantometer; (C) Stadiometer; (D) Method of measuring height with a stadiometer.

HEIGHT VELOCITY AND GROWTH PATTERN

Assessment of height velocity is an essential part of evaluation of a short child. Length of an average Indian child at birth is 50 cm. During infancy, the average height gain is 25 cm reaching 75 cm by first birthday. During second year, the growth rate is 12.5 cm followed by 6 to 7 cm during third and fourth years. After that, the growth rate is approximately 5 cm per year till pubertal spurt. A growth spurt is observed during pubertal period which may be up to 11 cm/year in girls and 12 cm/year in boys. Average total height gain during the pubertal period is 24 to 25 cm and 27 to 29 cm in girls and boys respectively. The majority of mean height difference between adult men and women results partly from the height difference at the age of pubertal onset, with boys being taller at their later age of takeoff than girls and partly from greater gain in height of boys during the pubertal growth spurt.

The growth pattern of a child should be recorded on a growth chart to have a longitudinal assessment of growth. Intrauterine environment affects the size of a baby at birth. During first 18 to 24 months of life, children pass through an important phase of growth, often called catch-up or catch-down growth. It is characterised by moving up or down on the growth chart which depends on the height of parents so that most children achieve their genetically determined height percentiles by 2 years of age. Thereafter, growth typically proceeds along the same percentile until the onset of puberty. Children with constitutional delay of growth and puberty (CDGP) grow at a rate parallel to but below the 3rd percentile, whereas children with conditions such as growth hormone deficiency or systemic illnesses have a growth pattern that progressively falls further below the 3rd percentile or crosses percentiles. Growth patterns of few common disorders causing short stature are shown in **Figure 2**.

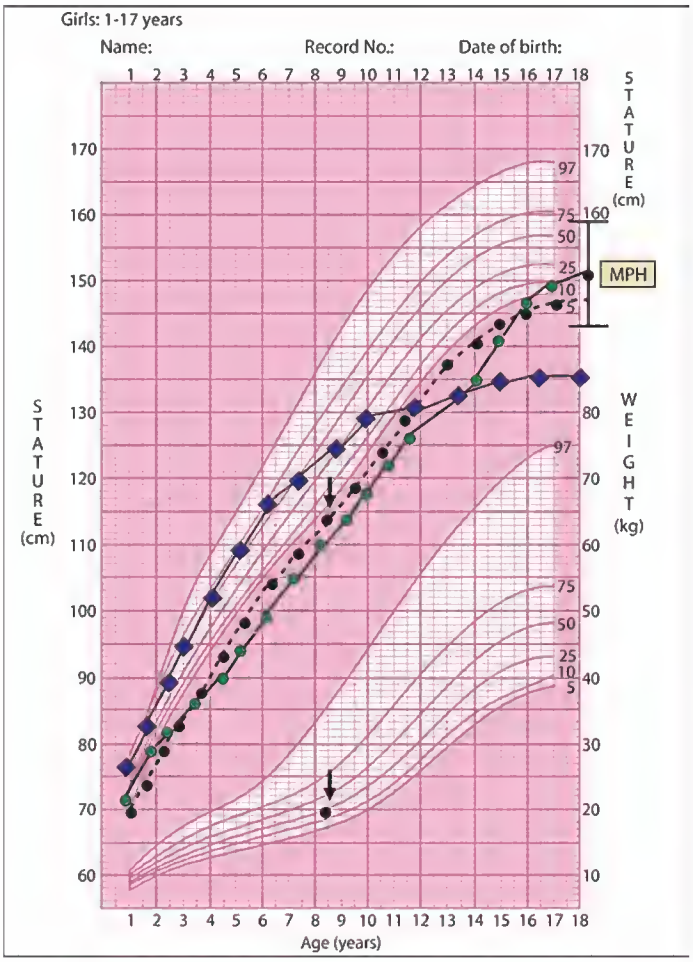

Figure 2: It Illustrates charting of height and weight of an 8½ years old short girl (height below 5th percentile line and weight at 25th percentile) marked by arrows. It also illustrates extension of height percentile parallel to 5th percentile line till 18 years of age (black circles) and compares it with mean parental height (MPH) and target height range which helps to differentiate familial short stature (black circles) from pathological short stature (blue diamonds). The figure also shows typical growth patterns of a child with constitutional delay in growth and puberty (green circles).

GENETIC POTENTIAL

Most commonly used but a crude method to assess the genetic potential is to calculate the midparental height (Target height). The midparental height is a child's expected adult height based on the heights of the parents. It is calculated by the formula: average of mother's height and father's height plus or minus 6.5 cm for boys and girls respectively. It is important to measure the parents' heights in the office, rather than use their reported height to avoid over-or underestimation of midparental height. A rough estimate of the child's projected height, without taking skeletal maturation or pubertal tempo into account, can be determined by extrapolating the child's growth along his or her own height percentile to the corresponding 18-year point. If the estimated final height is within 8 to 10 cm of the midparental height, the child's current height is appropriate for the family. However, if the projected height differs from the midparental height by more than 8 to 10 cm, a variant growth pattern or a pathologic cause should be considered.

BODY PROPORTIONS

The evaluation of upper-to-lower body segment ratios in short children helps to differentiate causes of disproportionate short stature like skeletal dysplasia from causes of proportionate short stature. Lower segment is determined by measuring the distance from the top of symphysis pubis to the floor in a child standing in erect position. The lower body segment is subtracted from the child's height to obtain the upper body segment value. The upper-to-lower body segment ratio (US:LS ratio) is then derived by dividing the upper body segment value by the lower segment value. Body proportions vary with age of a child. The average US:LS ratio is 1.7 at birth and decreases to 1.3 at 3 years, 1.1 at 6 years and 1.0 at 10 years of age. Children with achondroplasia have a normal sized trunk with short limbs, while children with spondyloepiphyseal dysplasias will have short trunk with normal limbs.

Measuring the arm span is also crucial in the evaluation of body proportions. The arm span is the distance between the tips of the left and right middle fingers when a child is standing against a flat wall with arms outstretched as far as possible, creating a 90 degree angle with the torso. Arm span is shorter than height by 2.5 cm at birth and equals height by 10 years of age. Children with long limbs like Klinefelter's syndrome and short trunk like scoliosis may have a disproportionately higher arm span than height.

PUBERTAL ASSESSMENT

Pubertal assessment has an important role in the diagnosis of short stature. Onset of puberty is followed by height spurt which

is seen during adolescence. Hence, onset and progression of puberty will affect the stature in the peri- and post pubertal periods. The stage of puberty is assessed by the Tanner's method of sexual maturity rating. Orchidometer is used for accurate measurement of testicular volume.

BONE AGE ASSESSMENT

Bone age estimation is an important investigation in the evaluation of short child. This is conventionally done from X-rays of wrist and hand. The bone age is estimated from the appearance of epiphysis, size and shape of bones using Greulich-Pyle atlas or Tanner-Whitehouse method. A child with delayed bone age has a better prognosis for future height gain than those with appropriate or advanced bone age. Children with familial genetic short stature have bone age appropriate for chronologic age whereas CDGP children have slightly delayed bone age. Children with endocrine causes such as growth hormone deficiency or hypothyroidism are likely to have markedly delayed bone age. Adult height can be predicted with the help of Bayley-Pinneau charts by using chronologic age and bone age.

SHORT STATURE

Short stature is defined as height that is two standard deviations below the mean height for age and sex (less than the 3rd percentile) or more than two standard deviations below the midparental height. A growth velocity disorder is defined as an abnormally slow growth rate, which may manifest as height deceleration across two major percentile lines on the growth chart. Many children with height SDS less than 2 SD may not be pathological and hence, evaluation for short stature may be limited to children with following features:

1. Severe short stature [height (Ht) SDS < -3SD)]
2. Severe growth deceleration [height velocity (HV) SDS < -2 SD over 12 months]
3. Ht SDS < -2 SD and HV SDS < -1SD over 12 months
4. Ht SDS < -1.5 SD and HV SDS < -1.5 SD over 2 years.

Causes of short stature are listed in **Table 1**. **Table 2** summarises the points to be focused during history-taking physical examination of a short child. **Figure 3** represents an algorithm for the evaluation of a short stature. **Figures 4A to H** shows few children suffering from one of the common disorders leading to short stature.

Table 1: Causes of Short Stature According to the ESPE Classification

A. Primary Growth Disorders

1. ***Clinically defined syndromes***
   - Turner syndrome
   - Cornelia de Lange syndrome
   - DiDeorge syndrome (velocardiofacial syndrome)
   - Down's syndrome
   - Noonan's syndrome
   - Prader-Willi-Labhart syndrome
   - Neurofibromatosis type 1
   - Silver-Russell syndrome
2. ***Small for gestational age with failure of catch-up growth***
   - IGF-I deficiency, IGF resistance
   - Due to known cause, e.g. prenatal infections, drugs, smoking, alcohol
   - Idiopathic
3. ***Skeletal dysplasias***
   - Achondroplasia
   - Hypochondroplasia
   - Dyschondrosteosis (Leri-Weil and other defects in the SHOX gene)
   - Osteogenesis imperfecta I-VI
   - Mucopolysaccharidosis (type IH, IS, II-VII)
   - Mucolipidosis (type II and III)
4. ***Dysplasias with defective mineralisation***
   - Hypophosphatasia
   - X-linked hypophosphataemic rickets

B. Secondary Growth Disorders

1. ***Insufficient nutrient intake (malnutrition)***
2. ***Disorders in organ systems***
   - Cardiac disorders
   - Pulmonary disorders, e.g. cystic fibrosis
   - Liver disorders
   - Intestinal disorders, e.g. Crohn's disease, malabsorption syndromes
   - Short bowel syndrome
   - Renal disorders, e.g. Fanconi syndrome, renal acidosis chronic anaemia, e.g. thalassaemia
3. ***Growth hormone deficiency (Secondary IGF-1 deficiency)***
   - Idiopathic
   - Genetic (HESX1, PROP1, POU1F1, LHX3, LHX4, GHRHR, GH)
   - Associated with syndromes of cerebral or facial malformations, e.g. septo-optic dysplasia, empty sella syndrome
   - Associated with perinatal conditions, e.g. Rubella
   - Acquired (craniopharyngioma, other pituitary tumours, e.g. germinoma, hamartoma)
   - Head trauma
   - Central nervous system infections
   - Granulomatous disease, e.g. histiocytosis
4. ***Other disorders of the growth hormone-IGF axis (primary IGF-I deficiency and resistance)***
   - Bio-inactive growth hormone
   - Abnormalities of the growth hormone receptor (growth hormone insensitivity syndrome)
   - Abnormalities of GH signal transduction, e.g. STAT5B defect
   - ALS (acid-labile subunit) deficiency
   - IGF-I deficiency
   - IGF resistance (IGF1R defects, postreceptor defects)
5. ***Other endocrine disorders***
   - Cushing syndrome
   - Hypothyroidism
   - Leprechaunism
   - Diabetes mellitus (poorly controlled)
   - Short adult stature caused by accelerated bone maturation, e.g. precocious puberty, hyperthyroidism, CAH, exogenous oestrogens or androgens
6. ***Metabolic disorders***
   - Disorders of calcium and phosphorus metabolism
   - Disorders of carbohydrate metabolism
   - Disorders of lipid metabolism
   - Disorders of protein metabolism
7. ***Psychosocial***
   - Emotional deprivation
   - Anorexia nervosa
   - Depression
8. ***Iatrogenic***
   - Systemic glucocorticoid therapy
   - Local glucocorticoid therapy (inhalation, intestinal, others)
   - Other medication
   - Treatment of childhood malignancy
   - Total body irradiation
   - Chemotherapy
   - Other specified iatrogenic causes

C. Idiopathic Short Stature

1. ***Familial (idiopathic) short stature***
2. ***Non-familial (idiopathic) short stature***

Table 2: Points to be Focused during History-taking and Evaluation of a Short Child

History	Comments
Birth size (length, weight, head circumference) and gestational age	To identify small for gestational age (symmetric vs asymmetric)
Birth history (breech delivery, asphyxia, jaundice, hypoglycaemia)	Associated with pituitary dysfunction
Previous growth information	May provide clues about the aetiology
Onset and progression of puberty	Has significant impact on stature
Current and previous medical history	***Identify organic or iatrogenic causes***
Cardiac: dyspnoea, anasarca, cyanosis	Cardiac failure, cyanotic heart disease
Pulmonary: chronic cough, dyspnoea	Cystic fibrosis, bronchial asthma, tuberculosis
Intestinal: abdominal distension, diarrhoea	Malabsorption syndromes like coeliac disease
Renal: polyuria, vomiting, fatigue	Chronic kidney disease, RTA
Neurological: headache, vomiting, focal neurological deficits	Neurotuberculosis, sellar or perisellar tumours, brain tumours treated with radiotherapy
Previous surgeries: intestinal resection	Short bowel syndrome
Medications like glucocorticoid	Glucocorticoid induced growth suppression
Feeding history (feeding difficulties, total calorie and protein intake)	Feeding difficulties during first year in PWS and poor nutrition affects growth (weight > height)
Parental height	Required to assess genetic potential to grow
Tempo of puberty in parents	To look for familial pattern of delayed puberty
Family history	To look for a genetic cause
Delayed milestones, mental retardation	Genetic syndromes and metabolic disorders
Social environment	To look for emotional deprivation
Physical examination	
Underweight	Malnutrition, malabsorption, hypocortisolism, metabolic disorders, SGA
Obesity	Hypothyroidism, Cushing's syndrome, IGF-1 deficiency, Pseudohypoparathyroidism
Microcephaly	Birth asphyxia, symmetric SGA, syndromes
Macrocephaly	Hydrocephalus, achondroplasia, storage disorders
Short trunk or short limbs	Skeletal dysplasias
Dysmorphic features	Primary growth disorders (syndromes)
Frontal bossing, mid-facial hypoplasia	IGF-1 deficiency
Round facies, facial plethora, virillisation	Cushing's syndrome
Pharyngeal examination	Look for adenotonsillar hypertrophy
Bradycardia, dry skin, goiter	Hypothyroidism
Hypertension	Kidney disease, Cushing's syndrome
Hepatosplenomegaly	Hepatic or metabolic disorder
Pubertal stage	Early, normal or late puberty
Micropenis	Hypogonadism, hypopituitarism
Fundoscopy, visual field defect	Central nervous system pathology
Signs of neglect or abuse	Emotional deprivation

MANAGEMENT

Identification and appropriate management of the systemic illnesses improves growth in most of the disorders. Chronic infections like tuberculosis should be treated with appropriate (anti-tubercular) medications. Haemolytic anaemias like thalassaemia should be treated with regular blood transfusions and iron chelating agents. Gluten free diet is the treatment of choice for coeliac disease. Nutritional rickets is treated with supplementation of vitamin D and calcium. Hypophosphataemic rickets is treated with phosphate supplementation and calcitriol while vitamin D dependent rickets are managed with normal to high doses of calcitriol. Distal renal tubular acidosis is treated with Shohl's solution and potassium supplementation while proximal renal tubular acidosis is treated with sodium bicarbonate and potassium supplementation. Hypothyroidism should be treated with L-thyroxine. Conditions which have received FDA approval for growth hormone (GH) therapy and the doses of GH advocated in these disease states are shown in **Table 3**. Growth hormone is given as daily subcutaneous injections before bedtime. IGF-1 treatment is effective in GH insensitivity.

Table 3: Indications and Doses of Growth Hormone Therapy in Children

Indication	Dose of GH (mg/kg/wk)
Growth hormone deficiency	0.18 to 0.3
Chronic kidney disease	0.35
Turner syndrome	0.375
SGA children with failure to catch up growth	0.47 to 0.48
Idiopathic short stature	0.48 to 0.37
Prader Willi syndrome	0.24
Noonan syndrome	0.46
SHOX gene haploinsufficiency	0.35

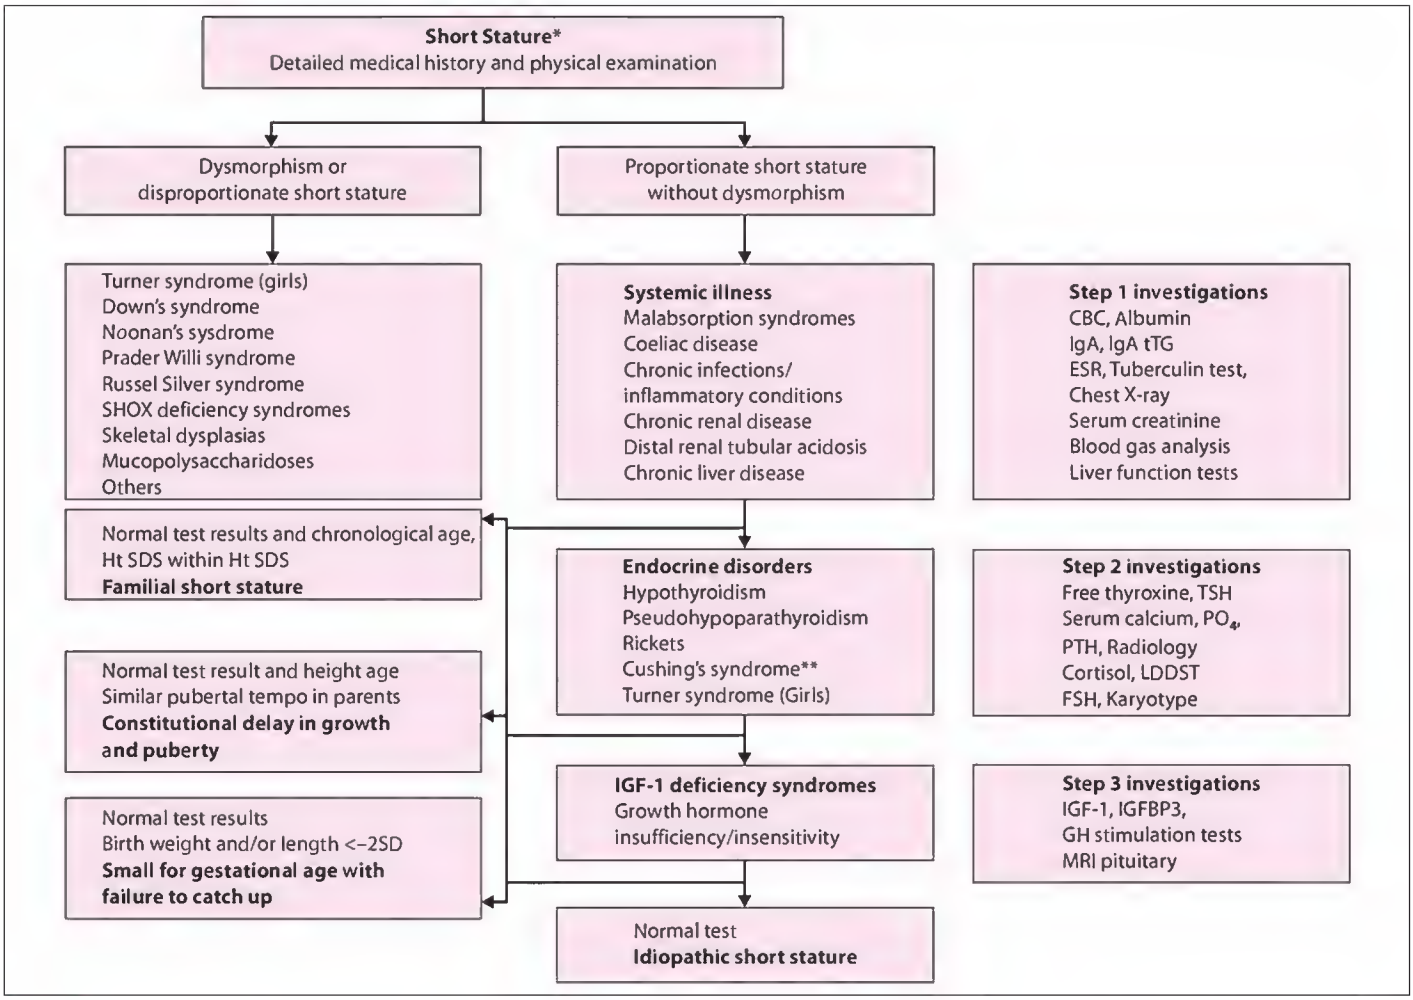

Figure 3: An algorithm depicting approach to a child with short stature.

**Consider psychosocial dwarfism at any step if features of abuse/neglect are identified; **Only if clinical features are suggestive. CBC = Complete blood count; ESR = Erythrocyte sedimentation rate; FSH = Follicle stimulating hormone; GH = Growth hormone; IgA tTG: IgA antibodies to tissue transglutaminase; IGF = Insulin-like growth factor; LDDST = Low dose dexamethasone suppression test; IGFBP3 = IGF binding protein-3; MRI = Magnetic resonance imaging; PO_4 = Phosphorous; SD = Standard deviation; SDS = Standard deviation score.*

TALL STATURE

Tall stature is defined as a height that is 2 SD above the mean for age and sex. Excessive growth could also manifest as height acceleration across two major percentile lines on the growth chart. It is important to distinguish the pathological causes from physiological causes of tall stature. Though only few tall children have a defined pathology, tall stature or height acceleration may be the initial manifestation of serious underlying diseases, such as congenital adrenal hyperplasia. Causes of tall stature are listed in **Table 4** and an algorithmic approach to a tall child is depicted in **Figure 5**.

Management of Tall Stature

Reassurance of the family and the patient is the key to the management of normal variant tall stature. Hypogonadism is treated by replacement with appropriate sex steroids. For eugonadal, extremely tall children whose parents feel strongly about treatment, a trial of sex steroid may be considered. However, it should be restricted to patients with predicted adult height more than 3 SD above the mean. Since, sex steroids act by accelerating puberty and epiphyseal fusion, initiation of therapy in prepubertal or early pubertal phase has better results.

Children with excess GH status are managed with one or more of the following modalities of treatment viz, excision of pituitary adenoma, somatostatin analogues (Octreotide LAR, Lanreotide),

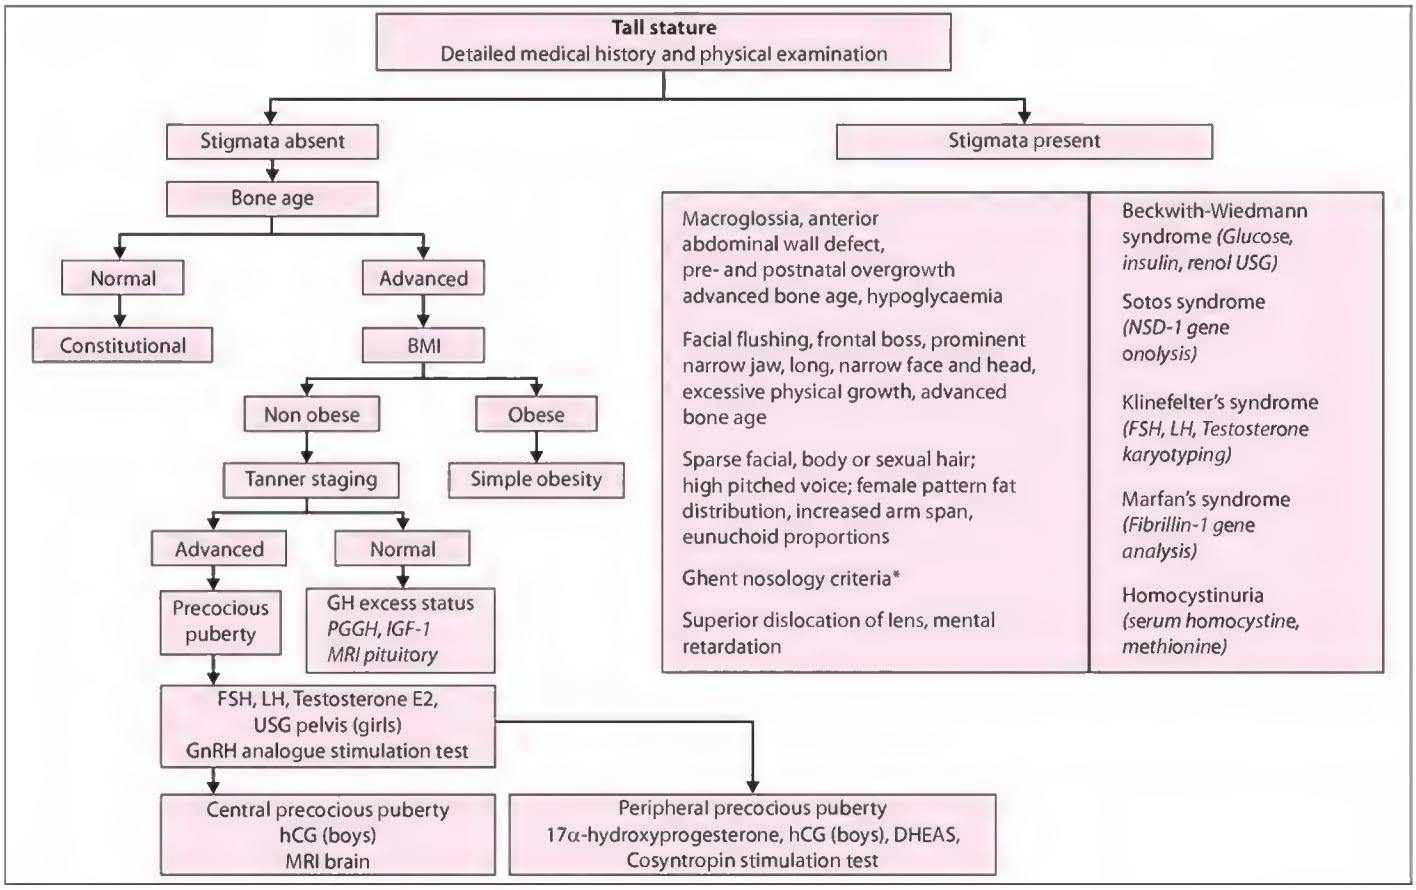

Figure 5: An algorithm depicting approach to a child with tall stature.

BMI = Body mass index; DHEAS = Dehydroepiandrosterone sulphate; E2 = Oestrodiol; FSH = Follicle-stimulating hormone; GH = Growth hormone; GnRH = Gonadotropin-releasing hormone; hCG = Human chorionic gonadotropin; IGF-1= Insulin-like growth factor-1; LH = Luteinising hormone; MRI = Magnetic resonance imaging; PGGH = Post-glucose growth hormone; USG = Ultrasonography.
**The clinical criteria for the diagnosis of Marfan syndrome, which requires a combination of findings in different organ systems.*

Table 4: Causes of Tall Stature

Foetal overgrowth
Maternal diabetes mellitus
Cerebral gigantism (Sotos syndrome)
Weaver syndrome
Beckwith-Wiedemann syndrome
Other IGF-2 excess syndromes

Post-natal overgrowth leading to childhood tall stature
Familial (constitutional) tall stature
Cerebral gigantism
Beckwith-Wiedemann syndrome
Exogenous obesity
Excess GH secretion (Pituitary gigantism)
Precocious puberty
Marfan syndrome
Klinefelter's syndrome
Weaver syndrome
Fragile X syndrome
Homocystinuria
XYY
Hyperthyroidism

Post-natal overgrowth leading to adult tall stature
Familial (constitutional) tall stature
Androgen/oestrogen deficiency or estrogen resistance in males
Testicular feminisation
Excess GH secretion
Marfan syndrome
Klinefelter's syndrome
XYY

GH receptor antagonist (Pegvisomant) or radiotherapy. Suppression of adrenal androgens with appropriate replacement of glucocorticoids (hydrocortisone, prednisolone or dexamethasone) with or without mineralocorticoids (fludrocortisone) forms the essential treatment of precocious puberty with congenital adrenal hyperplasia. Central precocious puberty is treated with GnRH analogues (Leuprolide acetate).

CONCLUSION

Disorders of growth, especially short stature are common problems in paediatric age group. Thorough clinical assessment using auxological parameters can lead to correct differential diagnosis and hence appropriate evaluation and management. Prudent use of endocrine tests can clinch diagnosis in most of the patients. Management options largely rest on correct diagnosis. Monitoring of therapy with appropriate dosage schedule modification and patient education to ensure compliance are keys to long-term success.

10.11 Disorders of Gonads

Shashank R Joshi

Gonadal disorders in females are treated by gynaecologists. Hence only gonadal disorders which occur in males are discussed here.

PHYSIOLOGY

Testosterone is the primary male hormone, not only responsible for normal development of the male characteristics and maintenance of bone and muscle, but also due to its positive effect on mood, energy levels and sexual drive. Testosterone is mainly produced in the Leydig cells located in the interstitial spaces of the testes. Normal adult men produce 4 to 10 mg of testosterone per day in a circadian pattern, with maximal plasma levels reached in early morning and minimal levels in the evening. Testosterone is the principal androgen of which 95% is made in testes, 5% in adrenals. It is synthesised from cholesterol at approximately 6 mg/day and metabolised by liver and excreted in urine. Testosterone can be bioconverted into two other steroids at target tissues—dihydrotestosterone and oestradiol.

Dihydrotestosterone (DHT) binds more readily to androgen receptors. Conversion takes place in the prostate, seminal vesicles and pubic skin. DHT is 10 times more powerful than testosterone, thus conversion amplifies the action of testosterone. DHT may be responsible for male pattern baldness and benign prostatic hypertrophy.

Oestradiol is an oestrogen of which 25% is made by testes and 75% bioconverted in the liver and the brain from testosterone. It is responsible for aggressiveness in men.

HYPOGONADISM

Hypogonadism is defined as 'inadequate gonadal function, as manifested by deficiencies in gametogenesis and/or the secretion of gonadal hormones'.

General Manifestations

Hypogonadism may manifest with testosterone deficiency, infertility, or both conditions. Symptoms of hypogonadism depend primarily on the age of the male patient at the time of development of the condition. Hypogonadism is seldom recognised before the age of puberty unless it is associated with growth retardation or other anatomic or endocrine abnormalities. When hypogonadism develops before the age of puberty, the manifestations are those of impaired puberty (**Table 1**).

Table 1: Pre-Pubertal Hypogonadism

Small testes, phallus, and prostate scant pubic and axillary hair
Disproportionately long arms and legs (from delayed epiphyseal closure)
Reduced male musculature
Gynaecomastia
Persistently high-pitched voice

Post-pubertal loss of testicular function results in slowly evolving subtle clinical symptoms and signs. In ageing men, these symptoms and signs may be difficult to appreciate because they are often attributed to 'getting older'. The growth of body hair usually slows, but the voice and the size of the phallus and prostate remain unchanged. Temporal hair recession and balding usually do not occur and would not be expected to prompt a patient to seek medical attention. Patients with hypogonadism may have the following findings (**Table 2**).

Table 2: Post-Pubertal Hypogonadism

Progressive decrease in muscle mass
Loss of libido
Impotence
Oligospermia or azoospermia
Occasionally, menopausal-type hot flushes (with acute onset of hypogonadism)

The risk of osteoporosis and attendant fractures is increased. Many cases of hypogonadism are disclosed during the course of infertility evaluations.

Evaluation

A comprehensive history should be elicited and a complete physical examination should be performed to help determine the cause and extent of the hypogonadism.

History

Any history of loss of libido, sexual dysfunction, or impotence should be generally noted. A history of use of medications, herbal preparations, or home remedies and any history of possible exposure to oestrogens should be elicited.

A history of anosmia or hyposmia, midline defects, or cryptorchidism may be suggestive of Kallmann's syndrome or other types of hypogonadotrophic hypogonadism. A family history may indicate an underlying genetic basis.

Primary testicular failure is usually associated with genetic syndromes such as Klinefelter's syndrome or congenital disorders such as anorchism. Testicular failure may also be associated with a history of testicular trauma, certain surgical procedures in the area, cryptorchidism, mumps orchitis, and, occasionally, toxic exposures, radiation treatment or chemotherapy.

A post-pubertal onset of hypogonadotrophic hypogonadism, generally manifesting as loss of libido, sexual dysfunction, or impotence, should suggest the likelihood of a pituitary tumour. Indications of other endocrine deficiencies such as central hypothyroidism or secondary adrenal insufficiency, visual field disturbances, headaches, or seizures may also be associated findings.

Physical Examination

The amount and distribution of body hair, including beard growth, axillary hair, and pubic hair, should be noted, as should the presence of a male pattern escutcheon. (The ethnic origin of the patient should be considered in this assessment. Some communities are more hairy than others).

The presence and degree of gynaecomastia should be recorded. The presence of galactorrhoea would suggest pronounced hyperprolactinaemia.

The testes should be measured (length and width) by using a Prader orchidometer or callipers. Some testicular disorders may selectively affect production of sperm without influencing production of testosterone. These disorders may sometimes be detected by careful physical examination, including determination of testicular size and consistency. Because approximately 85% of testicular mass consists of germinal tissue, a reduced germinal cell mass would be associated with a reduced testicular size and a soft consistency. Testicular growth is a reliable index of pubertal progression in peri-pubertal boys, in whom hypogonadism may frequently be difficult to distinguish from delayed puberty (**Table 3**).

Table 3: Approximate Ranges of Testicular Size

Age	Testicular volume (ml)	Testicular length (cm)	Testicular width
Pre-pubertal	3 to 4	<3	<2
Peri-pubertal	4 to 15	3 to 4	2 to 3
Adult	20 to 30	4.5 to 5.5	2.8 to 3.3

Testicular consistency should be noted. If the germinal epithelium was damaged before puberty, the testes are generally small and firm. If post-pubertal damage occurred, the testes are usually small and soft.

On examination of the scrotum, the presence of any masses or varicocoeles should be noted for further evaluation. For assessment of any potentially significant varicocoele, the patient should be asked to perform a Valsalva manoeuvre.

In prepuberty, the length of the stretched penis is about 4 to 8 cm, and the width is less than 2 cm in a flaccid state. In the adult, the length of the penis ranges from about 10 to 17 cm, and the width in the flaccid state is more than 3 cm.

With prepubertal onset of hypogonadism, the stature may assume eunuchoidal proportions, with a crown-to-pubis divided by a pubis-to-floor ratio of <1 and an arm span more than 6 cm greater than the height.

Laboratory Investigations

Testosterone

Testosterone levels vary from hour to hour; an overall diurnal rhythm is also present, and the highest levels of circulating testosterone occurring in the early morning hours. Therefore, testosterone levels should be determined in the morning, and patients with subnormal levels should have repeated studies, especially those with no definite signs or symptoms of hypogonadism. For a reliable testosterone determination, use of three pooled morning testosterone samples will minimise errors attributable to the variation in testosterone levels.

Testosterone circulates principally in bound form, mainly to sex hormone-binding globulin (SHBG) and albumin. It tightly binds to SHBG and is not biologically available, whereas the testosterone fraction associated with albumin is weakly bound and can dissociate to free, active testosterone. Only about 2% of testosterone is in the free form, 30% is bound tightly to SHBG, and 68% is weakly bound to albumin.

Although a testosterone determination is the threshold test in the evaluation of suspected male hypogonadism, the total testosterone concentration may be within the normal range in men with primary testicular disorders such as Klinefelter's syndrome. Low production of testosterone stimulates production of SHBG from the liver. Male patients with hypogonadism often have high SHBG levels because of enhanced production of oestradiol from increases in intratesticular aromatisation. Therefore, if the clinical findings indicate that hypogonadism is present and the total testosterone levels are normal or borderline low, an SHBG or free testosterone level should be determined. Free testosterone assays are method-dependent and may be difficult to interpret. Because albumin binds testosterone weakly, the amount of free testosterone measured will vary with the technique. Equilibrium dialysis free testosterone measurements are used to determine the amount of testosterone not bound to SHBG, but are generally not available.

Conversely, a low testosterone level may also be misleading under some circumstances. Slightly subnormal levels of total testosterone may occur in men with low levels of SHBG and normal circulating levels of free testosterone. A low SHBG level may be associated with hypothyroidism, obesity, or acromegaly. SHBG or free testosterone levels may be helpful for clarifying the underlying disorder, especially when the clinical findings are not suggestive of hypogonadism.

Gonadotropins

If a low testosterone level has been established, further laboratory testing is used to determine whether the hypogonadism is related to a primary testicular disorder (hypergonadotrophic hypogonadism) or to pituitary disease (hypogonadotrophic hypogonadism). The primary feature of hypogonadotrophic hypogonadism is the failure of a reciprocal increase in gonadotropins in the setting of a sub-stantially decreased testosterone level. In patients with signs and symptoms indicative of hypogonadism, determining luteinising hormone (LH) and follicle-stimulating hormone (FSH) levels together with the initial testosterone level in a single sample is usually most efficient.

FSH and LH may have variable biologic activity, depending on their carbohydrate content. Unlike standard radioimmuno-assays, highly sensitive, two-site radioimmunometric assays for gonadotropins yield results that generally correlate well with biologic assays. Because the biologic to radioimmunologic ratio of activity of gonadotropins may vary in aging and various disease states, the most accurate results will be obtained with these highly sensitive assays. Assays for gonadotropins currently lack the sensitivity to detect values below the normal range. Additional studies, such as gonadotropin-releasing hormone (GnRH) testing, by an endocrinologist may help in the further assessment of these patients.

Both FSH and LH are secreted in short pulses. FSH has a longer half-life than does LH and is more likely to provide adequate results on a single blood sample. In addition, most patients with progressive hypogonadism will have increased FSH levels well before LH levels increase. Because LH has a shorter half-life than does FSH, errors may be introduced in measurements made on single samples. Pooled samples for LH done 20 to 30 minutes apart are more accurate than single-sample determinations (albeit less convenient). Persistent borderline values may be further evaluated with dynamic endocrine testing. These tests may include the GnRH stimulation test, the clomiphene stimulation test, and the human chorionic gonadotropin (hCG) stimulation test. These specialised, dynamic studies should be conducted and interpreted by an endocrinologist and may have limited clinical value.

Dynamic Tests

GnRH stimulation test

In the GnRH stimulation test, intravenous injection of 100 mg of GnRH causes serum LH levels to increase three-fold to six-fold during a period of 30 to 45 minutes and FSH levels to increase between 20% and 50%. Various degrees of primary testicular failure cause higher than expected peak values for LH and FSH. Men with hypothalamic or pituitary disease may have a reduced or normal response that is often inadequate for distinguishing between a pituitary and a hypothalamic disorder. If the pituitary gland is primed with repeated doses of GnRH, the stimulation test may provide a more sensitive and reliable result.

Clomiphene stimulation test

In the clomiphene stimulation test, 100 mg of clomiphene citrate is given for 7 days as an evocative test of the hypothalamic-pituitary axis. Clomiphene acts by interrupting the negative feedback loop and thereby stimulating release of gonadotropin from the pituitary. A doubling of LH and a 20% to 50% increase in FSH are normal results indicative of an intact hypothalamic-pituitary response.

hCG stimulation test

Various protocols are used for hCG stimulation testing. In general for post-pubertal male patients, a single dose of hCG (5,000 IU intramuscularly) is administered, and pre-therapy and 72-hour post-therapy testosterone measurements are done (some protocols use 1,000 to 4,000 IU of hCG or multiday dosing). Generally, a post-therapy testosterone level of > 100 ng/dL is considered normal.

Prolactin level

In men with acquired hypogonadotrophic hypogonadism, who usually have a reduced libido and impotence, a prolactin level should be determined to evaluate for a prolactinoma or other cause of hyperprolactinaemia. About 5% of men who complain of impotence will have an increased prolactin level. Further endocrinological evaluation with magnetic resonance imaging (MRI) scanning of the pituitary gland is indicated for unexplained hyperprolactinaemia.

Semen analysis

A semen analysis is the primary test to assess the fertility potential of the male patient. Semen should be collected by masturbation after 2 to 5 days of abstinence and evaluated within 2 hours. Variability between specimens is common; with low or borderline samples, follow-up consisting of evaluation of three or more samples should be done during a 3-month period. A fertile sample is usually associated with a motility of more than 50% and a count that exceeds 20 million/mL. In general, semen volume should range from 1.5 to 6 ml. Morphologic features should be examined for abnormalities.

A fructose test should be done on a semen sample showing azoospermia. Because fructose is secreted by the seminal vesicles, absence of fructose may indicate complete obstruction of the ejaculatory ducts or congenital absence of the vas deferens and ejaculatory ducts.

Most often, a semen analysis is done in an otherwise asymptomatic man during the course of an infertility evaluation. Of note, in the evaluation of infertility of a couple, a semen analysis should be done early to determine appropriate further evaluation and therapeutic options.

Other Studies

Bone densitometry

Because hypogonadism frequently results in low bone density, osteoporosis, and future increased fracture risk, a baseline bone densitometry study should be performed to assess the initial situation and allow future interventions to be based on any deterioration in bone density that may occur overtime. Treatment options to maintain bone mass may include testosterone therapy, calcitonin, or bisphosphonates, in addition to the standard regimen of calcium, exercise, and vitamin D. From 1 to 2 years after therapy is initiated, a follow-up bone density study should be done to determine whether bone mass is being appropriately maintained.

Pituitary imaging

In cases of acquired hypogonadotrophic hypogonadism (low testosterone with low-normal FSH and LH) not clearly attributable to a specific cause, pituitary imaging studies with MRI or computed tomography may be needed to evaluate for structural lesions in the hypothalamic-pituitary region. MRI generally provides better pituitary images, but bony changes in the sella may be better characterised by computed tomography. In general, MRI done with and without a contrast agent is recommended as the initial pituitary imaging study in patients requiring delineation of a pituitary pathologic condition.

Genetic studies

Patients with hypergonadotrophic hypogonadism and impaired pubertal development associated with small, firm testes and often with gynaecomastia are likely to have Klinefelter's syndrome or a variant. Classically, a buccal smear was done to establish the diagnosis by revealing Barr bodies. Currently it is recommended to do genetic karyotype testing to confirm the diagnosis in a patient with these findings at initial assessment. Fluorescent *in situ* hybridisation (FISH) studies increase the sensitivity of detecting Klinefelter's syndrome associated with mosaicism.

Testicular biopsy and scrotal exploration

Since the advent of sensitive FSH assays, germinal cell function is now most often assessed through the FSH assay alone rather than testicular biopsy. In general, however, men with

azoospermia, normal FSH levels, and normal testicular size should usually undergo testicular biopsy and scrotal exploration to determine whether a germinal cell abnormality, an obstruction, or a congenital abnormality of the vas, is present.

Testicular ultrasonography

Testicular ultrasound examination should be done in patients with clinical findings suggestive of a scrotal or testicular mass.

Differential Diagnosis

The differential diagnosis of hypogonadism includes a large and diverse group of disorders affecting the testicles directly or affecting hypothalamic-pituitary regulation of the testes. The clinical setting, history, physical examination, and clinical judgement will, to a large degree, determine which possible aetiologic factors are present.

The different causes are listed in **Table 4**.

Table 4: Aetiology of Male Hypogonadism

Gonadal defects
Genetic defect—Klinefelter's syndrome, myotonic dystrophy, Prader-Willi syndrome
Polyglandular autoimmune failure syndromes (e.g. Schmidt syndrome)
Anatomic defects
Toxins—cytotoxic agents, spironolactone, alcohol
Radiation
Orchitis—usually due to mumps
Hypopituitarism
Idiopathic
Tumour
Other causes
Hyperprolactinaemia
Usually due to pituitary adenoma
Idiopathic increased prolactin production
Hormone resistance
Androgen insensitivity
Luteinising hormone insensitivity
Gonadotrophin deficiency
Hypogonadotrophic hypogonadism
Isolated congenital idiopathic GnRH deficiency
GnRH deficiency with anosmia—Kallman syndrome
Acquired GnRH deficiency is very uncommon
Respond to pulsatile GnRH administration
Hypothalamic insufficiency
LH or FSH deficiency
Systemic diseases
Chronic diseases
Malnutrition/starvation
Massive obesity
AIDS/HIV

The common syndromes are briefly discussed below. They can be broadly classified into hyper- and hypogonadotrophic.

Hypergonadotrophic Hypogonadism Situations

Klinefelter's syndrome

Klinefelter's syndrome (**Figure 1**) is caused by extra X chromosomes present in the male karyotype and occurs in about 1 in every 400 men. The most common karyotype is 47/XXY; mosaicism is sometimes present (in about 1 in every 400 men). Men with Klinefelter's syndrome classically have small, firm testes (generally <2 ml), gynaecomastia, eunuchoid habitus,

Figure 1: Tall stature and gynaecomastia in a patient with Klinefelter's syndrome.

and increased gonadotropin levels. Although production of testosterone is low, high levels of SHBG may result in normal-range testosterone levels in about 40% of patients with Klinefelter's syndrome. These patients have azoospermia, but those with mosaicism may have some spermatogenesis and may produce some pregnancies early in their reproductive lives. Virilisation may begin with puberty but frequently fails to progress. Gynaecomastia is often present and frequently necessitates surgical therapy. Bone density is significantly low. Autoimmune disorders are present with increased frequency in patients with Klinefelter's syndrome and may respond favourably to testosterone therapy.

47/XYY syndrome

The 47/XYY karyotype, which occurs in about 0.1% of males, has been thought to be associated with aggressive behaviour in some men with the disorder. Affected patients may have azoospermia

in association with maturation arrest of the germinal epithelium. Usually, serum FSH levels are increased, but Leydig cell function is normal, as are testosterone and LH levels.

Dysgenetic testes

Dysgenetic testes may occur in conjunction with mosaicism; the patient may have an XO karyotype, a mixed XO/XY karyotype, or pure XY with streak gonads. Occurrence of pure gonadal dysgenesis in conjunction with an XY karyotype and streak gonads imposes an increased risk of malignant disease, which necessitates gonadectomy. Such patients generally have genital ambiguity.

Androgen receptor defects

Patients with androgen receptor defects have an XY genotype and variable phenotype, depending on the degree of receptor defect. Such syndromes include testicular feminisation, Reifenstein's syndrome, and other partial defects, as discussed in the following paragraphs.

Testicular feminisation

Patients with testicular feminisation have a female phenotype but a blind vaginal pouch. Testosterone receptor is non-functional or absent. Laboratory testing shows normal to high male range testosterone and increased gonadotropin levels. The testes should be removed after puberty because of an increased risk of a malignant lesion. Administration of testosterone yields no response.

Reifenstein's syndrome

In Reifenstein's syndrome, patients have a male phenotype with variable pseudohermaphroditism. A partial androgen receptor defect is present; testosterone and gonadotropin levels are increased. Abdominal testes should be removed because of the risk of a malignant lesion. If hypospadias is present, surgical correction of the genitalia may be needed. Any significant gynaecomastia may also need surgical correction. Patients may respond to high doses of testosterone.

Other syndromes

Some male patients with gynaecomastia or oligospermia may have partial androgen insensitivity in association with mild increases in testosterone and gonadotropin levels.

5-alpha reductase deficiency

An autosomal recessive condition, 5-alpha reductase deficiency is associated with an XY genotype. The patients, however, have genital ambiguity until puberty, when increasingly male features develop. The diagnosis is based on clinical manifestations and an increased testosterone/dihydrotestosterone ratio both after puberty and in response to hCG before puberty. Sexual assignment is an issue, and patients may need corrective surgical procedures that necessitate speciality consultation.

Myotonic dystrophy

Myotonic dystrophy occurs only in male patients, by transmission from father to son. Because testicular failure usually occurs around age 40 years, patients often have children at risk for the disease.

Cryptorchidism

Unilateral or bilateral cryptorchidism can occur. The incidence of this condition is 3% to 4% at birth, but most testes ultimately descend. Thus, the 1-year incidence is about 0.8 per cent. Because normal testicular descent requires normal pituitary function and dihydrotestosterone levels, the incidence of cryptorchidism is increased in patients with Kallmann's syndrome. Problems associated with the management of cryptorchidism include distinguishing between cryptorchidism and retractile testes and recommending medical treatment with hCG or surgical therapy in an infant. Generally, the objective is to bring the undescended testicle into the scrotum before 1 to 2 years of age—to decrease the risk of gonadal malignant lesions associated with abdominal testes and to improve fertility potential. In pre-pubertal boys, hCG treatment should generally be used initially for 4 weeks to determine whether descent occurs before operative intervention is considered. Discussion of these problems is beyond the scope of these guidelines; appropriate specialty consultation should be obtained.

Vanishing testes syndrome (congenital anorchism or pre-pubertal functional castrate)

The initial manifestation of the vanishing testes syndrome is sexual immaturity in a male patient. The cause is unclear, but the syndrome may be due to testicular torsion during foetal life after sufficient testosterone exposure to produce masculinisation of the reproductive tract. Impalpable testes suggest the possibility of cryptorchidism. FSH and LH levels are increased, and testosterone levels are low. If the LH levels are only minimally increased, hCG stimulation testing of the gonad should be done. With vanishing testes syndrome, no response would be demonstrated. A response to hCG stimulation would raise the possibility of intra-abdominal testes, which would necessitate further evaluation because of the possibility of malignant transformation. In this setting, an MRI is recommended to assess the possibility of a retained intra-abdominal dysgenetic gonad because this would be associated with an increased risk of a malignant lesion and would necessitate removal.

Haemochromatosis

Iron overload may lead to primary gonadal failure or sometimes hypothalamic-pituitary dysfunction that results in secondary gonadal failure. The diagnosis is made in the setting of associated findings of haemochromatosis in conjunction with an increased ferritin level and is generally confirmed with a liver or bone marrow biopsy.

External Testicular Insults

Trauma

The patient may have a history of direct traumatic injury. Testicular torsion sometimes is associated with a 'bell-clapper' abnormality in which the testes lie horizontally because of incomplete closure of the surrounding tissues.

Mumps orchitis

In patients with postpubertal mumps, a 25% risk of orchitis exists. More than 50% of those with orchitis will be infertile. Increased FSH concentrations and oligospermia or azoospermia are present. Mumps orchitis can progress to produce low testosterone and high LH levels in some men.

Radiation treatment or chemotherapy

With irradiation or chemotherapy, testicular exposure can occur from treatment of another disease or inadvertently. A dose-

dependent recovery potential and variable Leydig cell dysfunction have been noted. Pretreatment sperm banking is possible if future 'fertility' is desired and sperm counts are normal.

Autoimmune syndromes

Anti-Leydig cell antibody-associated disorders or conditions associated with anti-sperm antibodies are autoimmune syndromes related to hypogonadism. These syndromes are poorly characterised, and further research is needed to determine diagnostic criteria and possible treatment options.

Sertoli cell only syndrome

The absence of germ cells in patients with small testes, high FSH levels, azoospermia, and normal testosterone levels should suggest the presence of Sertoli cell only syndrome. The diagnosis can be made only by testicular biopsy. The cause is currently unknown.

Hypogonadotrophic Hypogonadism Situations

Kallmann's syndrome

Classic Kallmann's syndrome is a congenital disorder inherited as an X-linked recessive trait manifesting as prepubertal hypogonadism with an incidence of about 1 in 10,000 male births. Low testosterone levels are present because of an impaired release of LH and FSH as a result of variable GnRH deficiency. LH and FSH are released in response to priming followed by stimulation with GnRH. The gene on the X chromosome for classic Kallmann's syndrome and associated anosmia has been identified and cloned. Autosomal recessive and autosomal dominant variants of hypogonadotrophic hypogonadism also exist and are referred to as idiopathic hypogonadotrophic hypogonadism.

Classically, Kallmann's syndrome is associated with anosmia as a result of defective development of the olfactory tract in the brain. The GnRH-containing neurones originate in the developing olfactory tract and therefore do not develop properly in this syndrome. This defective development of the olfactory tract can be diagnosed by MRI scanning. In some cases, other defects such as cerebellar dysfunction, cleft palate, and congenital deafness are present. Cryptorchidism may occur because gonadotropins contribute to normal testicular descent. The pre-pubertal testes in patients with Kallmann's syndrome tend to be larger than in patients with Klinefelter's syndrome and are appropriate for age up to puberty, in as much as normal initial amounts of germinal tissue are present. Partial pubertal development may be present in patients with partial defects; thus, Kallmann's syndrome may be difficult to distinguish from delayed puberty up through the teenage years. Once a patient with Kallmann's syndrome has been identified, other family members at risk (on the basis of mode of inheritance) should be assessed, if possible.

Other related syndromes

Congenital hypogonadotrophic syndromes are associated with secondary hypogonadism and other somatic findings. Prader-Willi syndrome is characterised by hypogonadism, short stature, mental retardation, hypotonia at birth, and obesity. Laurence-Moon-Bardet-Biedl syndrome is an autosomal recessive trait characterised by mental retardation, retinitis pigmentosa, polydactyly, and hypogonadism. These syndromes may be due to a hypothalamic deficiency of GnRH.

Fertile eunuch syndrome

Hypogonadotrophic hypogonadism in patients who have modest FSH secretion and selective LH deficiency is known as the fertile eunuch syndrome. Fertility may be present in some of these patients.

Pituitary disorders

Acquired hypogonadotrophic hypogonadism may indicate the presence of pituitary insufficiency or a pituitary tumour. Unless the reason for the pituitary defect is clear, imaging studies of the pituitary gland are indicated to determine whether a pituitary tumour is present. Hypothalamic tumours, metastatic tumours, granulomas, abscesses, and haemochromatosis may also be discovered.

Hyperprolactinaemia is a potential cause of hypogonadotrophic hypogonadism and generally, manifests with a low libido and impotence. A prolactin level should be determined in men with acquired hypogonadotrophic hypogonadism. High prolactin levels are usually associated with a prolactinoma, but certain medications may also cause hyperprolactinaemia.

Hypogonadotrophic hypogonadism from pituitary disease may also occur with granulomatous and infiltrative disorders, cranial trauma with or without stalk transection, irradiation, and hypophysitis.

Haemochromatosis

See earlier discussion in hypergonadotrophic hypogonadism section.

Serious illness, acquired immunodeficiency syndrome and stress

Transient hypogonadotrophic hypogonadism may occur in patients with serious disorders or malnutrition. Acquired immunodeficiency syndrome (AIDS) may be associated with low testosterone levels and generally low gonadotropin levels (consistent with hypothalamic-pituitary involvement). In some patients with AIDS, gonadotropin levels are increased (consistent with testicular disease).

Ageing, andropause or male menopause

Considerable controversy exists over the concept of a male climacteric. Growing evidence indicates that some aging men have reduced production of testosterone associated with decreased libido, impotence, decreased growth of body hair, decreased muscle mass, increased risk of myocardial infarction, and decreased bone mass in conjunction with osteoporosis. Measurements of free testosterone or SHBG with total testosterone are usually needed to demonstrate the abnormality. Often the FSH and LH levels are mildly increased; an indication that a primary testicular disorder may be present in conjunction with a secondary abnormality in LH burst frequency. Dynamic testing may disclose more subtle abnormalities of hypothalamic function. Data from long-term research studies are desperately needed to clarify the criteria for therapy considerations in aging men. Currently, men with symptomatic hypogonadism and clearly low testosterone levels (free or total, in consideration of SHBG) are potential candidates for therapy, although no specific recommendations can be given.

Short-term research studies have demonstrated improved lean body mass, increased haematopoiesis, decreased low-density

lipoprotein (LDL) levels with a constant LDL to high-density lipoprotein (HDL) ratio, improved libido, and improved well-being in men with low testosterone levels after treatment with testosterone. Generally, prostate size does not change in comparison with otherwise normal men, but prostate-specific antigen (PSA) levels have been found to increase in some men.

Treatment Options

The goals of therapy are to restore sexual function, libido, well-being, and behaviour; produce and maintain virilisation; optimise bone density and prevent osteoporosis; possibly normalise growth hormone levels in elderly men; potentially affect the risk of cardiovascular disease; and restore fertility in cases of hypogonadotrophic hypogonadism.

Testosterone therapy in adult male patients with hypogonadism

Ideally, testosterone therapy should provide physiologic range of testosterone (between 300 and 1,200 ng/dL) and physiologic range of dihydrotestosterone and oestradiol levels, which would allow optimal virilisation and normal sexual function. Testosterone therapy is used in the male patient with hypogonadism who is not interested in fertility or not able to achieve fertility. In late teenage male patients with delayed puberty, testicular size should be monitored for evidence of onset of puberty. In this setting, testosterone therapy should be withdrawn to determine whether spontaneous puberty will occur.

The following preparations of testosterone may be used: long-acting intramuscular preparations, short-acting intramuscular preparations, pellets, scrotal patches or transdermal patches.

Orally administered testosterone is quickly metabolised by the liver and cannot achieve sufficient blood levels overtime to be useful. The orally administered alkylated androgen preparations currently available are generally not recommended because of poor androgen effects, adverse lipid changes, and hepatic side effects, such as haemorrhagic liver cysts, cholestasis, and hepatocellular adenoma. Testosterone undecanoate may be a more acceptable oral alternative, but erratic testosterone levels, frequent dosing, high dihydrotestosterone levels, and occasional gastrointestinal side effects may limit the usefulness of this preparation. Testosterone pellets are sometimes used, and further study may prove them to be suitable for many men. For patients with hypogonadotrophic hypogonadism wishing fertility, hCG with or without human menopausal gonadotropin (FSH), or pulsatile GnRH therapy and hCG with or without assisted reproduction are options.

Parenteral testosterone preparations

These are the mainstay of therapy for all practical purposes. Testosterone enanthate and testosterone cypionate are long-acting testosterone esters suspended in oil to prolong absorption. Peak levels occur about 72 hours after intramuscular injection and are followed by a slow decline during the subsequent 1 to 2 weeks.

For complete androgen replacement, the regimen should be between 75 mg, 150 mg and 250 mg of testosterone enanthate or cyprionate administered intramuscularly every 7 to 10 to 21 days, which will allow relatively normal levels of testosterone throughout the time interval between injections. Longer time intervals are more convenient but are associated with greater fluctuations in testosterone levels. Higher doses of testosterone produce longer-term effects at the expense of higher peak levels and wider swings between peak and nadir circulating testosterone levels; the result is fluctuating symptoms in many patients. The use of 100 to 200 mg every 2 weeks is a reasonable compromise. Use of 250 to 300 mg injections every 3 weeks is associated with wider fluctuations of testosterone levels. With use of these longer-interval regimens, many men will have pronounced symptoms during the week preceding the next injection. In such instances, a smaller dose at closer intervals should be tried. As a guide, testosterone levels should be above the lower limit of normal, in the range of 250 to 300 ng/dL, just before the next injection.

When full androgen replacement is not required, lower doses of testosterone are used. One such category includes adult male patients with pre-pubertal onset of hypogonadism who are going through puberty for the first time on therapy and who often may require psychologic counselling, especially when a spouse is involved as well. In these patients, testosterone therapy should be begun at 50 to 100 mg every 3 to 4 weeks with a gradual increase during subsequent months, as tolerated, up to full replacement within 1 year. Men with appreciable benign prostatic hypertrophy who have hypogonadism and symptoms may be given 50 to 100 mg every 2 weeks as an initial regimen and maintained on this dosage with careful monitoring of urinary symptoms and prostate examinations; therapy can be withdrawn, if necessary.

Attaining full virilisation in the patient with hypogonadism may take as long as 3 to 4 years. Follow-up intervals should be between 4 and 6 months to monitor progress, review compliance, and determine whether any complications or psychologic adjustment problems are present.

Transdermal testosterone therapy

Transdermal testosterone delivery system—normal skin: A testosterone patch with permeability enhancement allows testosterone delivery through normal skin. Daily evening application generally results in normal-range testosterone levels, which mimic the normal diurnal changes in testosterone in normal men. In contrast to the situation with use of the scrotal patch, dihydrotestosterone levels remain within the normal range. Oestradiol and bioavailable testosterone levels also remain within the normal range. Skin irritation may be a problem in some patients. Therapy consists of two patches applied to normal skin. As with scrotal patches, treatment is more expensive than injections, but convenience of use, maintenance of normal diurnal testosterone levels, and elimination of office visits for injections may make this form of treatment useful in many patients.

Scrotal patch testosterone delivery system: Scrotal testosterone patches are available in 40 and 60 cm^2 sizes, which deliver, respectively 4 and 6 mg of testosterone daily. The patch is applied to the scrotal skin after preparation of the scrotum with dry shaving. The patch is non-adhesive, and a new patch is applied each morning. The testosterone levels mimic the diurnal rhythm present in normal men. Because genital skin contains high concentrations of 5-reductase, the dihydrotestosterone levels in treated patients increase initially but may return to

normal in some men. The cost of using the scrotal patch is greater than for testosterone injections, but the convenience of use may make this therapeutic option acceptable for many patients.

Side effects of testosterone therapy

Periodic follow-up of patients receiving testosterone therapy is recommended. During the first year of therapy, the patient should have the progress and the side effects monitored at 3 to 4 month intervals. Examination of the prostate should be done routinely. PSA levels should be determined annually in older men receiving testosterone replacement therapy, and the haematocrit should be determined at least yearly. An initial lipid profile should be recorded, and a follow-up profile should be done after 6 to 12 months of therapy. Testosterone, and especially dihydrotestosterone, stimulates the growth of the prostate and seminal vesicles.

Gynaecomastia may result from the aromatisation of testosterone to oestradiol and changes in SHBG levels. The use of aromatase inhibitors, such as testolactone, or surgical therapy may be considered for some patients.

Supraphysiologic levels of testosterone stimulate the bone marrow production of erythrocytes. The result is an increased haematocrit with the possibility of hyperviscosity side effects.

Lipid disturbances in testosterone treated male patients are generally not a problem because of the aromatisation of testosterone to estradiol. The HDL: total cholesterol ratio generally remains constant. Anabolic steroids that are not aromatised increase LDL and lower HDL levels and could increase cardiovascular risk.

Sleep apnoea may also be a problem in some men, and testosterone therapy should be discontinued until the sleep apnoea problem can be adequately addressed.

Gonadal Stimulation in Hypogonadotrophic Hypogonadism

Because gonadotrophin or GnRH therapy is effective only in hypogonadotrophic hypogonadism, this diagnosis must be firmly established before consideration of therapy. Although these agents may also be used to induce puberty in boys and to treat androgen deficiency in hypogonadotrophic hypogonadism, the major use of these preparations is in the initiation and maintenance of spermatogenesis in hypogonadotrophic men who desire fertility.

Gonadotrophin therapy in androgen deficiency

hCG binds to Leydig cell LH receptors and stimulates the production of testosterone. Peri-pubertal boys with hypogonadotrophic hypogonadism and delayed puberty can be treated with hCG instead of testosterone to induce pubertal development. The initial regimen of hCG is usually 1,000 to 2,000 IU administered intramuscularly two to three times a week. The advantages of hCG over testosterone in this setting include the stimulation of testicular growth, which may be an important issue for some men. hCG may also yield greater stability of testosterone levels with fewer fluctuations in hypogonadal symptoms. In addition, hCG treatment is necessary for stimulating enough intratesticular testosterone to allow the initiation of spermatogenesis. Problems with hCG include the need for more frequent injections and the greater cost.

Gonadotrophin therapy for induction of spermatogenesis

Males with pre-pubertal onset of hypogonadotrophic hypogonadism have not completed pubertal development and have testes generally smaller than 5 ml. These patients usually require therapy with both hCG and human menopausal gonadotropin (or FSH) to induce spermatogenesis. Men with partial gonadotropin deficiency or who have previously (peri-pubertally) been stimulated with hCG may initiate and maintain production of sperm with hCG alone. Men with post-pubertal acquired hypogonadotrophic hypogonadism and who have previously had normal production of sperm can also generally initiate and maintain spermatogenesis with hCG only. Fertility may be possible at sperm counts much lower than what would otherwise be considered fertile. Counts of less than 1 million/mL may be associated with pregnancies under these circumstances. It is imperative that the female partner undergo assessment for optimal fertility before or concurrently with consideration of therapy in the man.

GnRH therapy

In patients with hypogonadotrophic hypogonadism, GnRH can be given in a pulsatile fashion sub-cutaneously through a pump every 2 hours. GnRH therapy is monitored by measuring LH, FSH, and testosterone levels every 2 weeks until levels are in the normal range, at which point monitoring can be adjusted to every 2 months. GnRH can be used to initiate pubertal development, maintain virilisation and sexual function, and initiate and maintain spermatogenesis. In most patients, these effects may take from 3 to 15 months to achieve sperm production. As with gonadotropin therapy, fertility can be achieved with very low sperm counts—often in the range of 1 million/mL. GnRH may be more effective than gonadotropin stimulation in increasing testicular size and initiating spermatogenesis in many patients with hypogonadotrophic hypogonadism.

Contraindications to Testosterone, GnRH, and Gonadotrophin Therapy

Testosterone replacement, pulsatile GnRH therapy, and gonadotrophin therapy are contraindicated in men with prostate cancer or male breast cancer. Treatment with these medications can stimulate tumour growth in androgen-dependent neoplasms. Careful examination of the male breast and prostate is required initially and at follow-up visits. In addition to prostate examination, baseline and follow-up PSA levels should be determined in older men at increased risk for prostate cancer. Sleep apnoea and hyperviscosity states are relative contra-indications to the use of testosterone therapy.

Other Treatment Considerations

Anti-oestrogen therapy in oligospermia

Long-term use of low-dose clomiphene citrate at 25 mg daily or tamoxifen to increase pituitary stimulation of testicular function has often been attempted in men with oligospermia with limited success.

Assisted reproductive technology

The ability to perform *in vitro* fertilisation (IVF) with intracytoplasmic sperm injection (ICSI) directly into the egg has revolutionised the approach to male sub-fertility. A single sperm or immature form retrieved from the testicle is sufficient to

fertilise an egg and give a reasonable chance at pregnancy. *In vitro* fertilisation with intracytoplasmic sperm injection may be a viable option in many men with hypogonadism who cannot otherwise be induced to produce enough sperm to result in pregnancy as well as in the presence of a female factor that may further make pregnancy by the couple difficult or impossible. The procedure is expensive and seldom covered by health insurance; therefore, this technology will generally not replace conventional gonadal stimulation protocols. Intrauterine insemination (IUI) may also be a low-cost option in suitable women when the man has mild-to-moderate oligospermia.

Pituitary tumours

Patients with acquired hypogonadotrophic hypogonadism require assessment for a pituitary tumour with appropriate pituitary imaging studies, such as MRI, and determination of a prolactin level. Depending on the presence or absence of a tumour, other hormonal testing may be indicated, including thyroid and adrenal function tests. Further evaluation and treatment options would depend on what hormonal deficits are present, the size and site of the tumour, the operability of the tumour, and the patient's preferences in specific circumstances. If a prolactinoma is present, therapy would be directed toward correcting this problem before initiation of other therapy. Medical therapy with bromocriptine or pergolide may effectively reduce prolactin levels sufficiently to allow gonadal function to resume or allow stimulation with gonadotropins. Even when prolactin levels cannot be normalised, hCG therapy alone or in conjunction with human menopausal gonadotropin (or FSH) therapy may stimulate spermatogenesis and result in pregnancies. Surgical therapy should especially be considered for significant pituitary tumours that are not prolactin-secreting adenomas. Surgical treatment may also be an option in prolactin-secreting adenomas, if patients have severe side effects from medications or prefer this approach after being appropriately informed of the risks and benefits of medical versus surgical management.

Gynaecomastia

Many men have psychologic problems resulting from gynaecomastia. This problem should be taken seriously and discussed with the patient. Aromatase inhibitors, such as testolactone, tamoxifen or even clomiphene citrate may be helpful in some patients. Consultation with a plastic surgeon may be necessary in appropriate cases.

Psychologic counselling

Men with hypogonadotrophic disorders frequently have associated mood disturbances, including depression, aggression, poor self-esteem, and learning problems. In such cases, psychologic counselling is often needed to allow proper identification and treatment of these problems. Counselling should also include parents, spouse and relatives, if possible.

11.1 Introduction and Principles of Diagnosis in Dermatology

Vibhu Mendiratta

SKIN AS A VITAL ORGAN

Skin or the integument is the largest organ of the body and constitutes 16% of the body weight. It is composed of skin and appendages (sweat glands, sebaceous glands, hair and nails). It is not merely a covering for internal organs but is an active, functional organ that performs diverse functions, such as, protection from noxious environmental factors, as a sensory organ, participates in immunological defence mechanisms (skin has antigen presenting cells, and skin associated lymphoid tissue), endocrine functions (synthesis of vitamin D) and thermoregulation through sweating. The appendages of skin (nails, hair, sweat and the sebaceous glands) also perform various functions.

STRUCTURE OF SKIN

Skin is composed of three distinct zones — the epidermis, dermis and the subcutis (**Figure 1**). The epidermis is the outer layer of skin and is composed of keratinised stratified squamous epithelium. The dermis is mesodermally derived and consists of collagenous connective tissue that lies below epidermis and interdigitates with it. The hypodermis contains loose connective tissue with varying amounts of adipose tissue.

Epidermis

Epidermis is the outermost visible layer. The thickness is variable (0.05 mm on eyelids and the thickest on the palms and soles at 1.5 mm). Epidermis is thrown into folds over dermis in order to increase the area of absorption and for stronger cohesion to the dermis. Epidermis is composed of keratinocytes, melanocytes, Langerhans cells. It bears receptors for touch, pressure, temperature and free nerve endings. Epidermis is further composed of four sublayers, as described below:

1. Stratum corneum

It is the outer layer which consists of keratinised epithelial cells. The cells are flattened and anucleated. Thickness of the layer varies from 5 to 10 layers. *Stratum corneum* is regularly shed of and it renews itself every 14 to 30 days.

2. Stratum granulosum

Measures 3 to 5 cell layers of keratinocytes and contains keratohyaline granules. These granules are involved in the process of keratinisation.

3. Stratum spinosum

It is the thickest layer of epidermis and measures 5 to 8 layers.

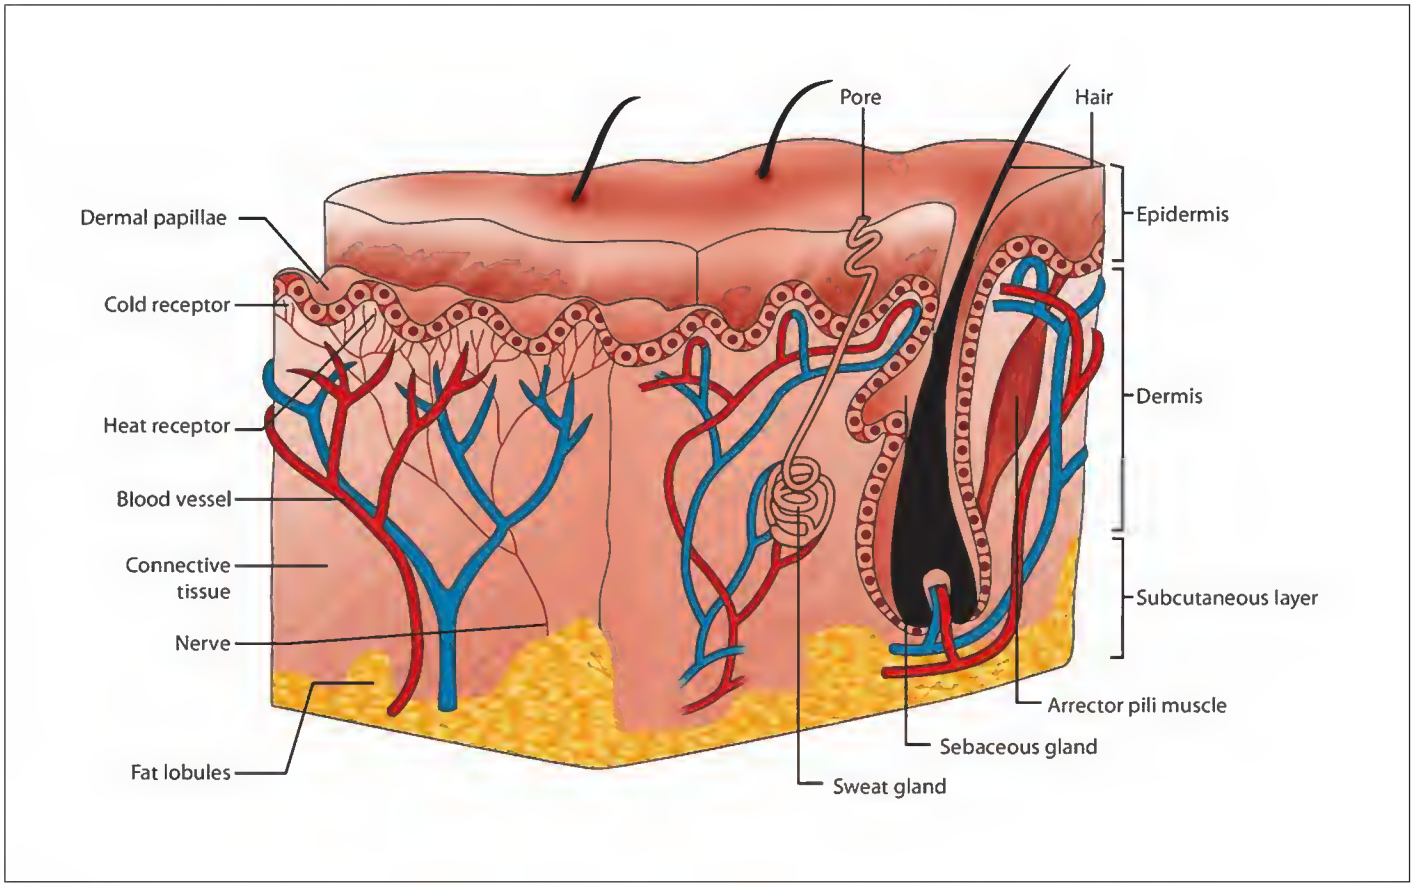

Figure 1: Skin structure with three distinct zones—epidermis, dermis and subcutis.

It is composed of cuboidal cells and appears more flattened than the underlying stratum basale.

4. Stratum basale

It is the lower most layer of the epidermis, which is composed of a single layer of cells that are columnar in shape, proliferate actively and lie interspersed with other cells. Stratum basale also has cells with dendritic processes which produce pigment (melanin). These are called the melanocytes. They remain in contact with keratinocytes. Langerhans cells also bear dendritic processes and belong to the macrophage-monocyte series. They lie in the living layers of the epidermis and perform the important task of antigen presentation to the T-lymphocytes. Merkel cells are special cells that are found in the basal layer of epidermis and act as touch receptors.

Dermis

Thickness of dermis is variable and measures 0.3 to 3 mm. It comprises of elastin, collagen and glycosaminoglycans. It contains extensive vasculature, neurones, smooth muscle, fibroblasts, sweat and the pilosebaceous apparatus with their ducts. It is the principal mechanical barrier of skin. Its network of elastic fibres functions to support the epidermis and binds the skin to the deeper hypodermis. The dermis contains two layers, the papillary layer and the reticular layer. The papillary layer is loosely woven, contains superficial connective tissue and interdigitates with the epidermal ridges and the deeper reticular layer. The dermal ridges contain Meissner's corpuscles, encapsulated nerve endings, and capillary loops that provide nutrients to the avascular epidermis. Dermis provides tensile strength, elasticity, and thickeness to the skin.

Subcutaneous Tissue/Hypodermis

It is the deepest part of skin composed of adipose tissue. The hypodermis provides insulation, shock absorption, energy storage, and the ability of skin to slide over joints. It also contains the major blood vessels of the skin.

PRINCIPLES OF DIAGNOSIS

Skin is the largest organ of the body. It reflects the state of internal organs. Various lesions based on their morphology are classified as primary or secondary lesions. A step-wise approach aids in correct diagnosis and includes the following steps:

History

History of drug intake, atopy, sexual history, recent travel, type of house, emotional status, illicit drug use and family history of skin diseases should be sought. Systemic diseases such as tuberculosis, diabetes, hypertension, hepatitis, blood transfusion, hospitalisations and major operative procedures should be recorded. History of local treatment, associated symptoms like pruritus, pain, stinging, burning, or anaesthesia should be enquired about.

Examination

Examination is performed in a well lit room. Skin, hair, nails, and mucous membranes should be examined. The clinician should recognise the primary lesions of a skin rash, determine pattern of distribution, and arrangement of eruption.

Identification of primary lesions of a skin rash

Primary lesions arise on the previously normal skin and have been classified further into various subtypes (**Table 1**).

Table 1: Different Types of Cutaneous Lesions (Primary/Secondary)

Primary lesions	Secondary lesions
Macule	Erosion
Patch	Crust
Papule	Ulcer
Plaque	Scale
Nodule	Lichenification
Vesicle	Atrophy
Bulla	Scar
Pustule	
Wheal	
Burrow	
Comedone	
Telangiectasia	

1. *Macule:* It is a flat, circumscribed area of skin showing an alteration in the skin colour, e.g. melasma, pityriasis and vitiligo (**Figure 2**).
2. *Patch:* A larger macule (>1 cm) is referred to as a patch. Patches are seen in leprosy, vitiligo and purpura (**Figure 3**).

Figure 2: Depigmented macules over tips of fingers in vitiligo.

Figure 3: A large purpuric patch over thigh in autosensitisation syndrome.

3. *Papule:* It is a circumscribed, raised elevated lesion which measures less than 0.5 cm, e.g. acne papules, lichen planus, *molluscum contagiosum* (**Figure 4**).
4. *Plaque:* A circumscribed area of skin which shows a change in the consistency of skin (**Figure 5**). Plaques are seen in lichen planus, psoriasis and neurodermatitis.
5. *Nodule:* An elevated, palpable lesion with greater depth than its height or width (**Figure 6**).
6. *Vesicle:* It is a clear fluid containing lesion measuring < 0.5 cm. Vesicles are seen in herpes zoster (**Figure 7**).
7. *Bulla:* A fluid filled lesion which measures more than 1 cm (**Figure 8**). The bullae are seen in pemphigus.
8. *Pustule:* A tiny lesion containing pus measuring less than 0.5 cm in size (**Figure 9**).
9. *Wheal:* Constitutes an erythematous, oedematous, transient, itchy papule or plaques seen in urticaria (**Figure 10**).
10. *Burrow:* It is a linear, thread like lesion in the web spaces of fingers, flexural folds of wrists, ankles and constitutes the primary lesion of scabies (**Figure 11**).
11. *Comedone:* It is a dark papule filled with keratin debris. Closed comedone is white in colour (**Figure 12**). Comedone is the primary lesion of acne.
12. *Telangiectasia:* Are the superficial, dilated capillaries, appear as wavy, thin, reddish blue lines (**Figure 13**). They are seen in connective tissue diseases.

Figure 6: Nodule over cheek (arrow).

Figure 4: Raised papule of acne over cheek.

Figure 7: Vesicles in herpes zoster.

Figure 5: Scaly plaque over the lower back in psoriasis.

Figure 8: A large fluid filled bullae in erythema multiforme.

Figure 9: Multiple pustules over knee and legs in pustular psoriasis.

Figure 10: Wheals. Erythematous, raised, itchy lesions over back in urticaria.

Figure 11: Burrows. Curvilinear, thread like structures over palms(arrows) burrows in scabies.

Figure 12: Comedone. Greyish-black, tiny, dark papules over cheeks in acne.

Figure 13: Telangiectasia. Multiple telangiectasia over nose and cheeks in systemic sclerosis.

Secondary lesions

Secondary lesions are changes in the primary lesions due to scratching, infection or treatment.

1. *Excoriations:* These are linear marks caused by scratching of skin (**Figure 14**). Excoriation marks are seen in scabies, dermatitis herpetiformis.

Figure 14: Excoriations. Linear marks with oozing of blood and crusting due to scratching in prurigo.

2. *Erosion:* Partial loss of epidermis constitutes an erosion (**Figure 15**). Erosions are seen in toxic epidermal necrolysis (TEN).
3. *Ulcers:* Loss of epidermis and partial loss of dermis forms ulcer (**Figure 16**). Ulcers arise secondary to trauma, burns, ischaemia or lack of nerve supply.

Figure 15: Erosion. Partial loss of epidermis causing a raw area in pemphigus.

Figure 16: Ulcer. Loss of epidermal cover with partial loss of dermis in an ulcer.

Figure 17: Scales in hand eczema.

4. *Scales:* Shedding of stratum corneum cells forms scales (**Figure 17**). Scale may be silvery, dry and abundant as in psoriasis.
5. *Crust:* Drying up of the exudates forms crust (**Figure 18**). A crust may be purulent, honey-coloured as seen in impetigo contagiosa, chocolate coloured in ecthyma.
6. *Lichenification:* Skin is thickened, leathery, pigmented with accentuated skin markings. It occurs in chronic eczema such as lichen simplex chronicus or neuro-dermatitis (**Figure 19**).
7. *Atrophy:* Decrease in the thickness of skin leads to atrophy. Epidermal atrophy is seen as smooth, shiny and wrinkled skin with easily visible dermal blood vessels. Dermal and subcutaneous tissue atrophy leaves behind a pit on the skin (**Figure 20**).
8. *Scar:* Destruction of skin and the underlying dermis results in scar which appears as a wrinkled area with loss of normal skin markings. It can be an atrophic (**Figure 21**) or hypertrophic scar. Atrophic scars are seen in acne, morphoea, post-burn. Keloid is a scar which is raised beyond the original lines of injury.

Figure 18: Crusts. Dried up exudate.

Figure 19: Lichenification.

Figure 20: Atrophy in linear morphoea.

Figure 21: Scar. An atrophic scar over leg.

Distribution of lesions

Lesions can be localised (limited to a discrete area) or generalised (widespread/affecting many areas). Distribution can be extensor (as in psoriasis) or flexural (neck, axillae, sub-mammary folds, groins). Intertrigo and candidal infections involve the flexural surfaces. Photosensitive disorders (systemic lupus erythematosus, photo-allergic dermatitis, polymorphous light eruptions) show photo distribution over the face, nape and V of the neck, extensor aspect of arms and dorsum of hands.

Identification of arrangement/configuration of lesions

Arrangement of lesions may vary. It may be linear, grouped, annular, targetoid, zosteriform, geographic, reticulated, and serpiginous.

Linear: Lesions arranged along a line as in linear lichen planus, linear psoriasis (**Figure 22**).

Grouped/Herpetiform: Lesions are closely clustered together, e.g. Herpes.

Annular: Arrangement in the form of a ring-plaques in borderline leprosy (**Figure 23**).

Targetoid: Lesion in concentric circles forming a target board that mimics the various zones of a target as in erythema multiforme (**Figure 24**).

Zosteriform or segmental: Distribution along one side of the body along a dermatome (area on the skin which is supplied by a dermal nerve) (**Figure 25**).

Figure 22: Linear lesions (in linear lichen planus on face).

Figure 23: Annular lesions in borderline leprosy.

Figure 24: Targetoid lesions in erythema multiforme.

Figure 25: Zosteriform lesions in herpes zoster.

Figure 26: Geographic tongue showing map-like pattern.

Figure 27: Reticulate lesions in livedo reticularis.

Geographic: Refers to large, bizarre lesion which have a map - like irregular outline. Borderline: borderline leprosy, geographic tongue (**Figure 26**).

Reticulated: Refers to a net work like distribution—oral lichen planus, cutis marmorata (**Figure 27**).

Serpiginous: Running along a zig-zag track like a snake-cutaneous larva migrans (**Figure 28**).

Blaschkoid: Along the lines of Blaschko as in epidermal naevi (**Figure 29**).

Figure 28: Serpiginous lesions in cutaneous larva migrans.

Figure 29: Blaschkoid lesions in hypomelanosis of Ito.

Final Categorisation of Skin Rash

Based on the morphological type of lesions the best way to categorise rashes would be presented as in **Table 2**.

Table 2: Morphological Types of Cutaneous Eruptions

Papulosquamous—As seen in psoriasis, pityriasis versicolour, lichen planus and *P. rosea*
Vesiculobullous—Herpes zoster, chickenpox, pemphigus vulgaris, bullous pemphigoid
Maculopapular—Drug rash, measles, rubella, toxic shock syndrome
Urticarial rash—Urticaria, erythema multiforme, vasculitis
Purpuric rash—Thrombocytopenia, drug hypersensitivity, vasculitis
Nodular rash—Syphilis, lepromatous leprosy
Pustular rash—Psoriasis, candidiasis, drug eruptions
Eczematous rash—Atopic dermatitis, seborrhoeic dermatitis, contact dermatitis

LABORATORY TESTS/LABORATORY TESTS AND PROCEDURES

The various tests are discussed below and summarised in **Table 3**.

Table 3: Common Investigative Procedures for Skin Diseases

KOH	Fungal infections, candidiasis
Gram's staining	Pyodermas, pustular lesions
Tzanck smear	Viral diseases, autoimmune bullous diseases
Skin biopsy	All kinds of rashes
Slit-smear preparation (Ziehl-Neelsen's staining)	Leprosy Mycobacteria (Tuberculosis and leprosy)
Immunofluorescence	Autoimmune bullous disease, connective tissue disease

KOH Examination

In case of itchy scaly lesions, the most active part of the lesion, (generally the border) is scraped gently with the help of a sterile, no. 14 blade and the scrapings are transferred onto a clean glass slide over which a drop of KOH (10%) is placed. Examination under the light microscope shows fungal hyphae as branching, septate, refractile filaments. *Candida* is seen as short, pseudo-hyphae which may show budding at places.

Wood's Lamp Examination

Wood's lamp contains a barium trisilicate filter that filters out all light except 311 nm. The lamp is used for examining the hair in suspected cases of tinea capitis as some causative dermatophytes fluoresce under ultraviolet light. It serves as a useful tool in the diagnosis of fungal infection of scalp. It is also used for examining the urine and teeth in certain congenital porphyrias and erythrasma.

Tzanck Smear

Fresh blister is de roofed using a sterile blade after cleaning it with spirit swab. Fluid is drained. The base of the blister cavity is scraped gently and smear is made on a clean glass slide. The smear is air dried and heat fixed and stained with Geimsa stain (1%). The smear is examined under the oil immersion lens of the light compound microscope. Multinucleate giant cells, acantholytic cells can be demonstrated in chickenpox and pemphigus group of diseases, respectively.

Gram's Stain

Smear is prepared from the pus filled lesions. It shows Gram-positive and negative cocci in pyodermas. It also demonstrates Gram-positive pseudohyphae of *Candida*. Absence of bacteria in the smear from a pus filled lesion indicates sterile pustules as in pustular psoriasis and drug-induced pustular eruptions.

Skin Biopsy

Histopathological examination of skin is carried-out by taking a tiny bit (0.4 to 0.6 mm) of the affected skin. Biopsy is taken with biopsy punche which come in various sizes (0.3 to 0.6 mm). Size of the punch is selected based on the depth of specimen required. An incisional biopsy is taken after administering local anaesthesia. It is an outdoor procedure. The specimen is transported in formalin (1%) for sectioning and staining.

Immunofluorescence

The technique is used in the diagnosis of autoimmune blistering diseases and autoimmune connective tissue diseases like systemic lupus erythematosus.

Slit-Smear Examination

It is a useful procedure to demonstrate the presence of *Mycobacterium leprae* in the skin. It is prepared from the ear lobes, eyebrows or from skin lesions. The site is cleaned with the help of sterile spirit swab, and kept pinched between the thumb and fingers for half a minute. A small nick (2 to 3 mm) is given with the help of a sterile surgical blade (No. 13-14). The area is gently scraped from the blunt margins of the blade. A smear is prepared on a clean glass slide. It is air dried and heat fixed and then stained with Ziehl-Neelsen stain. It is examined under the oil emersion lens for mycobacteria.

11.2 Cutaneous Infections

Vineet Kaur, Gurmohan Singh

BACTERIAL INFECTIONS OF SKIN (PYODERMAS)

The skin of newborn baby is sterile. Virgin skin is immediately colonised with non-pathogenic bacteria which include staphylococci, micrococci and diphtheroids. *Staphylococcus aureus* may also get colonised in neonatal period. Resident flora inhibits colonisation by pathogenic bacteria (bacterial interference). Hydration of skin promotes bacterial growth and desiccation limits the number of bacteria.

Impetigo Contagiosa

It is a superficial infection of the skin caused by *S. aureus* and/or *Streptococcus* beta haemolyticus. It is highly contagious in infants and young children. It is more frequent in hot and humid climates.

Staphylococci produce exotoxins which provoke inflammation of even intact skin. Streptococci can only infect the inflamed or traumatised skin.

It starts as vesicles on an erythematous base, containing clear fluid which becomes turbid in a day or two. In staphylococcal impetigo vesicles enlarge and become bullae and rupture after few days. In streptococcal impetigo, vesicles rupture fast, forming a honey coloured, loosely adherent crust (**Figure 1**). There may be regional lymphadenitis.

Diagnosis is straightforward. In recurrent cases one has to look for pre-existing skin condition like pediculosis capitis, mosquito bites or atopic eczema. Culture is seldom done unless it is not responding to treatment or is recurrent.

Figure 1: Impetigo contagiosa.

Good hygiene and regular baths in summer are helpful in prevention. Some cases of streptococcal impetigo may develop glomerulonephritis after 2 to 4 weeks.

Ecthyma

It is a deeper variant of impetigo occurring in older children with poor hygiene, malnutrition and repeated trauma, usually as a secondary infection. The crusts are thick chocolate coloured, more adherent with indurated base and surrounding erythema. It occurs mostly on lower extremities.

Folliculitis

It is staphylococcal infection of the hair follicle (**Figure 2**). It may be superficial or deep depending on the part of the hair follicle involved. Follicles may be infected after epilation or after oil massage. Deep folliculitis involves the whole depth of follicle. It commonly occurs on beard area (sycosis barbae) or neck (sycosis nuchae). Infection occurs through abrasions on shaving. Generally there is no destruction of hair follicles.

Figure 2: Folliculitis.

Furunculosis (Boils)

There is extended involvement of hair follicles including the perifollicular region in the dermis. It is caused by *S. aureus*. The boils are common during adolescence and early adulthood and are common during rainy season. Generally subjects are otherwise healthy but have poor hygiene or are carriers of *S. aureus*. In older patients factors like diabetes mellitus and intake of corticosteroids may be responsible for their increased frequency and greater severity.

Carbuncle

It is a group of boils which show deep infection of contiguous follicles with *S. aureus*. Infection spreads from one follicle to the other through subcutaneous tissue. Common sites are back of neck, shoulders, hip and thighs. It is usually associated with diabetes mellitus, exfoliative dermatitis or prolonged steroid therapy.

Erysipelas

It is streptococcal infection of the skin, mainly upper subcutaneous tissue and lymphatic vessels. The organism enters through a wound, injury or even a subclinically traumatised skin. Usually, there is a history of antecedent streptococcal throat infection. Skin is tense, erythematous, oedematous and lesions spread peripherally. Margins are sharply defined. Sites of involvement are abdominal wall in infants and face in children.

Cellulitis

It is a deeper variant of erysipelas and may be acute, subacute or chronic. The borders are less well defined. There may be associated systemic symptoms of malaise and fever.

Secondary Bacterial Infection

Staphylococcus aureus and streptococci can complicate any skin disorder.

Management of pyodermas

1. Improvement of local hygiene
2. Identification and elimination of immunocompromising factors, if any suspected
3. Avoidance of insect bites in children
4. Staphylococcal carrier sites (anterior nares) be treated with twice a day application of fusidic acid or mupirocin ointment for 3 months
5. Topical antibiotics may be useful in preventing streptococcal pyoderma when applied three times a day for minor skin trauma in children. In crusted lesions the crusts must be removed gently
6. Local application of heat is beneficial in cases of boils.

Topical treatment

Superficial localised skin infections like impetigo and superficial folliculitis may respond to rigorous topical treatment with antibiotic creams like fusidic acid or mupirocin. 1% gentian violet is a cheap but effective option. Bacitracin, polymyxin and neomycin are available in various preparations, often in combinations.

Systemic treatment

These are needed for all but the most localised infections. *Streptococci* are relatively easily amenable to treatment with antibiotics. Penicillin group of drugs are effective. *Staphylococcus* has developed resistance to many anti-microbials.

Empirically one can start with tetracyclines (including doxycycline), or cotrimoxazole. Hospital acquired infections are more often resistant and need treatment with cloxacillin, azithromycin or cephalosporins. Duration of treatment is 5 to 7 days for superficial infections and up to 3 weeks for deep infections.

DISORDERS DUE TO OVERGROWTH OF CORYNEBACTERIA (DIPHTHEROIDS)

These are commensals but persons who sweat more may develop malodorous axillae and trichomycosis axillaris (fine yellowish deposits on axillary hair). In those who have prolonged immersion of hands and feet in water develop pitted keratolysis.

FUNGAL INFECTIONS OF SKIN

There are two main groups of fungal infections of superficial skin: (i) those due to dermatophytes and (ii) those due to yeasts. A few fungi invade deeper tissues. These are the deep mycoses.

Dermatophytoses (Tinea/ Ringworm)

These are classified according to sites affected. They are often self treated or wrongly treated with topical steroids which may confuse the picture (tinea incognito).

Tinea Capitis (Scalp Tinea)

Usually a disease of pre-adolescents. Fungi may be contracted from family members having tinea anywhere on body, or school-mates with tinea capitis or from infected animals. There is patchy loss of hair (only broken hair) with variable degrees of inflammation (to differentiate from alopaecia areata in which there is no inflammation and total loss of hair from the root). There may be inflammatory tinea with boggy swelling (kerion) (**Figure 3**). This is usually acquired from animals and is often misdiagnosed as pyoderma.

Figure 3: Tinea capitis (Kerion).

Tinea Corporis

The lesions are itchy, erythematous and scaly patches with well-defined borders. The borders are more prominent and often have papules and pustules. There may be central clearing so that annular or circinate patterns are formed (**Figure 4**).

Tinea Cruris

It involves groins and buttocks. It is more common in adult males. Recurrence is usually due to autoinfection from other sites like tinea pedis. Tight clothing and humidity are predisposing factors.

Tinea Pedis and Tinea Manum

These are common and often associated with tinea unguium (**Figure 5**). There are three distinct forms.

Figure 4: Tinea corporis.

1. Tinea interdigitale. There is scaliness or maceration in the interdigital space.
2. Vesicles on sides of feet, extending to rest of soles.
3. Dry and scaly type, often treated as eczema or psoriasis. Presence of typical tinea lesions on the dorsum of the foot and other parts of body may assist in diagnosis. In tinea manum, the scales are powdery and start in creases.

Tinea manum is most often unilateral.

Tinea Unguium

Toe nail infection is common as isolated tinea or associated with tinea pedis. Free edge of nail becomes yellowish, crumbly, then developing subungual hyperkeratosis and separation of nail from its bed (**Figure 5**). Usually starts with one or two nails, but rarely all are affected. Finger nail involvement is less common and less severe and is always associated with tinea manum.

Figure 5: Tinea unguium.

Tinea Barbae

It is invasion of hairs of beard by fungus, resulting in inflammatory lesion with follicular pustules. Usually due to unhygienic shaving by road side barbers.

Tinea Faceii

It is infection of face outside the beard area. Face is involved if a person has tinea of other sites or due to sharing towels with another family member with tinea.

Treatment

Topical treatment alone is indicated when the disease is of limited extent and only one site is involved. Clotrimazole, miconazole, and terbinafine creams applied twice daily for 4 to 6 weeks are effective. On palms and soles where there are hyperkeratotic lesions, Whitfield's ointment is more effective.

Systemic treatments include griseofulvin, triazoles and terbinafine. Griseofulvin is the drug of choice for tinea capitis in doses of 15 to 20 mg/kg body weight for 8 weeks. Triazoles include itraconazole and fluconazole. Itraconazole 200 mg to be given twice per day for 7 days for tinea cruris and corporis and for tinea unguium 400 mg daily for 7 days every month for 3 months. Fluconazole 150 mg once or twice a week for 4 weeks for tinea cruris and corporis and for 6 months for tinea unguium. Terbinafine is given as 250 mg daily for 2 weeks in tinea cruris, corporis and manum; 3 months for tinea unguium of finger nails and 6 months for toe nails.

YEAST INFECTIONS

Most yeasts are true commensals and only invade skin under certain conditions.

Pityriasis Versicolour

Pityrosporum orbiculare, the causal organism, is a normal inhabitant, grows profusely in humid climates and on certain skin types. As the organisms are normal inhabitants, it is not a contagious disease. It commonly affects upper chest, back and upper arms. Some patients may have mild itching. Even after treatment the hypopigmentation may take a long-term to clear. Recurrences in humid season are common.

Treatment

Topical treatment with selenium sulphide and/or clotrimazole once weekly for few weeks. Oral fluconazole 400 mg single dose is an alternative.

Candidiasis

Candida albicans is an opportunistic pathogen, found naturally in the oral cavity and lower intestinal tract and vagina in half of the normal population. Predisposing factors for symptomatic invasion include obesity, high humidity, diabetes, pregnancy, use of contraceptive pills, topical or systemic steroids or systemic antibacterials. Its clinical picture varies with the site.

Oral

It is most common in children or the elderly. Persons on oral antibacterials or immunosuppressants are also more prone. It presents as thrush, which are white adherent patches that leave an erythematous or bleeding surface on wiping off. There may be angular cheilitis.

Flexures

The areas commonly involved are inframammary, axillae, groins and between fingers. There is glazed erythema and maceration. There may be satellite pustules. Often there is some burning sensation.

Genital

White curdy discharge with erythema and pruritis are the features of candidial vulvovaginitis. This may be associated with inguinal candidiasis. Conjugal infection in males results in balanitis (in circumcised) or balanoposthitis. The glans becomes erythematous and the prepuce is inflamed, indurated and becomes whitish. There is difficulty in retracting the prepuce. On forcible retraction fissures may develop on the prepucial orifice.

Nail folds

Common in bakers and housewives working with water. Proximal nail fold and later lateral nail folds get inflamed and swollen. On pressing the nail fold, some cheesy material may be extruded. This is called chronic paronychia. *Proteus* or *Pseudomonas* may be co-pathogens. Staphylococci or streptococci may secondarily infect producing acute paronychia (**Figure 6**).

Figure 6: Paronychia.

Treatment

Topical gentian violet 1%, clotrimazole and miconazole and oral fluconazole are effective. Dryness of the affected part needs to be maintained.

DEEP MYCOSES

There are many deep fungal infections but the most common among these is mycetoma.

Mycetoma (Madura foot)

It is caused by either filamentous bacteria (*Actinomyces* spp.) or fungi which are introduced by a penetrating injury. Indurated nodules develop which enlarge and soften. These are often neglected and the process extends to deeper tissues and may even involve bone. The nodules burst on the surface producing multiple sinuses discharging pus which is granular. The granules are colonies of infecting organisms. These are diagnostic.

Treatment

Bacterial mycetomas respond to high doses of penicillin, streptomycin, cotrimoxazole, tetracyclines, dapsone and saturated solution of potassium iodide given for long periods of time.

Fungal mycetomas respond to ketoconazole 200 mg twice a day, or itraconazole 200 mg a day for 6 to 9 months.

VIRAL INFECTIONS

Viral Warts (Verrucae)

Caused by human papilloma virus (HPV). A few of these have oncogenic potential. Clinically they present variously depending on the site involved.

Common Warts

Rounded or irregularly shaped papules with rough and hyperkeratotic surface, on hands and feet. These may spread by autoinoculation and may be in a linear pattern. In severe immunosuppression they may be generalised. These are painful, if present around or under the nail. Lesions on the neck are often pedunculated (filiform warts).

Plantar Warts

Warts on the soles are only slightly raised, even when they assume large size. These may or may not be present on pressure sites. Corns occur only on pressure points. Both are painful particularly on walking. Warts if present only on pressure points can be distinguished from corns by paring, when oozing capillary loops can be observed in warts.

Plane Warts

These are flat topped, smooth, skin coloured or slightly dark, usually present on the face in children. Lesions arranged along scratch lines, if present, help in diagnosis.

Anogenital Warts

These are mostly sexually transmitted. Rarely these may result from autoinoculation from warts on other parts of the body. Lesions increase in number and size and coalesce to become cauliflower like. In women these may also affect the vagina and cervix. Other sexually transmitted infections (STIs) should be excluded. In children with anogenital warts, sexual abuse should be considered.

Treatment

Topical treatment

Keratolytics: In plane warts, topical tretinoin 0.05% to 0.1% applied at night for few months may be effective. In common and plantar warts, 'wart lotions' or 'corn lotions' which contain salicylic acid and lactic acid may be used only on the lesions, protecting the surrounding normal skin, preferably after paring the affected skin. Trichloracetic acid (TCA) may be applied on the lesions. In anogenital warts, 50% TCA may be applied once or twice a week. On plane warts, this may be applied on the wart with a sharp wooden toothpick.

Cytotoxic agents: Podophyllum 20% is applied on the lesion and washed after 2 to 4 hours and repeated once a week. Podophyllotoxin is safer to apply.

Formaldehyde 5%: Soles or palms can be soaked for 10 to 15 minutes per day.

Destruction: Electrosurgery, cryotherapy or scalpel excision.

Topical immunotherapy: Sensitisation with DNCB, topical imiquimod.

Systemic therapy: Immunomodulators like levamisole.

Cellular modifying agents like oral retinoids.

Molluscum Contagiosum

It is a common skin infection in school children. It is transmitted by direct contact and rarely through swimming pools. In adults lesions near genitals are often sexually transmitted. Large lesions on the face may indicate immunosuppression.

The lesions are globular whitish or yellow papules which develop a central depression (umbilication). Cheesy material can be expressed from a well developed lesion.

Treatment

Options include topical application of phenol, TCA or 10% KOH with a toothpick, curettage with a hypodermic needle or cryotherapy.

Herpes Simplex

It is caused by herpes simplex virus, which has 2 strains HSV1 and HSV2. HSV1 causes lesions around the oral orifice but genital lesions are generally caused by HSV2. The disease is acquired by direct contact with an infected person. Once infection is acquired it persists in the nerve ganglion all through life. Recurrence is more common in genital herpes.

The first infection is often asymptomatic and passes off unnoticed in most people. In some children, however, there may be acute gingivostomatitis characterised by multiple vesicles and ulcers. There is regional lymphadenitis. In genital herpes, a similar picture may be seen. After the primary herpes simplex infection, the virus becomes latent and may remain so or may get activated and present as recurrent herpes. The precipitating factors include stress, fever, common cold, excessive exposure to sunlight and trauma.

Recurrent herpes I lesions usually occur on the same sites. There is tingling or burning followed few hours later by erythema on which tense grouped vesicles appear. Vesicles dry and crust or erode. These heal in 7 to 10 days. In genital herpes, lesions are painful. The recurrent, grouped vesicles on erythematous base make diagnosis straightforward. Antibody titres do not rise with recurrent infections and are of no diagnostic significance.

Treatment

As it is self-limiting, no treatment is indicated. Topical application of surgical spirit keeps it dry and prevents secondary infection. Anti-viral drugs like acyclovir reduce viral replication and shorten attacks. However, these are only effective if started at the first sign of recurrence. Acyclovir (5%) needs to be applied every 4 to 5 hourly after removing the roof of the vesicles. Oral acyclovir 200 mg five times a day after food for 5 days may be given. Suppressive therapy is given in cases getting more than 6 recurrences a year. Acyclovir 400 mg twice a day for a year is recommended. Other antivirals for herpes simplex are valacyclovir and famciclovir.

Varicella (Chickenpox)

It is caused by varicella-zoster virus, which spreads by droplet infection. Incubation period is around 2 weeks. Constitutional symptoms, which are absent or mild in children, are followed by appearance of itchy papules which rapidly turn into vesicles. These become pustular in 3 to 4 days and finally get crusted. Lesions appear in crops. The lesions are maximum on the trunk. The patient is infectious from prodrome to formation of crusts.

Treatment

This is only symptomatic. Acyclovir is indicated only for severe attacks and for immunocompromised patients.

Herpes Zoster

It is reactivation of V-Z virus lying in a latent phase in the sensory nerve ganglion. It may, however, transmit the virus to others and result in varicella in non-immune subjects.

Initial symptoms are burning sensation and pain, which is followed by typical herpetic lesions. These are unilateral and distributed dermatomally. The lesions become pustular and then crusted in 2 to 3 weeks. It may leave depressed scars on healing. If the ophthalmic division of trigeminal nerve is involved, corneal ulcers may develop. If there are vesicles on side of nose, it indicates the involvement of the above nerve. There may be persistent neuralgic pain after the lesions subside. This is usually seen in the elderly (post-herpetic neuralgia).

Treatment

As secondary bacterial infections are common, topical antibacterials may be used. Treatment is symptomatic, using analgesics. In older people with higher risk of post-herpetic neuralgia and in ophthalmic zoster, oral acyclovir can be given. The dose of acyclovir is 4 times that used in herpes simplex, i.e. 800 mg 5 times a day. It is useful only if given within first two days of the attack. If post-herpetic neuralgia develops, this can be managed with long-term use of tricyclic compounds (amitryptiline 25 mg BD) or gabapentine 300 mg to 900 mg daily.

11.3 Infestations and Insect Bites

Devinder Mohan Thappa, Laxmisha Chandrashekar

INTRODUCTION

Infestation refers to the state of being invaded or overrun by parasites. It can also refer to parasites living in or on a host. A parasite is defined as an organism that depends upon a living host for one or more of its essential metabolic requirements. Cutaneous lesions may result from direct damage by or presence of the parasite. Scabies, pediculosis and papular urticaria are caused by ectoparasites; patients usually present with itching.

SCABIES

There are two main types—human scabies and animal scabies.

Human Scabies

It is a contagious disease caused by the mite *Sarcoptes scabiei* var. *hominis* contracted through close personal contact or contaminated clothing. Over-crowding and poor hygiene helps its spread.

Sarcoptes scabiei var. *hominis* has an ovoid body, flattened dorsoventrally. The adult female measures approximately 0.4 mm long by 0.3 mm broad, and the smaller male 0.2 mm long by 0.15 mm broad. There are 4 pairs of short legs; the anterior 2 pairs end in elongated peduncles tipped with small suckers. In the female, the rear 2 pairs of legs end in long bristles (setae) (**Figure 1**). The adult male mite dies after copulation with adult female mite. After copulation the fertilised female mite excavates a burrow in the stratum corneum. Approximately 40 to 50 eggs are laid by each female during a lifespan of 4 to 6 weeks, during which time she does not leave the burrow. Six-legged larvae emerge from the eggs after 3 to 4 days and escape from the burrow by cutting through its roof. The larvae then dig short burrows (moulting pockets) in which they transform into nymphs. After further moults, adult males and females develop. On an average, an adult has 12 mites and an infant 20 mites.

First episode may take 3 to 4 weeks time to manifest. However, reinfection provokes immediate symptoms both due to immediate and delayed type hypersensitivity.

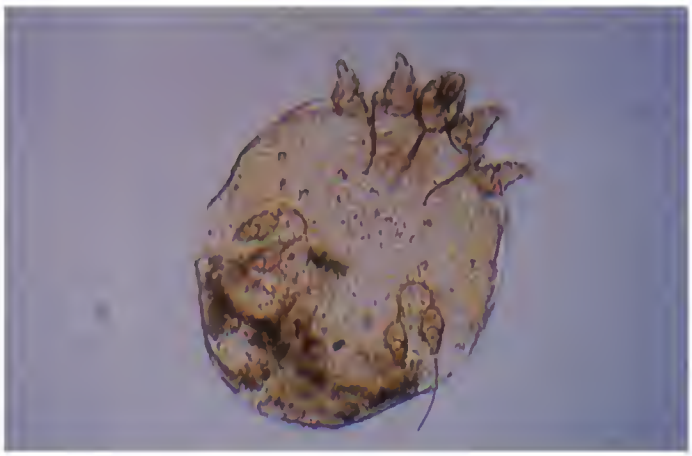

Figure 1: *Sarcoptes scabiei* var. *hominis* mite.

Clinical features

Often suspicion of scabies is based on nocturnal itching and family history of scabies. The pathognomonic lesions of scabies are burrows, which appear as fine, tortuous 'S' shaped slightly scaly blackish threads a few millimitres long. Sometimes, a papulovesicle is visible near the blind end of the burrow adjacent to which is the female mite. The burrows and associated papules and vesicles are directly related to the presence of the *Sarcoptes* whilst the generalised rash is related to the development of sensitisation.

Most worrying to the patient is the papular pruritic eruption, which is the result of hypersensitivity reaction to the mites and mite's products. Sites of predilection (**Figure 2**) include the finger web spaces (**Figure 3**), borders of hands, sides of fingers, feet particularly the instep, wrists, axillae, areolae, umbilicus (**Figure 4**), lower abdomen, genitals, buttocks (**Figure 5**). An imaginary circle intersecting the main sites of involvement—axillae, elbow flexures, wrists and hands and groins has long been called the 'circle of Hebra'. This predilection may be due to the fact that mites prefer non-hairy skin and areas of low sebum production. The involvement of genitalia of males (**Figure 6**) and itching of nipples in females are important clues.

In babies, the presentation may be slightly different with vesicles and vesiculopustular eruption on palms and soles, extensive

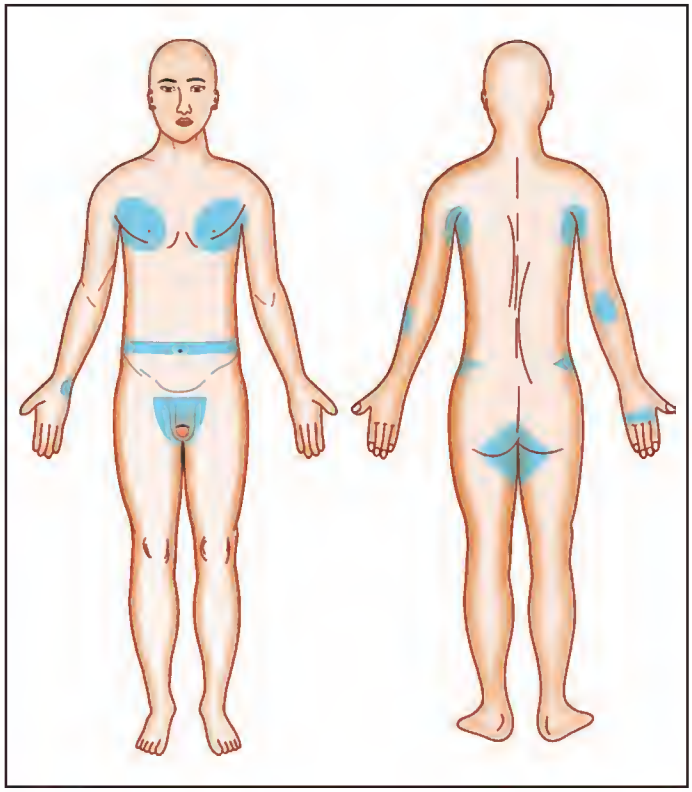

Figure 2: Characteristic distribution of scabies lesions over the body in adults.

distribution of burrows and crusted nodules including over the trunk and limbs, and extensive eczematisation is seen. Unlike in adults, the scalp and face may be involved in infants. In clean individuals only few scattered papules may be seen and itching may be mild.

Figure 3: Finger web spaces involved by papular and excoriated lesions.

Figure 4: Papular eruption of scabies around umbilicus.

Figure 5: Papular and excoriated lesions over the buttocks.

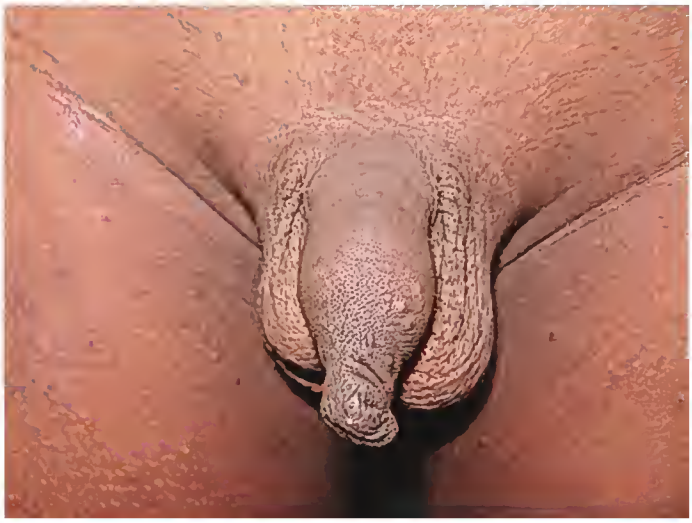

Figure 6: Typical burrows of scabies along with papules over the shaft of the penis.

Variants of scabies include nodular scabies and crusted scabies. Bullous pemphigoid like eruption and cutaneous vasculitis are unusual presentations. Secondary changes may confuse the clinical picture frequently. Secondary infection manifests as folliculitis and impetigo and infection with beta haemolytic streptococci may be responsible for secondary sepsis and post-streptococcal glomerulonephritis. Eczematous changes are common and severe.

Diagnosis

Scabies can be easily diagnosed based on history of nocturnal itching, family history of itching and typical localisation of lesions. Confirmation of diagnosis if desired may be accomplished by demonstration of burrows, mites (**Figure 1**) and mite's products like scybala, eggs, etc. from skin scrapings or epiluminescence microscopy. To identify burrows quickly, a drop of India ink or gentian violet can be applied to the infested area, and then removed with alcohol. Thin thread-like burrows retain the ink.

Anti-scabietic agents used in the treatment include:

Topical Agents

- Permethrin 5% cream
- Lindane (gamma benzene hexachloride) 1% lotion or cream
- Benzyl benzoate 10% and 25% lotion or emulsion
- Malathion 0.5% lotion
- Monosulfiram 25% lotion
- Crotamiton 10% cream
- Precipitated sulphur 2% to 10% ointment
- Esdepallethrine 0.63% aerosol
- Ivermectin 0.8% lotion

Oral drugs

In infants and pregnant women, sulphur ointment and crotamiton is preferred. The 5% permethrin cream may be used in infants over 2 months of age. In adults and children over 5 years of age, 5% permethrin cream is standard therapy for scabies. In children less than 5 years of age, the cream must be applied to the head and neck, as well as the body.

Single overnight application with permethrin is sufficient. However, gamma benzene hexachloride lotion needs to be kept on the body for 8 to 12 hours. Benzyl benzoate if used, 3 applications need to be given at 12 hourly interval without intervening bath. Sulphur ointment though messy is thought to be most effective treatment given once daily for 3 days. Similarly, crotamiton may be used. Additional advantage with crotamiton is its antipruritic effect. Monosulfiram is available as soap. Now even, gamma benzene hexachloride is marketed as soap. Ivermectin, an antihelminthic agent can be given in a single oral dose (200 µg/kg body weight, adult dose is 12 mg). Side-effects include headache, pruritus, pain in the joints and muscles, fever, maculopapular rash, and lymphadenopathy. It is contraindicated in patients with an allergy to ivermectin and central nervous system disorders. It is increasingly being used in the treatment of scabies in India.

Symptomatic relief of itching can be achieved with antihistamines. The older sedative antihistaminics are to be preferred over newer non-sedative ones. Prior to anti-scabietic treatment, secondary pyoderma and eczematisation should be treated appropriately. Treatment of other family members is important. Clothing and bedding can be laundered and put in sunlight.

Nodular Scabies

In some cases, itching nodules persist for several months on the genitalia. They are found most commonly on the scrotum. Topical therapy, intra-lesional steroids, tars or excision are methods of treatment. Histologically, it may suggest lymphoma.

Crusted Scabies (Norwegian or Hyperkeratotic)

It is found in immunocompromised or debilitated patients, including those with neurologic disorders, Down's syndrome, organ transplants, graft-versus-host disease, adult leukaemia, leprosy, or AIDS. It is characterised by psoriatiform or warty lesions accompanied by nail hyperkeratosis but no burrows and minimal itching is present. The average number of mites in these cases is 2 million; it is highly contagious and may be the source of epidemics. Ivermectin is the treatment of choice in addition to keratolytics.

Scabies incognito occurs on inappropriate use of topical steroids as steroids suppress the inflammation to the mites and reduce itching, so there is less scratching and destruction of burrows.

Animal Scabies

Various itch mites affect animals with which man comes in close contact. These animals are dogs, cats, birds, etc. Itchy papular eruption is localised to site of contact of animal with human skin. The eruption is self-limiting, with no burrows. Animals need to be treated with anti-scabietic agents and symptomatic treatment is given to the person concerned.

PEDICULOSIS

Infestation with lice is called pediculosis. Lice are called ectoparasites because they live on the body. Close personal contact or contact with objects shared by others helps in the transmission of lice. They are classified as wingless insects because they have three pairs of legs. Three kinds of lice infest humans: *Pediculus humanus* var. *corporis* (body louse), *Pediculus humanus* var. *capitis* (head louse) and *Phthirus pubis* (pubic or crab louse) (**Figure 7**). The body louse is the largest and the crab louse is the smallest with a short oval body with prominent claws resembling sea crabs. Lice feed by piercing the skin with their claws, injecting irritating saliva and sucking blood. The female lays approximately 6 eggs or nits each day. The egg hatches in 8 to 10 days and reaches maturity in approximately 18 days. Nits are glued to the bases of hair shafts (**Figure 8**). The incubation period of pediculosis is about 30 days.

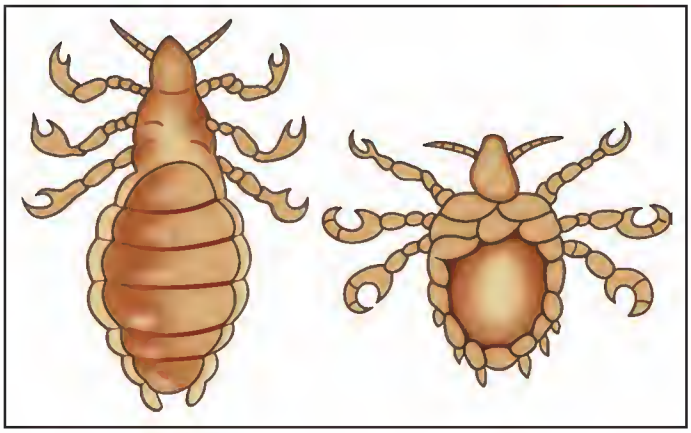

Figure 7: *Pediculus humanus* var. *capitis* (head louse) and *Phthirus pubis* (pubic or crab louse).

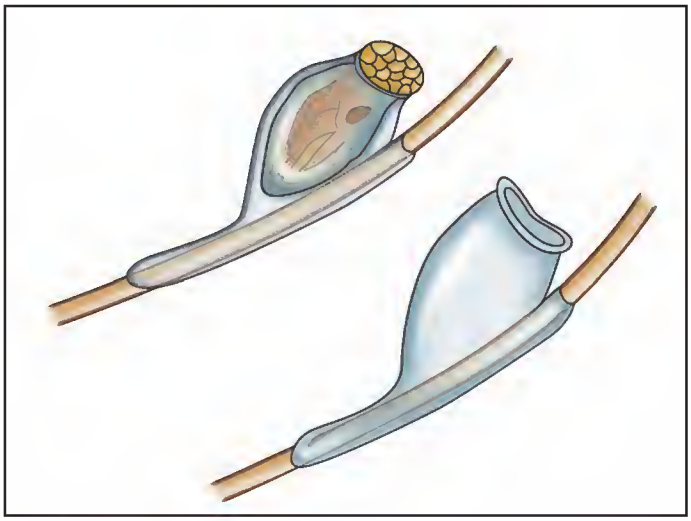

Figure 8: Viable nit (top left) and non-viable nit, empty egg case (bottom right) glued to hair.

Pediculosis Capitis

Lice infestation of the scalp is most common in children especially girls with long hairs. Itching and secondary pyoderma in the scalp are presenting manifestations. The diagnosis is made by seeing the lice in the scalp or more often, nits glued to the hair shaft (**Figure 9**) in the retro-auricular and occipital region of the scalp. Ova close to the scalp are only viable; along the distal hair shaft are empty egg cases. Peripilar keratin hair casts are remnants of inner root sheath that encircle the hair which can be mistaken for nits. While nits are firmly cemented to the hair, casts move freely along the hair shaft.

Pediculocidal treatment with 1% permethrin rinse or gamma benzene hexachloride lotion/shampoo may be instituted. Malathion, crotamiton and lindane have also been found to be effective. Combing with a metal or plastic comb after conditioner (8% formic acid solution) is an adjunctive measure.

In case of secondary infection of the scalp, cotrimoxazole may do the dual function of treating pyoderma and killing all adult lice. Repeat treatment with pediculocidal agents may be necessary after 1 week, as they may not kill nits. Shaving the head will cure head lice but has poor patient compliance. Orally, ivermectin has also been used. Family members and contacts should be treated.

Figure 9: Nits glued to scalp hair.

Pediculosis Corporis (Vagabond's Disease)

Pediculosis corporis is a disease of the unclean. Body lice live and lay their nits in the seams of clothing and return to the skin surface only to feed. It induces pruritus that leads to scratching, copper coloured macules, wheals, lichenification and secondary infection. The diagnosis is positively established by finding the lice or nits in the seams of clothing. Body lice are vectors for relapsing fever, trench fever and epidemic typhus.

Treatment is directed at clothing and bedding. Simple laundering and ironing is successful. Permethrin or malathion spray can be used to disinfect clothing.

Pediculosis Pubis

Phthirus pubis infestation is found in the pubic region, as well as hairy areas of legs, abdomen, chest, axillae, arms and also eyelashes (pediculosis palpebrum) and scalp rarely. Itching or crawling sensation of something are the complaints in the majority of patients. It is transmitted by close sexual contact, hence a screening for sexually transmitted diseases should be done. Diagnosis is made on seeing black speck like bodies attached to the root of hair at an angle—the crab lice. Occasionally, in fair skinned individual, one may encounter gray blue macules (maculae caeruleae) varying in size from 1 to 2 cm in the groin, inner thighs and sides of trunk. They are probably caused by altered blood pigments.

Gamma benzene hexachloride lotion or permethrin may be used topically for pediculosis pubis. For eyelash involvement a thick layer of petrolatum can be applied twice daily or fluorescein can be used. Shaving of pubic hairs is another alternative treatment. Sexual partners should be treated simultaneously.

PAPULAR URTICARIA

Definition

Papular urticaria is a term used to describe a chronic or recurrent eruption of pruritic papules, often grouped in irregular clusters, frequently seasonal in incidence, and affecting predominantly children between the ages of 2 and 7 years. Adult cases are seen but are less common than childhood cases.

Aetiopathogenesis

Papular urticaria is an allergic hypersensitivity reaction to arthropod bites. The role of arthropods in papular urticaria gradually gained support because of the following observations:

1. The lesions usually appear in the summer months;
2. The disease is more common in lower socioeconomic groups; and
3. Papular urticaria is seen with greater frequency among households with pets.

The most commonly implicated arthropods are the mosquitoes, bed bugs and the fleas.

Clinical Features

The condition consists of small, 3 mm to 10 mm diameter, pruritic, urticarial papules, sometimes surmounted by a vesicle, that are present on exposed areas of the body (**Figure 10**). The papules may last from weeks to months and, in some cases, years. They form in clusters and are characteristically distributed on the extensor surfaces of the arms and legs.

Figure 10: Papular excoriated lesions over the lower limb of a child.

The genital, perianal and axillary regions are not usually involved. Excruciating pruritus frequently leads to excoriations, which may become secondarily impetiginised. The lesions generally persist for 2 to 10 days and may result in temporary hyper-pigmentation once they resolve.

Differential Diagnosis

Differential diagnosis includes:

- Scabies,
- Prurigo simplex,
- Urticaria,
- Atopic dermatitis,
- Papular drug reaction,
- Miliaria rubra and
- Allergic contact dermatitis.

Treatment

The treatment is based on identification and removal of the cause. Mild topical steroids and oral antihistamines can be used to control pruritus. Oral antibiotics can be used for secondary infections. Disinfection of all pets along with fumigation of the home in recommended. Patients should use insect repellent creams on the skin before venturing outdoors.

11.4 Eczemas

Ashok Kumar Bajaj

INTRODUCTION

Eczema or dermatitis is a group of inflammatory skin diseases provoked by a wide variety of stimuli, i.e. direct injury from toxic chemicals, mechanical trauma and immunological reactions. The word eczema is derived from the Greek word 'eczein' meaning 'to boil over' or 'to effervesce'. The terms, dermatitis and eczema are often used as synonyms, but the term eczema is preferably used for exudative dermatitis.

Depending upon the clinical manifestations, eczema can be subdivided into the following three stages:

Acute Eczema

It represents wet dermatitis characterised by intense pruritus, erythema, oedema, papules, vesicles, oozing, crusting, and even blister formation.

Subacute Eczema

It is characterised by diffuse erythema, oedema and scaling. In this stage, oedema, vesiculation and oozing components come down. The lesion starts scaling.

Chronic Eczema

It is represented by severe itching, hyperkeratosis and lichenification (thickening, hyper-pigmentation and accentuated skin markings).

Just like clinical features, histopathology varies with the stage of eczema. In the acute stage, there is spongiosis (intercellular oedema) and intraepidermal spongiotic vesicle formation. Features that predominate in the chronic stage are acanthosis (thickening of stratum malpighii with elongation of rete ridges), hyperkeratosis (thickening of stratum corneum) and parakeratosis (nuclei seen in stratum corneum). In the subacute stage, there is combination of these two reaction patterns.

CLASSIFICATION

Eczematous disorders are classified according to the aetiology (**Table 1**) as follows:

Table 1: Classification of Eczema

Endogenous eczema	Exogenous eczema
Atopic dermatitis	Irritant contact dermatitis
Seborrhoeic dermatitis	Allergic contact dermatitis
Nummular eczema	Photodermatitis
Pompholyx (Dyshidrotic eczema)	Infectious eczematoid dermatitis
Asteatotic eczema	
Stasis dermatitis	
Juvenile plantar dermatitis	
Lichen simplex chronicus	

Endogenous Eczema

In this type of eczema, the course of the problem arises mainly from the patient's inherent constitutional factors and partly due to the superimposed environmental factors.

Exogenous Eczema

When the patient develops eczema as a result of the exposure of the patient's skin to environmental noxious agents.

In many cases both external and internal factors contribute to the pathogenesis of eczema.

ATOPIC DERMATITIS (ATOPIC ECZEMA)

Atopic dermatitis is a common form of endogenous eczema and its incidence is increasing in India. The exact aetiology is unknown but genetic and environmental factors are probably equally important in the development of atopic dermatitis. A family history of asthma, hay fever (rhinitis and conjunctivitis), atopic dermatitis and even urticaria is common in patients with this condition. Around half of the children with atopic dermatitis go onto develop asthma or hay fever or both. These disorders are inherited as autosomal dominants with incomplete penetrance. The environmental factors which act as triggers for atopic dermatitis are climatic changes, food items (eggs, dairy products, nuts, etc.), bacterial infection and dry skin.

Clinical Features

Atopic dermatitis usually develops around the age of 3 months and is labelled as infantile eczema. It classically affects the cheeks, scalp and extensor surfaces of the limbs and trunk (**Figure 1**). There is erythema, oedema and papulovesicular oozing lesions with severe itching. It is the itch which produces the lesions rather than the lesions which cause itching. The affected children may sleep poorly and may be hyperactive. After a variable course of relapses and remissions the disease subsides in over 80% of the children by the age of 18 months. In the rest of them it continues into *childhood phase* which is characterised by itchy papular lesions in the cubital and popliteal fossae, ankles, wrists, and sides of the neck. The skin may also become thickened and rough

Figure 1: Atopic dermatitis (infantile eczema).

(lichenification). Patients often have fairly dry skin. Multiple scratch marks and abrasions are seen in patients with severe itching. It affects the school and social life of such children.

In about two-thirds of the childhood eczema patients, the disease subsides by the age of puberty, and in the remaining it continues on to the *adult phase*. The distribution in the adult phase is similar to childhood phase with morphology of subacute or chronic eczema. Relapses and remissions depend upon the activation of various trigger factors like mental and physical stress, climatic changes, secondary infection, etc.

Common complications include secondary bacterial infection with staphylococci and viral infections. Most patients of atopic eczema are colonised by *Staphylococcus aureus* all the time with or without apparent evidence of infection and anti-staphylococcal therapy frequently leads to improvement. This emphasises the role of bacteria in perpetuation of dermatitis. Common viral infections complicating atopic eczema are molluscum contagiosum and herpes simplex which can become widespread. Kaposi's varicelliform eruption (eczema herpeticum) is disseminated herpes simplex infection in an atopic dermatitis patient and it can be life-threatening if it is primary infection by the herpes virus.

Management

There are hardly any confirmatory laboratory investigations for the diagnosis of atopic eczema. The classical morphological pattern, i.e. dry skin, severe itching, clinical course, history of atopy in the family/patient, and raised IgE serum levels strongly suggest the diagnosis. The management has to be individualised depending upon severity, age, complications and associated disorders.

General principles

(a) Avoid aggravating external factors like extreme variations of temperature, contact with woollen and synthetic clothes.

(b) Skin barrier should be restored by using mild neutral pH soaps and liberal use of emollients.

(c) Food items like dairy products, nuts, eggs, fish, etc. may be avoided though their role is questionable.

Pharmacotherapy

The pharmacotherapy is aimed at controlling the acute attacks and keeping the disease under control till remission. Various effective topical and systemic agents are:

(a) Topical corticosteroids of appropriate potency taking into consideration the age of the patients and extent of involvement. Prolonged use of topical steroids should be discouraged to minimise side effects like skin atrophy and side effects due to systemic absorption. Potent corticosteroids are quite affective but should be used in short bursts to overcome acute attacks and then followed-up by low potency steroids and other agents.

(b) Topical immunomodulators like tacrolimus 0.03 to 0.1%, pimecrolimus are effective alternatives for topical corticosteroids especially for the face and flexural skin due to their minimal side effects, except initial burning and irritation. Pimecrolimus can be used under the age of 2 years while tacrolimus should be preferred for older age groups.

(c) Oral antihistamines with sedative effects such as diphenhydramine, promethazine hydroxyzine and doxepin should be preferred to relieve pruritus.

(d) Oral antibiotics like dicloxacillin, cephalexin and other cephalosporins are useful in improving dermatitis by controlling colonisation and secondary infection by staphylococci.

(e) In severe recalcitrant cases, to improve the quality of life, systemic steroids, cyclosporine, azathioprine, mycophenolate mofetil, low-dose methotrexate have been found to be effective. Interferon gamma, narrow band ultraviolet B (UVB) and psoralen and ultraviolet A (PUVA) have also been advocated in such cases.

Atopy means a genetically determined state of hypersensitivity to environmental allergens and includes asthma, hay fever and dermatitis. Early age of onset, severe itching, face and flexural involvement, family or personal history of atopy, dry skin and raised IgE are suggestive of atopic dermatitis.

SEBORRHOEIC DERMATITIS

Seborrhoeic dermatitis is a common chronic inflammatory disorder with a characteristic distribution of lesions in the areas rich in sebaceous glands. The exact cause of the disorder is as yet unresolved, but overgrowth of the yeast *Malassezia furfur/ Pityrosporum ovale* has been implicated as a causative factor. This is further supported by increased incidence of seborrhoeic dermatitis in acquired immune deficiency syndrome (AIDS) patients with extensive involvement. Seborrhoeic dermatitis has a bimodal occurrence and can manifest in early infancy (infantile seborrhoeic dermatitis); or adult life (adult seborrhoeic dermatitis), but the two are not related.

Infantile Seborrhoeic Dermatitis

It generally appears in the first three months of life. The areas affected are the scalp, face, axillae, and napkin areas. The scalp shows erythema and sticky scales (cradle cap). The napkin area may be sore and weepy but there is no itching unlike atopic eczema. It usually remits in a couple of months. Oil applications, mild shampooing may suffice in most of the cases, but some may require application of steroid and antifungal agents topically.

Adult Seborrhoeic Dermatitis

Occurs commonly in the age group of 20 to 40 years. Pityriasis capitis (dandruff) is probably the mildest form of the disease. In severe cases there is marked erythema, scales, and even exudation on the scalp. Red, somewhat greasy-looking scales are also seen on other areas rich in sebaceous glands like the face, nasolabial folds, front and back of the upper chest, retroauricular areas, eyebrows, and eyelids (blepharitis). Some patients develop lesions in the axillae and groins which may be mild or quite troublesome. Though the severity of the disease may fluctuate, the tendency persists throughout life. Dandruff is treated with shampoos containing selenium sulphide, zinc, pyrithione, tar, ketoconazole or fluconazole. To treat mild to moderate cases of seborrhoeic dermatitis, mid-potency topical steroids and topical antifungal agents are sufficient. More severe cases may require oral ketoconazole or fluconazole and systemic steroids. Oral antibiotics and antihistamines can be prescribed as and when required. *Isotretinoin* in smaller doses of 20 mg on alternate days is also quite effective in treating seborrhoeic dermatitis.

Seborrhoeic dermatitis commonly affects the face, scalp, front and back of chest of adults in the 20 to 40 years age group.

NUMMULAR ECZEMA (DISCOID ECZEMA)

Nummular eczema is a chronic and recurrent endogenous eczema of unknown aetiology. Many cases have an atopic background. It manifests as itchy, multiple, sharply demarcated, coin shaped or oval lesions with papulovesicles (**Figure 2**) or papules and scales on an erythematous base. It is more commonly seen in the elderly with dry skin and usually affects the extensor aspects of extremities. The course of the disease varies from a few months to a few years with recurrences and remissions. Treatment consists of avoidance of contact with irritants, mid-potency topical steroids, and resistant cases may require systemic steroids, antibiotics and sedating anti-histamines.

Figure 2: Nummular eczema.

POMPHOLYX (DYSHIDROTIC ECZEMA)

Pompholyx is a distinctive, chronic relapsing, vesicular eczematous dermatitis of unknown aetiology. It affects young adults and is characterised by sudden crops of highly pruritic, deep-seated sago-like vesicles on the palms, sides of fingers and/or soles (**Figure 3**). The disease may be isolated, asymmetrical or bilaterally symmetrical. Summer aggravation is common and lesions frequently get secondarily infected. Vesicles resolve slowly over 1 to 3 weeks. In patients with bilateral symmetrical lesions, fungal infection of the feet should be ruled-out by KOH examination and contact sensitivity should be ruled-out by patch testing. Nickel and chromate as well as neomycin and quinoline contact sensitivity have been implicated to produce pompholyx lesions. Ingestion of nickel, chromate and cobalt can elicit lesions even if the patch tests are negative. The acute form is treated with soaks and compresses of potassium permanganate and topical steroids. Subacute and chronic stages are treated with topical steroids and dapsone. In severe cases oral steroids and even methotrexate (15 to 20 mg weekly) may be required. Majority of patients who are sensitive to metals improve markedly on low nickel diet (avoid canned foods, beans, mushroom, onions, corn, spinach, tomatoes, peas, whole grain flour, cocoa, chocolate, baking powder, etc.).

Figure 3: Pompholyx (dyshidrotic eczema).

ASTEATOTIC ECZEMA (WINTER ECZEMA; ECZEMA CRAQUELE)

Asteatotic eczema is an endogenous eczematous disorder that is caused by excessive dryness and chapping of the skin. Factors leading to dryness are reduced skin surface lipid, low humidity and decreased water binding capacity of the stratum corneum. It is a form of subacute eczema that is low grade with aggravation in winter season. Clinically, it is characterised by dry scaling and cracking giving the skin a fissured appearance (**Figure 4**). Later, the skin may become red and inflamed. It commonly affects the lower limbs, trunk, arm, and hands of elderly males but the face and moist flexural areas are often spared. Rarely, similar changes may be widespread requiring exclusion of underlying lymphoid malignancy. Treatment of asteatotic eczema involves the removal of underlying aggravating factors and rehydration of the skin surface by advocating the use of greasy emollients, bath oils and emollient cleansers. Mild or mid-potency topical steroids for a short period may be required, but oral steroids should be avoided.

Figure 4: Asteatotic dermatitis.

STASIS DERMATITIS (GRAVITATIONAL ECZEMA/VARICOSE ECZEMA)

Stasis dermatitis is a chronic relapsing eczema that occurs secondary to venous incompetence and hypertension. It commonly affects middle-aged or elderly individuals. It usually begins as pruritic, dry scaling skin on the medial aspect of the leg above the ankle that later becomes fissured, erythematous and hyperpigmented (**Figure 5**). The skin may become thin

and atrophic. Fibrosis may lead to tight, bound-down, indurated skin prone to chronic ulceration. Secondary spread of eczematous eruptions to distant sites is common and may indicate allergic contact sensitivity to topical medicaments which is not uncommon in varicose eczema. The management requires rest, elevation of the legs, and use of elastic bandages or stockings. Only mild topical steroids should be used to relieve irritation and to minimise atrophy. Surgical intervention may be helpful in some cases.

Figure 5: Stasis dermatitis.

JUVENILE PLANTAR DERMATOSIS (DERMATITIS PLANTARIS SICCA)

It is a common dermatosis of childhood characterised by shiny, dry, fissured skin of the soles with loss of the epidermal ridge pattern. The sites affected are the weight-bearing areas particularly the forefeet and undersides of the toes. The toe webs and instep are spared. It is thought to be due to excessive sweating and blockade of sweat ducts due to occlusive footwear. Some consider the condition to be a manifestation of atopy. The condition is usually worse during winter and sometimes during dry summer season. It usually subsides during late teens.

The treatment consists of avoiding occlusive footwear, and preferably to use cotton socks. Emollients are usually effective but topical steroids of mid potency may be required in patients with itching and discomfort.

LICHEN SIMPLEX CHRONICUS

Lichen simplex chronicus also known as neurodermatitis, it is a localised patch of chronic eczematous inflammation which is created by habitual scratching in predisposed individuals. The initiation and perpetuation of the lesions is due to the development of an 'itch-scratch' cycle. It is characterised by a lichenified plaque and many of these patients have an atopic diathesis. The areas most commonly involved are those that are conveniently reached. These sites are nape of the neck, ankles, legs, forearms, wrists, and genitalia (scrotum or mons pubis). Emotional factors have an exacerbating effect.

The treatment consists of use of potent topical steroids alone or in combination with keratolytic agents under occlusion except in cases with genital involvement. Anxiolytics and sedating antihistamines are helpful. PUVA, UVB therapy and sometimes immunosuppressants may help some patients.

CONTACT DERMATITIS

Contact eczema develops as a result of contact with injurious material. These materials may injure by direct toxic action (irritants) or may induce immunological reaction of delayed hypersensitivity type (allergens). The first type of reaction is known as irritant contact dermatitis whereas the latter is termed as allergic contact dermatitis.

Irritant Contact Dermatitis

This type of dermatitis occurs due to contact with irritants like detergents, acids, alkaline chemicals, oils, organic solvents, oxidants, and reducing agents. The intensity of the inflammation is related to the concentration of irritant and the exposure time. Mild irritants cause dryness, fissuring and erythema (cumulative irritant dermatitis; wear and tear dermatitis) and strong irritants may produce an immediate reaction characterised by burning, erythema, oedema, blistering, and possibly ulceration of skin (**Figure 6**). Housewife's eczema, diaper dermatitis and industrial dermatitis are common examples of cumulative irritant contact dermatitis. Housewife's dermatitis and industrial/occupational dermatitis commonly affect the hands.

Treatment of acute irritant dermatitis requires washing quickly with water or a weak neutralising solution or frequent wet compresses, followed by the application of a bland or antibacterial with mid-potency steroid cream. For chronic cases, removal of all adverse chemical and physical factors and the use of bland barrier creams and mid potency topical steroids are necessary along with protective gloves.

Figure 6: Irritant dermatitis.

Allergic Contact Dermatitis

It is a type IV delayed type hypersensitivity reaction mediated by T-lymphocytes against certain chemicals coming in contact with the skin. In India, the common sensitisers are metals (nickel, chromium), plants (parthenium, also known as congress grass), antibacterial agents (neomycin, nitrofurazone), rubber chemicals (mercaptobenzothiazole, thiuram) and hair dyes/*Kali Mehndi* (paraphenylenediamine), etc. The eczematous rash

often develops at the sites of skin contact with the allergen but an irritant dermatitis eruption can develop at distant sites. Moreover, autoinoculation of the antigen can lead to widespread lesions. Parthenium dermatitis is the most common and severe type of allergic contact dermatitis seen in India. It is caused by a weed *Parthenium hysterophorus* (**Figure 7**) which grows wild along roads, railway tracks and in the fields. It commonly manifests as air-borne contact dermatitis affecting mainly the face including the eyelids, neck, flexures of the extremities, and sometimes the whole body surface may be involved (**Figure 8**). Distribution of lesions on sun-exposed areas is not uncommon. There is worsening during summer and rainy season while the lesions undergo partial or complete remission during winter.

Figure 7: *Parthenium hysterophorus*.

Figure 8: Parthenium dermatitis.

Nickel sensitivity is quite common and manifests as dermatitis due to ear rings (**Figure 9**), bangles, necklace, zips, metal buttons, and safety pins. Occupational nickel sensitivity affects the hands. Chromium allergy is also quite common and is usually due to leather footwear, cement and ink. Footwear dermatitis (**Figure 10**) is another common type of allergic contact dermatitis in our country due to the hot and humid weather. Rubber and leather are the most common causes. Topical medicament dermatitis (**Figure 11**) is commonly due to nitrofurazone and neomycin. Neomycin sensitivity is quite often superimposed on varicose and footwear eczema, and remains

Figure 9: Ear ring dermatitis.

Figure 10: Footwear dermatitis.

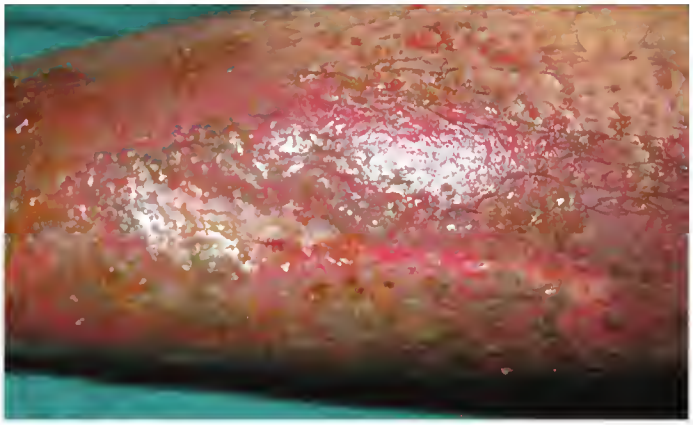

Figure 11: Topical medicament dermatitis.

undetected due to its use with topical steroids. Hair dye dermatitis is also not uncommon and it is becoming common due to high concentrations of paraphenylenediamine (PPD) in *Kali Mehndi* (black henna) (**Figure 12**). Other types of allergic contact dermatitis peculiar in our country are bindi dermatitis (**Figure 13**), black henna dermatitis (**Figure 14**), and tooth powder dermatitis (**Figure 15**).

Figure 12: Hair dye dermatitis.

Figure 13: Bindi dermatitis.

Figure 14: Black henna dermatitis.

Diagnosis of allergy is confirmed by patch testing. Management includes detection and avoidance of contact sensitisers, use of barrier creams and topical steroids of appropriate potency. For severe attacks, systemic steroids, azathioprine, methotrexate and even cyclosporine can be used. Azathioprine is quite effective in parthenium dermatitis as a steroid-sparing agent.

Figure 15: Tooth powder dermatitis.

The common allergens in India are metals (nickel, chromium), rubber chemicals (mercaptobenzothiazole), Parthenium (a weed), medicaments (nitrofurazone, neomycin) and hair dye (PPD).

Medicament dermatitis is fairly common in patients of stasis dermatitis, footwear dermatitis and atopic dermatitis.

PHOTODERMATITIS

It is the result of exposure of skin to sunlight following the topical or systemic administration of certain photosensitising agents (drugs and chemicals). Photodermatitis could be either phototoxic or photoallergic and is mainly distributed over the sites exposed to light. For further details, refer to the chapter titled 'photosensitivity dermatoses'.

INFECTIOUS ECZEMATOID DERMATITIS

Infectious eczematoid dermatitis or infective eczema or bacterial eczema is caused by an allergic reaction to micro-organisms or their products. It manifests as advancing erythema with exudation and predominantly affects the retroauricular areas, scalp, legs and areas around the discharging sinuses and wounds. The eczema responds to treatment with appropriate topical and systemic antibiotics.

AN APPROACH TO A CASE OF ECZEMA

Diagnosis of eczema is based on the clinical features (especially morphology and distribution). The predominant features depend upon the stage: lesions in acute eczema are often exudative while chronic eczema is associated with severe pruritus, scaling and lichenification. The next important step is to differentiate between endogenous and exogenous eczema.

Clinical features suggestive of an endogenous eczema are bilaterally symmetrical distribution of lesions and well established patterns of lesions, e.g. atopic dermatitis or seborrhoeic dermatitis. Clinical features suggestive of an exogenous eczema are asymmetrical distribution, linear or rectilinear configuration of lesions, history of contact with irritant and/or allergens, and improvement on change of environment.

INVESTIGATIONS

Although clinical examination is quite sufficient to suggest the diagnosis of eczema, as a general rule it is advisable to treat acute eczemas without investigations. On the other hand, chronic and recurrent eczemas should be investigated thoroughly to find the cause of eczema.

Patch Testing

It is the only scientific method available to confirm the diagnosis of allergic contact dermatitis but is not useful for irritant contact dermatitis as it detects the allergens responsible for type IV allergy only. It should be performed after the acute stage subsides. A series of allergens in adequate concentration are applied on the back with adhesive tape and left on for 2 days. The readings are taken on day 2 and day 4. The offending allergens will produce erythema and papulovesicles at the site of application. A good patch test should indicate contact sensitisation and produce no false positive reactions.

Photopatch Testing

These tests are performed to find the cause of photo allergic contact dermatitis. It should be performed in photo distributed dermatitis. In photopatch testing also, the patches of chemicals are applied as for ordinary patch testing, except that they are applied in duplicate and after 24 hours one set of patches is removed and the underlying skin is irradiated with ultraviolet light. After irradiation, the patch sites are covered again and evaluated at day 2 and day 4.

Prick Testing

These are performed to detect the type I hypersensitivity reactions. Relevance of positive prick tests in establishing the cause of the eczema is questionable.

Serological Testing

Estimation of total serum IgE and IgE antibodies specific to certain antigens are useful diagnostic criteria for atopic dermatitis. Radio-allergosorbent test (RAST) is helpful to detect specific dietary environmental allergens, which could be aggravating the dermatitis, especially in atopics.

Skin Biopsy

A skin biopsy is rarely required to diagnose the eczema and histopathological findings will depend upon the stage.

TREATMENT

Successful management of dermatitis requires a multipronged approach. Apart from the specific therapy, appropriate general measures are very helpful in treating the eczemas.

GENERAL MEASURES

Identification of any offending allergen, irritant or triggering factor is very important. Adequate measures to avoid the offenders may help in treating the dermatitis.

Eczemas like atopic dermatitis and asteatotic dermatitis are associated with dry skin and hence increased susceptibility to irritants. Maintaining proper hydration of the skin is important in treating dry eczema.

Topical Treatment

Wet compresses with a solution of either potassium permanganate (0.01%/light pink colour) or aluminium sulphate (0.65%) followed by application of steroid lotion/cream is best in the oozing stage of eczema. These compresses help by suppressing inflammation, removal of crusts, have antibacterial action and cause drying of the lesions.

In the subacute stage, wet compresses should be discontinued and only mid-potency topical steroid cream can be prescribed.

Chronic eczema requires potent steroid in ointment base for topical application. In lichenified lesions, a topical steroid can be combined with keratolytic agents like salicylic acid or urea. For secondary bacterial infection a topical antibiotic can be combined with a steroid.

Systemic Treatment

A short course of systemic steroids may be needed for extensive lesions and when an irritant dermatitis eruption (spread of an acute inflammatory dermatitis to distant sites is termed irritant dermatitis eruption or autosensitisation) develops in acute eczema.

Systemic antibiotics are required for infected lesions.

Oral antihistamines may be prescribed, as and when required, but may not be helpful in contact dermatitis. Steroid sparing agents like methotrexate in small weekly doses, azathioprine, and even cyclosporine may be required in recalcitrant cases like atopic dermatitis, parthenium dermatitis, etc.

11.5 Drug Reactions

M Ramam

INTRODUCTION

A fairly large number of drug reactions present with a skin rash. Patients who are taking medicines and develop a skin eruption pose an important clinical challenge because a decision needs to be taken whether the drug can be continued safely or should be changed.

A simple way to avoid this problem would be to stop using those drugs that cause reactions. But if we look at the list of drugs causing reactions, we find that these are medications which are commonly used (**Table 1**). Unfortunately, there is no way of predicting which patient will develop a reaction and which patient will not and so there is no good way of preventing drug reactions. We will continue to be faced with this problem as long as we use drugs to treat our patients.

Table 1: Drug Groups Usually Causing Eruptions

Nonsteroidal anti-inflammatory drugs
Antibiotics
Anti-tuberculosis drugs
Anti-convulsants

A genetic suspectibility to certain drug eruptions has been identified, e.g. HLA B*1502 is associated with carbamazepine reactions and in South-Asian populations where this allele is frequent, it is recommended that HLA typing be performed before prescribing the drug. The presence of certain infections make drug eruptions more likely, e.g. infectious mononucleosis and human immunodeficiency virus infection. However, in the vast majority of patients there are no identifiable factors that can be used to predict (and prevent) the development of drug eruptions. At the level of a community, the strongest determinant of which drugs cause reactions appears to be the prescription practices of its physicians. The most robust method of preventing drug reactions is to use drugs only when required.

Typically, drug reactions do not occur at first exposure to a drug. Usually, the drug has to be first taken for about a month before a reaction develops. However, once a reaction has developed, subsequent exposure to the drug will lead to a reaction within a few hours after re-exposure. Stopping the drug leads to improvement of the eruption over the next few days. Development of a drug eruption after the drug has been stopped is distinctly unusual and indicates that the diagnosis may be incorrect.

Drug eruptions can be suspected if a widespread, symmetric, itchy, rapidly progressive rash develops in a patient taking medications. In such a situation, it is wise to stop the drugs being taken and seek an urgent medical/dermatological consultation. If the rash is accompanied by fever, a feeling of being ill, or blisters and ulcers in the skin and mouth, a severe drug reaction is likely. Less severe drug eruptions may manifest as localised areas of redness and inflammation.

All eruptions that develop following drug intake are not drug eruptions. The eruption may be related to the underlying disease and may have manifested itself later in the course of the illness after medication was begun, e.g. viral exanthems or rashes of connective tissue disease. Or, the eruption may be due to an unrelated disorder of the skin that developed during treatment for another illness, e.g. pityriasis rosea developing in a child on anticonvulsant therapy or scabies in a man receiving antituberculosis therapy.

TYPES OF ACUTE CUTANEOUS DRUG ERUPTIONS

It is commonly stated that drug eruptions are great mimics and that any eruption can be caused by drugs. Fortunately, there is a limited number of ways in which the vast majority of important drug eruptions present and this is helpful in recognising them. But it is good to remember that eruptions that closely resemble drug eruptions can be caused by other agents including viral infections, connective tissue diseases and other skin diseases, among other causes.

Urticaria and Anaphylaxis

This is probably the most common type of drug reaction and presents with itchy wheals. Typically, the wheals are irregular and amoeboid in shape. Individual lesions last a few minutes to hours but new wheals often continue to appear leading some patients to state that the wheals do not subside. If the reaction is severe, wheals may be widespread and accompanied by hypotension, bronchospasm, abdominal pain and syncope. Non-steroidal anti-inflammatory drugs are a common cause.

Exanthematous Eruptions (Figure 1)

This is also a common type of drug eruption. Exanthematous or morbilliform rashes present as symmetrical, generalised, itchy, erythematous, small and large inflamed papules with a

Figure 1: Exanthematous (or maculo-papular) drug rash. Symmetrical, extensive, itchy erythematous eruption.

tendency to coalesce. In the early stages, it may be difficult to differentiate the oedematous papules of an exanthem from a wheal, but persistence of individual lesions for longer than 24 hours excludes urticaria.

Erythroderma

Persistent exanthematous eruptions evolve into erythroderma or exfoliative dermatitis. Some eruptions begin as erythroderma from the beginning. There is redness and scaling over most of the skin surface accompanied by severe itching.

Photosensitive Drug Eruptions (Figure 2)

Some drugs produce an eruption only on areas exposed to sunlight. The appearance of the rash can range from erythema to papules and blisters. The distribution of the rash predominantly on exposed skin with relative or complete sparing of covered areas is the most important clue to this type of reaction.

Figure 2: Photosensitive eruption. Erythema and oedema in a butterfly distribution. The patient was taking doxycycline.

Vesicular/Bullous/Pustular Eruptions

When inflammation is severe, fluid-filled lesions may develop leading to clear vesicular eruptions. Some eruptions consist predominantly of pustules (which are typically sterile). Constitutional symptoms often accompany these eruptions.

Erythema Multiforme/Stevens-Johnson Syndrome/Toxic Epidermal Necrolysis

This group of disorders is characterised by necrosis of the skin of varying extent. In erythema multiforme, there are erythematous papules and small plaques which show central darkening due to necrosis. Stevens-Johnson syndrome shows similar skin lesions accompanied by severe mucosal erosions and fever. Toxic epidermal necrolysis is characterised by dark brown necrosis of large areas of the skin accompanied by fluid collection and erosions (**Figure 3**). The mucosae of the eyes, mouth and genitals is often affected and bronchial mucosa may also be involved. These patients are usually very ill.

Fixed Drug Eruption

In fixed drug eruptions, intake of a drug leads to inflammation of the skin and or mucosae at exactly the same sites in every episode (**Figure 4**). In the acute phase, there is redness accompanied by blistering and erosions if the reaction is severe.

Figure 3: Toxic epidermal necrolysis. Extensive, confluent, superficial brown necrosis of the skin.

Figure 4: Fixed drug eruption. Circumscribed, pigmented, inflamed macule.

The lesions tend to be circular and to be limited in number but some patients may develop widespread lesions that may be difficult to differentiate from Stevens-Johnson syndrome or toxic epidermal necrolysis. Lesions subside with a characteristic brown-black pigmentation that is very persistent. Subsequent exposures to the drug lead to inflammation of all previously affected sites and may be accompanied by the development of new lesions.

SUBACUTE/CHRONIC DRUG ERUPTIONS

These eruptions develop over a longer period of time and can take long to subside, in spite of the causative drug having been stopped. Such eruptions include lichen planus-like drug eruptions, lupus erythematosus-like drug eruptions and pemphigus and pemphigoid-like eruptions. The resemblance of the eruption to the idiopathic disease can be remarkably close on clinical, histopathological and immunological criteria. The diagnosis is usually made on careful history-taking and subsidence of the eruption on discontinuing the causative drug (though this may be delayed).

SYSTEMIC MANIFESTATIONS

Severe drug eruptions may be accompanied by constitutional symptoms, signs, and laboratory abnormalities. Fever, pneumonitis, eosinophilia and transaminitis are frequently noted. Typically, they resolve along with the drug eruption though subsidence may be delayed till after the rash has subsided.

LABORATORY TESTS

There are no laboratory tests that reliably help to diagnose an eruption as a drug rash or to identify the causative drug. Haematological, biochemical, and radiological investigations provide information on the involvement of other organ systems, such as the liver, lungs and bone marrow.

TREATMENT

Once an eruption is confirmed or strongly suspected as being a drug eruption, the first principle of treatment is stopping the causative drug. Unfortunately, there are no reliable methods to identify the causative drug quickly in the setting of an acutely ill patient with a drug reaction. It is common practice to stop the most recently introduced drug in the belief that it is the most likely causative drug, but this may not be correct. Similarly, educated guesses about which one of the several drugs caused the eruption can be mistaken. In view of this, when the reaction is severe, all but absolutely essential drugs should be stopped. Essential drugs should be substituted by chemically unrelated drugs, if these are available. When the reaction is less severe and it would be difficult to stop all drugs, one or a few drugs that are suspected to be the cause can be stopped and the patient closely monitored. If the rash improves, it is likely that the causative drug was correctly identified. However, if the rash does not improve, or it worsens, other drugs will also need to be stopped.

The second principle of the treatment of drug eruptions is suppression of inflammation. If the reaction is mild or diagnosed early, stopping the drug may be enough to achieve this goal. In urticarial eruptions characterised by the development of wheals, anti-histamines are specifically and highly effective in controlling the eruption. However, other types of drug eruptions are not mediated by histamine and antihistamines are not as effective and provide only some relief in itching. They should not be considered 'anti-allergic' drugs useful in all types of drug reactions. Other measures to relieve symptoms of itching and burning include the use of cold compresses. Anaphylactic reactions require adrenaline injections along with other measures used in the treatment of urticarial eruptions.

In severe reactions, systemic corticosteroids are required, and are usually administered as a short, sharp course that is tapered rapidly over 2 weeks. There is controversy about the use of systemic corticosteroid therapy in toxic epidermal necrolysis but most workers believe that the drugs are effective in the early, inflammatory stage of the disease. Slower tapering over about 4 weeks is recommended in exanthematous drug eruptions and even longer therapy is required in drug-induced erythroderma.

Supportive care is paramount in the treatment of severe drug eruptions as these may lead to reduced intake and painful micturition because of oral and genital erosions, fluid and electrolyte imbalances, renal failure, pneumonitis following bronchial mucosal erosions and transaminitis as a consequence of liver involvement.

DRUG THERAPY DURING AND FOLLOWING A DRUG REACTION

Which drugs are safe in a patient who has had a drug reaction? This question comes up while caring for patients suffering from a drug reaction (and also after they have recovered from the reaction but require treatment for another illness). The simple answer is that all drugs are safe except the causative drug. There is no need to prescribe 'safe' drugs that are reported to cause eruptions less frequently. To spell this out, there is no safe antibiotic, anti-convulsant, nonsteroidal anti-inflammatory drug or anti-tuberculosis drug that can be uniformly given to a patient who has developed a drug reaction. The list of drugs that are safe will vary from one patient to another depending on the drugs taken before the onset of the reaction.

In real life, this situation is complicated by the fact that a large number of drugs may be suspected to be the cause. In such cases, the group of drugs suspected to be the cause of the eruption should be avoided; drugs from chemically dissimilar groups can be used. Additional challenges include the multiplicity of brand names under which a particular molecule is sold in different markets. This makes it difficult to identify the drug even when the patient is carrying a prescription. Over-the-counter (OTC) dispensing of medications without a prescription or other record by chemists, practitioners of alternative systems of medicines, and even doctors, is another hurdle in evaluating drug eruptions. Hostility to the prescriber of drugs that caused a reaction also makes it difficult to find out the medicines that were prescribed. A phone call to the prescribing physician is a simple technique that can provide much useful information.

Techniques to identify the causative drug include intradermal testing, patch tests and *in vitro* tests using the lymphocyte transformation test or the lymphocyte toxicity assay, but there are problems with the availability, applicability and reliability of these tests. Challenge or provocation tests consist of the administration of a small dose of the drug under medical supervision in an in-patient setting where reactions can be diagnosed and treated early. The goal of challenge testing may be to identify the causative drug, or more conservatively and pragmatically, it can be used to generate a list of drugs that can be safely taken. The procedures and the precautions

required are similar but the risks are lower with the latter goal. If a drug is strongly suspected to be the cause of an eruption, it is not administered. The risk of adverse effects during supervised administration is relatively small. When assessing the utility and safety of challenge testing, it should be remembered that adverse effects are likely to be significantly more severe if a patient who does not know the causative drug is inadvertently prescribed the drug and takes it in full doses at home.

In exceptional circumstances, it may be considered imperative to administer a drug that the patient has reacted to. Desensitisation protocols have been described that allow successful re-administration of the drug but the procedure must be undertaken with due care and caution.

11.6 Abnormal Vascular Responses

AK Jaiswal, TS Nagesh

The phenomenon of abnormal cutaneous vascular response plays an important role in the aetiopathogenesis of many dermatoses. This chapter aims at providing a brief overview of some of the common dermatological conditions with abnormal vascular response.

URTICARIA AND ANGIOEDEMA

Definition

Urticaria is a vascular reaction pattern characterised by transient, erythematous, oedematous papules or plaques (wheals) of varying sizes and shapes which are usually pruritic. Angioedema is the same process but involves the deep dermis, subcutaneous and submucosal tissues.

Epidemiology

Around 20% of the population suffers from this condition once in their lifetime. Common in young adults (female > male). In children it is frequently associated with infection.

Classification

The simplest classification of urticaria and angioedema is according to their aetiology (**Table 1**).

Table 1: Aetiological Classification of Urticaria and Angioedema

Drugs	Aspirin, penicillin, nonsteroidal anti-inflammatory drugs (NSAIDs), sulphonamides and others
Ingestants	Nuts, eggs, fish, milk, wheat and others
Inhalants	Pollens, house dust, animal dander, fungi
Injectants	Vaccines, serum, blood
Infections	Foci of bacterial, viral, parasitic and fungal infections
Contactants	Cosmetics, animal and plant products
Physical urticarias (15%)	Dermographism (4% to 5%) Heat Cold Pressure Solar Cholinergic Aquagenic
Hereditary	Angioneurotic oedema Vibratory angioedema
Other conditions	
Systemic	Collagen vascular diseases, thyroid disorders, polycythemia vera, uraemic states
Dermatologic	Pemphigoid, dermatitis herpetiformis, urticaria pigmentosa
Psychogenic	

Clinical Features

Urticaria can be acute (<6 weeks) or chronic (>6 weeks) depending on the duration of episodes. Clinically urticaria manifests as wheals of varying sizes and shapes which are transient, well defined, erythematous or pale swellings of the dermis (**Figure 1**). The lesion may appear pale centrally during the initial stage of fluid collection. Very rarely, a vesicle or a bulla can develop in an urticarial plaque. Individual wheals rarely persist longer than 12 to 24 hours. No mark is usually left behind when wheals resolve. The lesions are usually pruritic and stinging and often preceded by pricking sensation. Urticarial lesions may be localised or generalised.

Figure 1: Urticaria showing wheals of varying sizes.

Angioedema is the term used to describe giant wheals or wheals involving mucous membrane surface lasting longer that urticaria. Angioedematous swelling may occur over the face (primarily periorbital area, lips, tongue), an entire extremity or within a vital organ system (**Figure 2**). Urticaria and angioedema may coexist in 50% of cases. Systemic symptoms like malaise, abdominal pain, dizziness, arthralgia, hoarseness, syncope or even anaphylaxis may sometimes be associated with urticaria and angioedema.

Figure 2: Angioedema of the eyelids.

Variants of urticaria with distinctive clinical features:

Dermographism

It is characterised by the rapid appearance of linear itchy wheals with a surrounding bright red flare at sites of scratching or rubbing (**Figure 3**). The prevalence is 4% to 5%.

Figure 3: Dermographism.

Cholinergic urticaria

One of the most common physical urticaria.Usually induced by exercise.The lesions are characterised by extremely pruritic, small 2 to 3 mm scattered wheals surrounded by large erythematous flare.

Pathophysiology

Histamine and chemokine release from mast cells and basophils is the basic pathogenetic mechanism in urticaria and angioedema.These chemical mediators act on the blood vessels causing vasodilatation (erythema), sensory nerve stimulation (itch), increased vascular permeability and leakage of fluid into the skin leading to dermal oedema.

The activation of mast cells and basophils may be both immunologic and nonimmunologic. Immunologic activation involves Type I—Type IV hypersensitivity reactions depending upon the cause, whereas nonimmunologic activation happens due to direct degranulation of mast cells by certain agents (drugs—morphine,codeine;foods—strawberries and shell fish).

Diagnosis

The diagnosis of urticaria and angioedema is essentially based on clinical observation and detailed history.If a complete review of systems is normal and physical urticarias are ruled-out, it is often futile to carry-out extensive laboratory investigations to determine the offending agent in chronic urticaria. However, investigations like complete blood count (CBC), stool and urine examination, thyroid function tests, hepatitis screening, anti-nuclear antibodies (ANA), total IgE, skin prick test, serological ELISA test,autologous serum skin test and ultrasonography may be carried-out if any underlying illness is suspected.

Management

- The goal of managing urticaria is to identify and then remove the offending agent/cause.
- Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) may aggravate urticaria and should be avoided.
- Soothing lotions (calamine) and cool compresses are given for relieving pruritus.
- A trial of elimination diet or a course of antibiotic,antifungal and antihelmintic drugs may be useful in some cases.
- H_1 anti-histaminic drugs (AHD) are the mainstay of treatment. Algorithm for the pharmacologic management is shown in **Figure 4**.

Key Points

- Urticaria and angioedema are easily identifiable symptoms, not a disease.

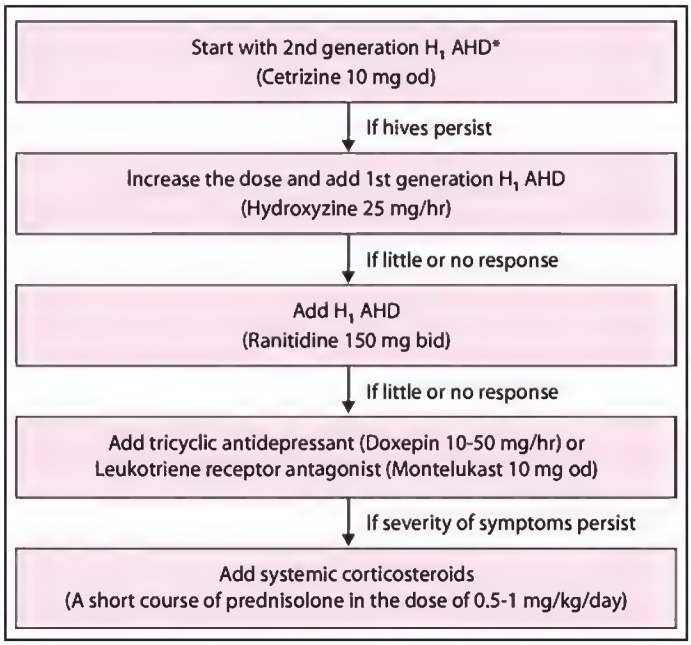

Figure 4: Pharmacologic therapy of chronic urticaria and angioedema.

- Meticulous history helps in determining the cause of urticaria more than any tests.
- Cyproheptadine 2 to 4 mg tid is the treatment of choice in cold urticaria.
- Epinephrine should be used for acute attacks in the presence of angioedema of the respiratory tract.

INTERESTING HISTORICAL HIGHLIGHT

In 1772, Herbeden described urticaria as follows: "the little elevations upon the skin in the 'nettle' rash often appear involuntarily, especially if the skin be rubbed or scrubbed and seldom stay many hours in the same place, and sometimes not many minutes. There is nobody exempt from 'them' and by far the greatest number experience no other evil from it besides the intolerable anguish arising from the itching....". This appropriately designed description of urticaria holds good even after more than 200 years.

ERYTHEMA MULTIFORME

Definition

Erythema multiforme (EM) is an acute, self-limiting, usually mild, often recurrent inflammatory syndrome characterised by symmetrically distributed erythematous papular, urticarial and typical iris/target shaped lesions. This classic form of EM is currently defined as EM minor.The more severe variant with extensive mucous membrane involvement and constitutional symptoms is called EM major (Stevens-Johnson Syndrome).

Epidemiology

EM affects primarily children and young adults (male > female). Mostly seen in spring and fall.

Aetiopathogenesis

EM appears to be a symptom complex secondary to many triggering agents causing the responsible hypersensitive phenomenon.

The common causes are:

Infections—Herpes simplex, *Mycoplasma, Streptococci*,

Drugs—Antibiotics, anti-convulsants.

Idiopathic (up to 50%)—Probably also due to undetected herpes simplex or *Mycoplasma* infections.

Clinical Features

The lesions of EM are predominantly erythematous papular, macular urticarial and *classical iris* or *'target' lesions*. The lesions appear suddenly in crops for 2 to 3 weeks and are usually symmetrical with a predilection for palms, soles and extensor surface of limbs. The characteristic iris (target) lesion is urticarial with a dusky center that may blister and have successive bright red bordering rings (**Figure 5**). There is little or no mucous membrane involvement. Vesiculobullous lesions may be seen at times.

Figure 5: Erythema multiforme with typical target lesions.

Diagnosis

The diagnosis is usually not difficult in the presence of symmetrical distribution of typical target lesions.

Treatment

As majority of cases of EM resolve spontaneously in 2 to 3 weeks, treatment is only symptomatic in the form of oral antihistamines and topical corticosteroids. The underlying precipitant cause, when appreciated, should be treated. A short course of prednisolone (0.5 to 1 mg/kg/d) may be given in patients with extensive skin lesions. Recurrences can be suppressed with long-term treatment for herpes simplex infections (acyclovir 400 mg bid).

Key Points

- Herpes simplex infection is the most common cause of recurrent EM.
- Classical target or iris lesions are characteristic of EM.

VASCULITIS

The term vasculitis is used to describe a group of diseases characterised by an idiopathic primary inflammation and necrosis of blood vessels, having many common clinical features. The primary cutaneous lesion in vasculitis is *palpable purpura*.

Classification

The vasculitis has extensively been discussed in section Rheumatology chapter "The Vasculitides".

11.7 Papulosquamous Disorders

K Pavithran

Papulosquamous disorders are a group of unrelated skin diseases that share the morphological feature of scaly papules and plaques. Important conditions in the group are psoriasis, lichen planus, and pityriasis rosea.

PSORIASIS

Psoriasis is one of the common skin diseases characterised by scaly papules and plaques. Prevalence of psoriasis in different parts of the world varies from 0.1% to 3%. Onset of psoriasis is most common in the second to fourth decades of life though it can appear just after birth or in old age. A high familial occurrence of psoriasis (7% to 36%) suggests that genetic factors play a role in its aetiology. Psoriasis occurs in equal frequency in males and females.

Aetiopathogenesis

Genetic factors

Twin and population genetic studies support the hypothesis of multifactorial inheritance which requires both polygenic and environmental factors for its clinical expression.

The immunologic basis of psoriasis

T-lymphocyte mediated T-helper cell (Th-1) type of immune response is responsible for psoariasis. Unidentified triggers or infective agents like bacteria, HIV, drugs, etc. induce antigens which are presented to T-lymphocytes by Langerhans cells of skin leading to T-cell activation. Activated T-cells secrete cytokines that promote dermal inflammation and resultant hyperproliferation of the epidermis.

Triggering factors

Psoriasis is a chronic disease marked by periods of remissions and exacerbations. Remissions may last for a few weeks to many years. Triggering factors may be local or systemic and include trauma (Koebner phenomenon), season (worsens in winter), emotional stress, upper respiratory tract infections and drugs like beta-blockers, lithium and chloroquine. Withdrawal of systemic steroids can lead to precipitation of pustular psoriasis.

Histopathology

Characteristic histopathological features of psoriasis are regular elongation of rete-ridges, parakeratosis, hypogranulosis, and presence of Munro's microabscesses in the horny layer and spongiform pustules of Kogoj. The psoriatic epidermis shows rapid transition of epidermal cells in as fast as 2 days as compared to 13 days in normal epidermis.

Clinical Features

Psoriasis is characterised by the development of erythematous, well-defined, dry, scaly papules and plaques of sizes ranging from a pinhead to palm-sized or larger. The scales are abundant, loose, dry and slivery white or micaceous. On skin scraping, capillaries at the tips of elongated papillae are torn leading to multiple bleeding points (Ausptiz sign).

Psoriasis: Key Diagnostic Points

1. Erythematous scaly plaques
2. Well-defined border
3. Scales dry loose and micaceous
4. Koebner phenomenon seen
5. Auspitz sign positive
6. Regular, circular pits on nail plates
7. Involvement of distal interphalangeal joints of fingers and toes
8. Histopathological: Spongiform pustules of Kogoj

Koebner phenomenon is more common during the acute or eruptive stage of psoriasis or in patients with florida or progressive psoriasis. Psoriasis as a Koebner phenomeon may develop at sites of mechanical, physical, chemical or allergic trauma.

Clinical Variants of Psoriasis (Table 1)

Guttate psoriasis

This is usually seen in children, follows streptococcal infection and tends to resolve spontaneously. Pinhead to pea-sized erythematous papules erupt abruptly and are distributed bilaterally symmetrically all over the body.

Table 1: Various Clinical Types of Psoriasis

Guttate psoriasis
Chronic plaque psoriasis (psoriasis vulgaris)
Exfoliative psoriasis (psoriatic erythroderma)
Pustular psoriasis
Generalised—Von-Zumbusch type
Exanthematic type
Annular type
Localised pustular psoriasis
Psoriasis unguis
Mucous membrane lesions in psoriasis
Psoriatic arthritis
Classical type
Rheumatoid type
Arthritis mutilans
Oligoarticular arthritis
Psoriatic spondylitis
Follicular psoriasis
Psoriasis verrucosa
Linear psoriasis

Chronic plaque psoriasis

This common type of stable psoriasis manifests as coin-sized to large palm-sized well defined erythematosquamous plaques-distributed bilaterally on extensors of body (**Figure 1**). The extensor surfaces of the body, the elbows and knees lumbosacral area and back are commonly involved.

Figure 1: Chronic plaque psoriasis, erythematosquamous lesions.

Palmoplantar psoriasis

This common form usually affects only the palms or soles but may extend to the dorsa of hands and feet or occasionally may evolve into psoriasis vulgaris.

Flexural psoriasis

Affliction of axillae and groins may simulate dermatophyte infection or erythrasma. Rapid response to topical steroids is a rule.

Nail psoriasis

Nails are commonly affected in psoriasis. Pitting, thickening of nail plate, subungual hyperkeratosis, onycholysis and oil spots are some of the frequent nail findings in psoriasis.

Exfoliative psoriasis (psoriatic erythroderma)

It is a generalised form of the disease and is characterised by erythema and scaling of more than 90% of the body surface area (**Figure 2**).

Pustular psoriasis

When tiny, superficial, sterile pustules top a plaque of psoriasis, it is called pustular psoriasis. Pustular psoriasis is broadly classified into a localised form and a generalised form. Localised form may affect only the palms and soles or may be more widespread.

Generalised pustular psoriasis is the most severe form of pustular psoriasis. The skin lesions start abruptly as multiple erythematous, tender plaques which soon become studded with pinhead-sized, tiny sterile pustules that appear in waves. Features of systemic toxicity such as fever, chills, polyarthralgia and malaise may be associated. Geographic tongue and hypocalcaemia may be associated. The disease may last for weeks or even months.

Psoriasis in HIV-infected persons

The prevalence of psoriasis seems not to be increased in HIV-infected patients. But psoriatic arthritis, dactylitis and enthesitis are more common in them.

Psoriatic arthritis

Psoriatic arthritis (**Figure 3**) is an inflammatory arthritis associated with psoriasis usually with a negative test for rheumatoid factor. Arthritis occurs in about 5% to 0% of patients

Figure 2: Psoriatic-erythroderma, involving more than 90% of body surface area.

Figure 3: Psoriatic arthritis; multiple small skin distal joint uncolourment.

with psoriasis. Onset of arthritis is concurrent with the skin disease in 10% of cases but may precede it. There are 5 clinical patterns of psoriatic arthritis: classical psoriatic arthritis affecting distal interphalangeal joints; rheumatoid type of psoriatic arthritis; arthritis mutilans; oligoarticular arthritis (commonest type) and psoriatic spondylitis.

Treatment

Psoriasis usually has a chronic but unpredictable course with periods of remissions and exacerbations. The aim of psoriasis therapy is to control the disease, to improve quality of life, rather than to cure it. Avoiding alcohol and reducing weight, help in better control of psoriasis (**Table 2**).

Table 2: Treatment of Psoriasis

Topical therapy
Emollients
Topical corticosteroids
Dithranol
Tars
Salicylic acid
Vitamin D analogues—Tacalcitol, calcipotriol
Tazarotene

Dapsone
Methimazole
Tacrolimus
Sulfasalazine
Fumaric acid

Other forms of therapy
UVB phototherapy
Photochemotherapy
Excimer laser
Treating psychological factors
Photodynamic therapy
Surgical treatment
Hyperthermia (Balneotherapy)
Sea bathing
Diet control

Topical therapy

Majority of the cases of psoriasis can be controlled with topical therapy. Emollients like white soft paraffin and liquid paraffin form the mainstay of topical psoriasis therapy but are best suited for unstable psoriasis cases who cannot tolerate other topicals. Stable plaque psoriasis responds well to strong topical steroids and keratolytics, like salicylic acid. Efficacy of topical steroids can be improved by occlusion therapy or by intra-lesional injection. Use of strong topical steroids like clobetasol, betamethasone, over large areas of body can lead to systemic absorption with its resultant side-effects. Modern topical steroids like mometasone or fluticasone in ointment form are preferred as they do not cause much skin atrophy or systemic absorption.

Non-steroidal topical options for psoriasis include topical tar and dithranol. Tazarotene, a topical synthetic retinoid is used for the treatment of plaque psoriasis. It has a rapid onset of action and its beneficial effect is sustained for up to 12 weeks after cessation of therapy. Tazarotene's potency is comparable to that of mid-to-high-potency corticosteroids. This drug should not be given to pregnant or lactating women or women not practicing adequate contraception. But they can sometimes exacerbate psoriatic lesions. Topical calcipotriol, a vitamin D derivative is free of serious side-effects but is expensive.

Systemic therapy

The systemic drugs commonly used for the treatment of psoriasis include oral retinoids, methotrexate and photochemotherapy (PUVA) and narrow band UVB phototherapy. Availability of cyclosporine and biological agents like etanercept or infliximab has increased options but these drugs are still prohibitively expensive for most patients. Systemic corticosteroids, although dramatic in short-term effectiveness are contraindicated in psoriasis as they cause rebound increase after stoppage.

Oral retinoids: Acitretin, a second-generation oral retinoid, is useful in severe unstable disease, including pustular and erythrodermic psoriasis. Elevation of transaminases and triglycerides need to be watched for during the 3 to 6 months required for complete response. Oral retinoids are absolutely contraindicated in women of childbearing potential.

Methotrexate: Methotrexate improves psoriasis by its action on T-cells. It is indicated in disabling or widespread psoriasis unresponsive to topical therapies, pustular psoriasis and erythrodermic psoriasis. Methotrexate is also helpful to control psoriatic arthritis. Contraindications include pregnancy or those who desire to get pregnant, moderate-to-severe hepatic or renal compromise, blood dyscrasias, peptic ulcer and chronic alcoholism. Cytopaenia occurs in 10% to 20% of patients on long-term methotrexate therapy (> 6 weeks) for psoriasis and manifests as leucopaenia, thrombocytopaenia or pancytopaenia. Hepatotoxicity is a major concern, with a 7% overall risk of severe fibrosis/cirrhosis in psoriatics. It is administered as 7.5 to 22.5 mg in 3 equally divided weekly oral doses at 12 hourly intervals or a single dose of 10 to 25 mg methotrexate every week.

UVB phototherapy and PUVA therapy

Modern narrow band UVB phototherapy has its emission almost exclusively in the narrow band between 311 nm and 313 nm. This minimises the potential for causing skin cancer and avoids skin effects associated with the use of oral psoralens in PUVA therapy. Patients with extensive stable psoriasis are candidates for UVB phototherapy.

PUVA therapy consists of administration of 8-MOP, 0.6 mg/kg/body weight, on alternate days followed by exposure to ultraviolet rays 2 hours later. Nausea, vomiting, headache, vertigo, erythema, pruritus, blistering and worsening of psoriasis may occur as side-effects of PUVA therapy. Long-term side-effects include cataracts, and in white skinned persons, skin cancers.

LICHEN PLANUS

Lichen planus (LP) is a pruritic disease affecting the skin, mucous membranes and hair follicles. The characteristic primary lesions are tiny, shiny, violaceous, flat-topped, polygonal papules. Surface shows scant adherent scales. Koebner phenomenon may occur. Sites commonly affected are the front of wrists, shins, trunk, medial thighs and glans penis. The cutaneous lesions (**Figure 4**) are intensely pruritic and the lesions on legs may become hypertrophic. The oral

mucosal lesions of LP may be reticular, annular, atrophic, or erosive. The buccal mucosa is commonly affected though tongue and gingiva may also be involved (**Table 3**).

Figure 4: Lichen planus purple, papulosquamous flat topped lesions.

Table 3: Lichen Planus: Key Diagnostic Features

Intense pruritus
Erythematous-to-violaceous colour for early lesion
Flat topped polygonal papules
Intense black pigmentation on healing
Koebner phenomenon present
Lace-like pattern for oral lesions

Nail changes occur in 5% to 10% patients and manifest as pterygium, longitudinal streaks and atrophy. Clinical variants of LP include linear, annular, ulcerative, hypertrophic (**Figure 5**) and bullous forms (**Table 4**).

Actinic
Inverse

The exact aetiology of LP is not fully understood. Some cases are associated with HCV infection. LP may co-exist with many diseases with an immunologic basis for their aetiopathogenesis, e.g. lupus erythematosus thymoma. The immunologic reaction in LP is mediated by T-cells.

The course of the disease is unpredictable. The spontaneous remission is known but the period is variable with different types of lichen planus. Treatment include antihistamines, topical steroids, intralesional steroids, topical PUVA in localised cases

Figure 5: Hypertrophic lichen planus.

and low dose systemic steroids or oral pulse steroids, dapsone, anti-malarials, oral retinoids, systemic PUVA and mycophenolate mofetil in generalised lichen planus. Topical tacrolimus is used to treat cutaneous, oral and genital erosive lichen planus. Appearance of new lesions, increase in size of existing lesions and Koebner's phenomenon indicate the activity of the lesions and requires therapy. Long standing lesions run a small risk of developing squamous cell carcinoma.

PITYRIASIS ROSEA

Pityriasis rosea (PR) is an exanthem characterised by oval, or circinate salmon-coloured macules that are covered with finely crinkled epidermis which often desquamates leaving a collarette of scaling. Sometimes the eruption may be papular, purpuric, urticarial, lichenoid, bullous, or vesicular. The exanthem is often preceded by a single herald plaque which is much larger than the succeeding lesions. The eruption has a characteristic 'bathing suit' distribution (trunk and proximal parts of limbs). Mild pruritus is often present and the rash persists for 6 to 8 weeks and subsides spontaneously. Recurrence may occur in 2% of the cases.

The exact aetiology of PR is not known though HHV-6 and -7 have been implicated.

There is no specific treatment of PR. Antihistamines may relieve pruritus. UVA and UVB therapy and oral erythromycin and acyclovir also are reported to be beneficial. Topical emollients often relieve pruritis.

11.8 Autoimmune Bullous Disorders

KK Raja Babu

Autoimmune bullous disorders are a group of immunobullous diseases of unknown aetiology where circulating antibodies target specific components in the epidermis and the adhesion complex that links the epidermis and dermis.

INTRAEPIDERMAL AUTOIMMUNE BULLOUS DISORDERS

Pemphigus

Pemphigus is the most common and also potentially the most severe immunobullous disorder involving the skin and mucous membranes. The disease has a worldwide distribution with an incidence of 0.1 to 0.5 per 100,000 population. Circulating IgG autoantibodies targeting antigens in the intercellular attachment plaques (desmosomal complexes) of the epidermal keratinocytes, identified as desmogleins, lead to acantholysis and cell separation, and intraepidermal blister formation. The reason for this anomalous antibody activity is not known. HLA-linkage analysis suggests that there may be some genetic predisposition.

Broadly two types of pemphigus are recognised, each with one variant: *Pemphigus vulgaris* and its variant, pemphigus vegetans; and pemphigus foliaceous and its variant, pemphigus erythematosus. In *P. vulgaris* blisters occur in the immediate suprabasal layers, and in pemphigus foliaceous they develop subcorneally. Desmoglein1 is the target antigen in pemphigus foliaceous and desmoglein 3 and less frequently desmoglein 1 are the target antigens in *P. vulgaris*. The clinical phenotype of pemphigus is defined by the anti-desmoglein antibody profile.

Pemphigus vulgaris is a very common disease in India and young adults of both sexes are preferentially affected. In more than 50% of cases, the disease begins with oral erosions and 90% have oral lesions at some stage of their life. Oral erosions are painful and tender and heal very slowly. They frequently occur on the buccal and palatine mucosae. Conjunctival, nasal, pharyngeal, laryngeal, anal and genital mucous membranes are uncommonly affected. Skin lesions are generalised flaccid blisters of varying sizes that quickly rupture to leave large denuded raw areas which crust and continue to spread without further blistering at the same site. Blisters frequently appear on a normal looking skin without any background erythema. Scalp, face, axillae and groins are the common sites of involvement. Tangential shearing pressure on the unaffected skin may cause separation of the epidermal layers and denudation of skin. This is called Nikolsky's sign. Lateral or perpendicular pressure applied on intact blisters may lead to their extension and is called bulla spreading or Asboe-Hansen's sign.

Pemphigus vegetans is a much milder disease compared to pemphigus vulgaris, and intertriginous involvement is common. The disease may begin either as vesicles and blisters or as pustules and eventually evolve into hypertrophic, granulomatous or vegetative lesions. Oral lesions may occasionally occur.

Pemphigus foliaceous presents as very superficial blisters and erosions in a seborrhoeic distribution. Intact blisters are rarely found. Nikolsky's sign is strongly positive. Extensive disease may present as erythroderma. Oral lesions are rarely seen. Fogo selvagem is a special form of pemphigus foliaceous that is endemic to Brazil and other South American countries. The affected skin has a burnt appearance and patients experience a painful burning sensation in the lesions (fogo selvagem = wild fire).

Pemphigus erythematosus presents with erythematous, scaling plaques over the nose and malar skin, upper part of the back, chest and intertriginous areas closely mimicking the rash of systemic lupus erthyematosus (SLE).

Other important variants of pemphigus are drug-induced pemphigus and paraneoplastic pemphigus. Drugs with highly reactive sulfhydryl groups like penicillamine and captopril can induce pemphigus. Enalapril, penicillin, cephalosporins and rifampicin are other drugs that are occasionally responsible. Both immunological and non-immunological mechanisms operate in the occurrence of drug-induced pemphigus. Most examples of drug-induced pemphigus are of the foliaceous type. Eighty percent of patients show direct immunofluorescence positivity.

Paraneoplastic pemphigus is characterised by severe, persistent and painful mucosal erosions and a polymorphic skin eruption that is resistant to treatment. The underlying malignancies are generally lymphoproliferative and approximately 80% of cases are linked to non-Hodgkin's lymphoma, chronic lymphocytic leukaemia and Castleman's disease.

Light microscopy reveals acantholytic intraepidermal blisters. Direct immunofluorescence of the perilesional skin is of singular value in the diagnosis of pemphigus. A fish net-like intercellular fluorescence is characteristic. Indirect immunofluorescence detects circulating IgG antibodies directed against antigens of the desmosomal complex. Recently ELISA tests that can detect IgG autoantibodies to desmoglein 1 and 3 have been developed and these have paved the way for a rapid diagnosis of different forms of pemphigus.

General supportive measures, attention to fluid and electrolyte balance and control of infection are of paramount importance in the management of fulminant forms of pemphigus. Systemic corticosteroids (prednisolone 1-2 mg per kg body weight per day) along with cytotoxic immunosuppressive agents like cyclophosphamide or azathioprine (1 mg/kg/day) are the mainstay drugs in the treatment of pemphigus, especially of the severe forms. Cyclophosphamide pulse therapy or cyclophosphamide+steroid pulse therapy have been found to be beneficial for severe and recalcitrant examples of pemphigus vulgaris. Topical and intralesional steroids help milder forms.

With appropriate treatment, most cases of pemphigus go into extended remissions. Untreated pemphigus vulgaris carries significant morbidity and mortality.

SUBEPIDERMAL AUTOIMMUNE BULLOUS DISORDERS

Bullous Pemphigoid

Bullous pemphigoid (BP) (**Figures 1 and 2**) is an autoimmune, subepidermal blistering disorder of the elderly. Men are likely to be affected twice as frequently as women. BP is mediated by IgG autoantibodies directed against hemidesmosame-associated proteins. Two pathogenetically important BP antigens are recognised: BP 230 and BP180. Though BP230 is the principal antigen, serum levels of antibodies to BP 180 correlate well with disease activity. Association between HLA DQ7 and DRB1 and susceptibility to BP has been reported. Recent studies reveal that a small, nonetheless significant, association between BP and visceral malignancy exists. Drugs sometimes induce pemphigoid-like eruptions. Examples are frusemide, sulphasalazine, penicillamine, penicillins, captopril and PUVA therapy. BP has also been reported to be associated with a variety of disorders like SLE, multiple sclerosis, diabetes mellitus, rheumatoid arthritis, psoriasis and lichen planus. Bullous pemphigoid also shares many immunopa-thological characteristics with pemphigoid gestationis and cicatricial pemphigoid.

Figure 1: Bullous pemphigoid. Erythematous oedematous plaques, tense blisters and erosions.

Large, tense blisters arising on an erythematous and oedematous background are typical of BP. The blisters are filled with thick, fibrinous fluid and can occasionally be haemorrhagic. The common sites of involvement are the lower abdomen, inner thighs, groins and the flexor aspects of the limbs. Nikolsky's sign is negative, and so is Asboe-Hansen's sign. Blisters do not quickly rupture. Additionally patients may also have erythematous macules, papules and urticarial plaques. Occasionally eczematous eruptions occur. All these clinical lesions may sometimes precede blisters by weeks or months (Prodromal bullous pemphigoid). Mucosal lesions are uncommon. Pruritis is often present but may range in severity. Ruptured blisters heal rapidly leaving behind post-inflammatory pigmentary changes. Scarring does not occur.

Several clinical variants of BP exist.

Histologically, BP manifests as a subepidermal blister with a mixture of inflammatory cells. Direct immunofluorescence (DIF) demonstrates a linear pattern of IgG and C3 deposition across the basement membrane zone (BMZ). On indirect immunofluorescence, approximately 70% of patients have circulating anti-BMZ IgG antibodies. DIF of biopsy samples of perilesional skin that have been incubated in 1 molar saline skin-splitting buffer at 4 °C for 36 to 72 hours results in a split in the lamina lucida of the BMZ. In BP, the IgG deposits are mostly found on the epidermal (roof) surface of the blister while in epidermolysis bullosa acquisita, the antibodies are detected on the dermal side (floor) of the blister.

Figure 2: Bullous pemphigoid. Tense blisters and erosions.

Localised disease can be treated with topical or intralesional steroids. Systemic steroids are indicated for a generalised disease. Moderate doses (prednisolone 30 to 40 mg per day) are enough to control the disease unlike in pemphigus vulgaris. Azathioprine, cyclophosphamide or methotrexate can reduce steroid dependency. Tetracycline or erythromycin along with nicotinamide has been found to help some patients of BP in whom corticosteroid use is contraindicated.

Cicatricial Pemphigoid

Cicatricial pemphigoid (CP) is another subepidermal blistering disorder and primarily affects the mucous membranes of the mouth, eyes and genitalia. Occasionally oesophagus, pharynx and larynx are involved. Scarring and its attendant sequelae are frequent. Skin lesions are uncommon and are predominantly seen on the head and neck. Both scarring and non-scarring lesions occur on the skin.

BP180 is the most frequently recognised autoantigen. Direct immunofluorescence findings are similar to those seen in BP. On indirect immunofluorescence, circulating IgG anti-BMZ antibodies in low titres are detectable in 10% to 25% of patients.

Localised oropharyngeal lesions are treated with topical or intra-lesional steroids. Systemic steroids (0.5 to 1 mg/kg per day of prednisolone) are indicated in more severe disease. Dapsone or azathioprine help resistant cases. Surgical intervention is required in the presence of scarring and strictures of vital structures.

Dermatitis Herpetiformis

Dermatitis herpetiformis (DH) is a rare (at least in India), chronic, intensely itchy papulovesicular disease associated with gluten-

sensitive enteropathy. The enteropathy is mostly asymptomatic. Less than 10% of patients with DH have gastrointestinal symptoms suggestive of coeliac disease. Some patients manifest diarrhoea, steatorrhoea, abdominal distension and weight loss. Both the skin lesions and the enteropathy respond to a strict gluten-free diet, and recur when gluten-containing products are ingested. Gluten is present in wheat, barley, oats and rye but not in rice and corn. The enteropathy is believed to be due to non-allergic sensitivity to the gliadin fraction of gluten. Circulating IgA2 antibodies directed against gliadin and connective tissue autoantigens (reticulin and endomysium) are found in the sera of DH patients. There is a strong association between HLA B8, DRw17 and DQw2 and DH.

DH most often is seen in the second and third decades. The disease is slightly more common in males. The skin eruption is characteristically polymorphic although at any given time, only one type of lesions (papules, vesicles, wheals or bullae) predominater. The lesions are typically grouped or herpetiform. Itching is intense and excoriations are common. Lichenification may follow chronic scratching. The areas of predilection are the elbows, knees, shoulders, buttocks, sacrum and scalp. Facial involvement is uncommon and mucous membranes are rarely affected. Iodides exacerbate the disease. Patients with DH manifest a high incidence of autoimmune abnormalities. There is an increased risk of developing lymphomas, especially of the gastrointestinal treat.

Histologically, neutrophilic microabscesses at dermal papillary tips are typical of DH. Eventually unilocular subepidermal blisters form. On direct immunofluorescence of the perilesional skin, granular deposits of IgA are found in the dermal papillae. No circulating anti-BMZ antibodies are detectable by indirect immunofluorescence.

Gluten-free diet and dapsone therapy are the mainstay treatment of DH. In most cases, with an initial dose of 100 mg of dapsone per day, burning and itching ceases within 24 hours. If there is no response after 2 weeks, the dose should be increased by 50 mg every 2 weeks. Doses higher than 300 mg per day are rarely required. Once the disease is under control, a maintenance dose of dapsone (as low as 50 mg once a week) is all that is needed. Patients who are intolerant of dapsone may respond to sulfasalazine (500 mg three times a day, increased to 2.0 g per day). Cochicine (0.6 mg three times a day) may occasionally be helpful.

Linear IgA Bullous Dermatosis

Linear IgA bullous dermatosis (LAD) is a rare subepidermal blistering disorder characterised by a linear deposition of IgA along the dermoepidermal junction. Chronic bullous disease of childhood (CBDC) although clinically distinctive, is the childhood variant of LAD. The best characterised antigen in LAD is a 97 kDa antigen and this reacts with IgA1 subclass of antibodies.

The onset of CBDC is rather abrupt with large tense bullae filled with clear or haemorrhagic fluid on or near genitalia. The eruption gradually extends to involve such areas as buttocks, scalp and face, particularly the perioral and periocular areas. Clustering of blisters is common. New, small, tense blisters may appear around a crusted, healing, erythematous plaque giving a 'string of jewels' appearance. Mucosal lesions are sometimes found.

LAD generally has its onset in the fifth decade. There is considerable variation in the morphology and distribution of lesions. Flexural and truncal involvement with scattered vesicles and tense blisters, as in BP, is common. Bullae occasionally are linear and sausage-shaped. DH-like eruptions may appear in some patients. Oral lesions, though mild, are frequent. There is increased incidence of lymphoproliferative disorders in patients of LAD. Drug-induced LAD has been reported following vancomycin, diclofenac and captopril use.

Histologically, a subepidermal blister is seen. Direct immunofluorescence of uninvolved skin demonstrates linear deposition of IgA along the BMZ. Circulating anti-BMZ antibodies are demonstrable in 30% of adults and 80% of children.

Dapsone in a dose of 1.5 to 2 mg/kg per day is a very useful drug for both children and adults, and has to be given for a long time. Some patients additionally require prednisolone (0.5 to 1 mg/kg per day) to control their disease. In two-thirds of children, remission occurs by the time they reach their puberty. In others, the disease may persist into adult life. In adults, the disease is chronic but eventually remits.

Other Subepidermal Autoimmune Bullous Diseases

Other important autoimmune bullous disorders are pemphigoid gestationis that occurs in pregnancy and puerperium, epidermolysis bullosa aquisita, and bullous systemic lupus erythematosus which develops in a setting of SLE.

11.9 Disorders of Pigmentation

Bhushan Kumar

Normal human skin colour is produced by skin pigments – red (haemoglobin), yellow (carotenoids), brown (melanin). Of these, melanin which is produced by melanocytes forms the major component of the skin colour. Normal human skin colour is primarily related to size and the arrangement of melanosomes in melanocytes.

MELANIN SYNTHESIS

Melanocytes originate from neural crest and then migrate to populate the skin, inner ear, choroid, iris, leptomeninges, mucous membranes and the hair. The skin melanocytes are located in the epidermal basal layer and project their dendrites into the malpighian layer of the epidermis where a melanocyte secretes melanosomes into a finite number of neighbouring keratinocytes (approximately 36); this partnership of a melanocyte and a neighbouring group of keratinocytes is called an epidermal melanin unit. Melanocytes in the hair follicle provide the melanin for hair shaft pigmentation. The major differentiated function of melanocytes is to synthesise melanin in specialised organelles within the melanocytes, the melanosomes, and to transfer melanosomes to neighbouring keratinocytes to provide protection from ultravoilet (UV) irradiation. Pigmentation, the synthesis and distribution of melanin in the epidermis, involves several steps. Disruption in any of these steps results in hypopigmentation. Melanin in the melanocytes is produced in two forms—the brown black, eumelanin and the light coloured red, yellow, pheomelanin. Tyrosinase, a melanocyte specific copper binding enzyme catalyses the oxidation of catechols to their corresponding quinones. *In vivo* tyrosinase converts tyrosine through DOPA and various precursors to brown or yellow/red melanin.

MELANIN PIGMENTARY DISORDERS

Broadly there are three categories of melanin pigmentary disturbances:

1. Hypomelanosis or lighter than individual's skin colour or complete loss—leucoderma,
2. Brown hypermelanosis (melanoderma), and
3. Gray, slate or blue hypermelanosis (ceruloderma).

All these disorders for the purposes of better understanding can be described under the heading as melanotic, melanocytotic and non-melanocytotic. Classification of various disorders of pigmentation is given in **Tables 1 and 2**.

Table 1: Hypopigmentation: Clinicopathologic Classification

Aetiologic factors	Melanocytopaenic (Melanocytes decreased or absent)	Melanopaenic (Melanin decreased or absent)	Non-melanotic (No melanin defect)
Chemical	Catechols	Arsenicals, Chloroquine, Glucocorticoids,	—
	Monobenzylether of hydroquinone	Hydroxychloroquine, Hydroquinone, Retinoids	—
	Para-substituted phenols		—
	Sulphydryls		
Endocrine	—	Addison's disease, Hypopituitarism, Hypothyroidism	—
Genetic	Ataxia telangiectasia	Albinism	Naevus anemicus
	Piebaldism	Chediak-Higashi syndrome	—
	Vitiligo	Homocystinuria	—
	Vogt-Koyanagi-Harada syndrome	Fanconi's syndrome	—
	Waardenburg syndrome	Hypomelanosis of Ito, Naevus depigmentosus	—
	Xeroderma pigmentosum	Tuberous sclerosis	—
Inflammatory	Actinic reticuloid	Leprosy, Pityriasis alba, Post-inflammatory	Woronoff's ring (hypopigmentation around psoriasis lesions)
	Mycosis fungoides		—
	Onchocerciasis		—
	Pityriasis lichenoides chronica	(Discoid lupus, Eczema, psoriasis),	—
	Pinta		—
	Yaws		—
		Post-Kala-azar, Sarcoidosis,	
		Syphilis: (endemic, secondary), Pityriasis versicolour	—
Neoplastic	Halo naevus	Melanoma	—
	Leucoderma acquisitum centrifugum	Halo around primary or metastatic lesions	—
Nutritional	Vitamin B12 deficiency	Chronic protein loss— Kwashiorkor, Malabsorption,	—
		Nephrosis—Ulcerative colitis	—
Physical	Burns (Ionising, Thermal, UV)	Post-dermabrasion	—
	Trauma	Post-laser	—
Miscellaneous	Alopaecia areata, Scleroderma	Canities, Idiopathic guttate hypomelanosis	Anaemia oedema

Table 2: Epidermal Hypermelanoses: Clinicopathologic Classification

Epidermal factors	Melanocytotic (Increase in number of melanocytes)	Melanotic (Increase in melanin)	
Heritable or developmental	Lentigines, neurodysraphic Centrofacial lentiginosis Peutz-Jegher syndrome PUVA therapy	*Cafe-au-lait* macule, Neurofibromatosis, Albright's syndrome, Bloom's syndrome, Becker's melanosis, Naevus spilus, Ephelides (freckles)	Neurocutaneous melanosis Familial periorbital hyperpigmentation Dowling-Degos disease Dyskeratosis congenita Acropigmentation of Dohi Reticulate acropigmentation of Kitamura
Metabolic		Porphyria cutanea tarda Haemochromatosis, Gaucher's disease, Niemann-Pick disease	
Endocrine		Melasma, ACTH- and MSH-producing tumours, Exogenous ACTH therapy,Pregnancy, Addison's disease, Oestrogen therapy	
Chemicals and drugs		Arsenicals, Busulfan, Photochemical agents (psoralens, tar), Berloque dermatitis	5-fluorouracil, cyclophosphamide nitrogen mustard, topical bleomycin
Nutritional		Kwashiorkor, Pellagra, Sprue Vitamin B12 deficiency	
Physical	Lentigo, solar, ultraviolet (radiation tanning)	Ultraviolet radiation- (sun tanning), Thermal radiation, Ionising radiations Trauma (e.g. chronic pruritus)	
Inflammation and infection		Post-inflammatory melanosis (exanthems, drug eruptions) Discoid lupus erythematosus	Lichen simplex chronicus, Atopic dermatitis, Psoriasis, Lichen planus
Neoplastic		Melanoma, Mastocytosis, Acanthosis nigricans with or without, adenocarcinoma and lymphoma	
Miscellaneous	Lentigines, eruptive lentigo	Systemic scleroderma, Chronic hepatic insufficiency Whipple's syndrome	

HYPOMELANOSIS

Table 1 shows that pigmenatry disturbances may be congenital or acquired, localised or generalised and the loss of colour is either partial (hypomelanosis) or complete (amelanosis). De-pigmentation is applied for the condition when there is complete loss of pre-existing normal pigmentation. Localised or circumscribed hypomelanosis refers to islands of hypopigmented/depigmented skin amidst clinically normal skin. Hypopigmentation here may be amelanotic and progressive (vitiligo, chemical leucoderma), amelanotic congenital and stable (piebaldism, Waardenburg syndrome), hypomelanotic and progressive (pityriasis versicolour, post-inflammatory) or hypomelanotic and stable (tuberous sclerosis, naevus depigmentosus).

Certain features in circumscribed hypomelanotic macules facilitate diagnosis, which include size, shape, hue, arrangement, etc. Small 1 to 2 mm macules may be seen in vitiligo, chemical leucoderma, and tuberous sclerosis. Lesions of *Pityriasis alba* and post-inflammatory hypopigmentation are larger but have fuzzy, indistinct margins, unlike the sharp margins in idiopathic guttate hypomelanosis. Convex borders are usually seen in vitiligo or chemical leucodema. The lance ovate shaped white lesions are characteristic of tuberous sclerosis. Macules of vitiligo and piebaldism are milky or chalk white as compared to the off white colour of naevus depigmentosus (**Figure 1**), tuberous sclerosis or post-inflammatory hypopigmentation. *Vitiligo:* It is a common acquired disorder characterised by milky white macules with the likely incidence between 1% to 2%. All races are affected. Both sexes are affected equally. Vitiligo occurs more commonly on the sun exposed areas and in darker skin types. Vitiligo may develop at any age—birth to 81 years of age. A typical vitiligo macule has a chalk or milky white colour, round to oval in shape often with convex margins which are usually well defined, varying from few millimetres to many centimetres in diameter. Trichrome vitiligo refers to the presence of an intermediate colour (uniform tan colour), an interface between the white lesions of vitiligo and the normally pigmented skin. Quadrichrome refers to fourth colour—perifollicular or marginal pigmentation seen in some cases of re-pigmenting vitiligo. Inflammatory vitiligo has an erythematous raised border similar to the one sometimes seen in pityriasis versicolour.

CLASSIFICATION AND TYPES OF VITILIGO

Focal, segmental, generalised and universal are the most common patterns of vitiligo. Vitiligo is also classified as

Figure 1: Naevus depigmentosus.

segmental, acrofacial, generalised and universal or by pattern of involvement as focal, mixed and mucosal.

Focal Vitiligo

There is either a single or few macules limited in both size and number. About 20% of the children have this pattern.

Segmental Vitiligo

The lesions are distributed in a dermatomal or quasi-dermatomal pattern. This is earlier in onset but is considered a stable type of vitiligo.

Generalised Vitiligo

It is the most common type of vitiligo and is characterised by few to many to widespread macules. The lesions are often symmetrical and involve extensor surfaces, areas over small and large joints. Periungual involvement may occur alone or with simultaneous involvement of lips, distal penis and nipples. The names lip tip and acrofacial vitiligo are given to this peculiar distribution of lesions (**Figure 2**).

Figure 2: Generalised vitiligo.

Universal Vitiligo

It indicates almost total involvement of the body with few remaining areas of pigmentation and has been associated with various endocrinopathy syndromes. Koebner's phenomenon is not uncommon and on sites of burns, injury or laceration, the depigmentation appears in that shape. Mucosal involvement is not infrequent, genitalia, lips, gingiva are often involved. Involvement of palms and soles though uncommon does occur. Vitiligo may be associated with leukotrichia, prematurely gray hair, halo nevi, and alopaecia areata. Depigmented hair are often found in isolated vitiligo lesions. Leucotrichia (poliosis) has been reported in up to 45% of cases of vitiligo. Rarely vitiligo patients may have pigmentary abnormalities in iris and retina. Many authors have reported an association of vitiligo and thyroid function abnormalities. Pernicious anaemia though uncommon occurs with increased frequency in patients with vitiligo. Association with systemic lupus erythematosus, diabetes mellitus, Addison's disease, inflammatory bowel disease, rheumatoid arthritis, etc. is well known.

Aetiology and Pathogenesis

Though vitiligo is mostly a single entity, the aetiology is complex. Several hypothesis to explain its aetiopathogenesis have been propounded which include-genetic, autoimmune, self destruct, neural and composite hypothesis. Familial cases of vitiligo are common, suggesting a genetic basis. However, the transmission is more complex, most likely polygenic. In the self destruct hypothesis, formation of hydrogen peroxide (H_2O_2), certain tyrosine analogues and intermediates in melanin synthesis are thought to cause the destruction of melanocytes. In the autoimmune hypothesis, presence of antibodies against the melanocytes, various melanocyte antigens and transcription factors have been cited as the evidence. Diagnosis is easy in the presence of progressive chalk white macules in typical sites. Wood's lamp examination may help.

Differential Diagnosis

The picture is mostly classical but it should include chemical leucoderma, leprosy (**Figure 3**), post-inflammatory hypo-pigmentation, pityriasis alba, pityriasis versicolour, tuberous

Figure 3: BT leprosy.

sclerosis (**Figure 4**), piebaldism, etc. Small lesions of naevus depigmentosus, and idiopathic guttate hypomelanosis have to be considered when the vitiligo lesions are focal.

Figure 4: Ash leaf macules of tuberous sclerosis.

Treatment

Most patients require reassurance and an understanding of their affliction. Re-pigmentation is the basic aim of the treatment. Currently available options include psoralens, topical calcineurin inhibitors (tacrolimus, pimecrolimus), topical and systemic corticosteroids, topical and systemic PUVA, narrow band UVB, immunosuppressives and skin grafting according to the type of vitiligo.

Topical steroids are probably first-line therapy for most patients with limited disease. Topical tacrolimus (0.03% and 0.1%) ointment has been found to be safe and effective in childhood vitiligo. Narrow band UVB is currently considered the treatment of choice for generalised vitiligo. Surgical techniques include skin grafting, cultured/non-cultured melanocyte grafting, punch grafting, etc.

Albinism

Albinism refers to genetic abnormalities of melanin synthesis (in hair, skin and eye) associated with normal number and structure of melanocytes. Characteristic ocular changes include nystagmus, iris translucency, reduced melanin in the retinal pigment epithelium. It results in a characteristic albino with white hair, white skin and blue eyes.

Piebaldism

This is an uncommon, autosomal dominant, congenital, stable leucoderma characterised by chalk or milk-white macules like that of vitiligo and a typical white forelock.

Chemical Leucoderma

Acquired hypomelanosis is due to repeated exposures to specific chemical compounds particularly phenols and sulphydryl compounds. Monobenzylether of hydroquinone (MEBH) was the first compound identified producing leucoderma in tannery workers. The lesions of chemical leucoderma resemble lesions of vitiligo, but usually do not have sharp margins. They appear not only at the site of contact with the offending compound but also remotely. The sites affected may be specific or very odd which come in contact with these chemicals due to footwear, watch straps, waist bands of undergarments, condoms, purses left in contact with the breast, bindi and hair dye, etc.

Post-Inflammatory Hypopigmentation

A number of inflammatory dermatoses may be associated with or resolve to leave hypopigmented lesions corresponding to areas of involvement and are seen commonly after healing of a lesion of dermatitits and psoriasis, etc.

Pityriasis Alba

It usually affects young children of both sexes equally. The macule is pale or light brown with indistinct margins. Erythema if present fades over weeks to leave behind off-white or tan-white macule with fine scales. All parts of the face, forehead, malar prominences, around the mouth are common sites. Pityriasis alba is probably a non-specific eczematous dermatosis with post-inflammatory hypomelanosis.

Pityriasis Versicolour (Tinea Versicolour)

It is caused by lipophilic yeast *Malassezia furfur.*

Typical lesion is a round, scaly, hypomelantoustic macule, which sometimes may be raised and has erythematous raised margins. Affected sites are the upper back and chest but also occur on upper arms, neck and even face. The lesions are more extensive in patients living in tropics. The lesions can be tan, hyperpigmented and erythematous or a mixture with the hypopigmented lesions. Various topical and systemic antifungals are effective in treating this condition.

HYPERMELANOSIS

Table 2 shows that hypermelanosis may be melanotic or melanocytotic in origin which may be congenital or due to nutritional, hormonal, chemical factors or due to neoplasia or post-inflammatory. Epidermal hypermelanosis refers to brownish pigmentation due to increased melanin in the epidermis (**Figure 5**). Some of the hypermelanoses may be associated with a dermal component (mixed hypermelanoses) characterised by melanin in dermal macrophages. Hypermelanosis may be diffuse or localised (ephelids, *café- au-lait* spots, Dowling-Dego disease).

Lentigines

These are small (usually less than 0.5 cm in diameter), circumscribed, brown to dark brown to black, variegated to uniformly coloured

Figure 5: Becker's naevus.

macules. They may be found as isolated macules or multiple lesions mostly on sun-exposed areas. Mucosal lesions are localised to lips, oral mucosa, palate and tongue in Peutz-Jeghers syndrome. Although most of the hamartomatous polyps are benign, there is a chance of them turning malignant.

Café-au-lait macules (CALMs)

These are discrete, well-circumscribed, 2 to 20 mm, uniformly pale brown macules characterised by serrated or irregular margins, appearing at or soon after birth. CALMs are common cutaneous findings but can be markers for multisystem disease such as neurofibromatosis.

Melasma

It is an acquired symmetric hypermelanosis, with light brown to gray brown macules or patches on sun exposed areas of the skin. The most common sites involved are centrofacial pattern affecting the cheeks, forehead, upper lip, nose, and chin (**Figure 6**). It is much more common in women and is seen more often in people with dark skin. Important aetiologic factors are genetic predisposition, UV radiations (sun exposure), endocrine disorders, nutritional deficiencies, female sex hormones and certain drugs. The majority of cases appear related to pregnancy or oral contraceptives. Melasma like hyperpigmentation has been described in HIV disease. High expression of α-MSH in the lesional keratinocytes may play an important role in the melanisation of skin. Increased number of melanocytes have been reported in the lesions. Use of sun block and bleaching forms the mainstay of treatment though majority of the times the treatment is unsuccessful and the relief is temporary as long as the treatment lasts. The sun screen must be a broad-spectrum, chemical sunscreen (both UVA and UVB protecting) or an opaque physical (zinc oxide, titanium dioxide). Topical hydroquinone (2% to 4%) with retinoids and or steroids is the usual treatment. Steroids should be used with care.

Post-inflammatory hyperpigmentation

In many dermatoses, pigmentation follows the healing of the lesions. Eczemas and various dermatoses can lead to post-inflammatory hyperpigmentation (**Figure 7**). The pigmentary

Figure 6: Melasma.

Figure 7: Lichen planus pigmentosus.

macules are discrete, with hazy feathered margin corresponding to the primary eruption.

DERMAL HYPERMELANOSIS (CERULODERMA)

This results from the presence of pigment in the dermis. Circumscribed dermal melanocytotic melanoses are generally developmental and mostly occur among Asians like Mongolian spots, naevus of Ota, naevus of Ito, etc. Circumscribed dermal melanotic hyperpigmentation are—incontinentia pigmenti, macular amyloidosis, etc.

Fixed Drug Eruption

This is a very special type of process where the lesions occur repeatedly on the same spot and the pigment darkens every time.

11.10 Disorders of Skin Appendages

Raj Kubba, Tanvi Pal

Hair follicles, sebaceous glands (pilosebaceous units), eccrine (sweat) glands and nails are the key appendages of the skin. This section identifies and describes the solitary, most relevant disease entity in each of these, namely, miliaria, acne vulgaris, rosacea, and alopaecia areata.

MILIARIA

Definition

Miliaria results from blockage of the acrosyringium, the long thin duct that carries sweat from the coiled secretory portion located in the reticular dermis and the subcutaneous fat to the skin surface, with secondary leakage of sweat in the epidermis and papillary dermis.

Aetiopathogenesis

Immaturity of the acrosyringium is the most likely reason for miliaria in newborns. Sudden, excessive, unaccustomed sweating and febrile illnesses are some of the known triggers in both children and adults. Miliaria affected skin is reported to have three fold greater counts of bacteria such as *Staphylococcus epidermidis* and *Staphylococcus aureus*, suggesting yet another aetiologic factor.

Clinical Features

Depending upon the level of the blockage, three sub-types of miliaria are recognised. The details are given below:

Miliaria crystallina

The acrosyringium is blocked superficially—in the stratum corneum—resulting in sheets of uniform, delicate, 1 mm sized, vesicles with clear serous contents on the scalp, face, neck, and upper torso. This subtype is seen mostly in newborns.

Miliaria rubra

Also known as 'prickly heat', this subtype is clinically characterised by uniform, non-follicular, 1 to 3 mm, erythematous papules, occurring in sheets with a predilection for back, flexures and frictional areas. Itching is intense and there is a propensity for secondary bacterial infection as impetigo and 'boils'.

Miliaria profunda

When the acrosyringium is blocked at a deeper level the sweat leaks into papillary dermis producing 1 to 3 mm, flesh coloured papules that are typically non-itchy. The anatomic distribution is similar to *Miliaria rubra*.

Treatment

Physical readjustment, in the form of confining to a cooler environment, avoiding known triggers, frequent cold baths and applying a soothing lotion containing calamine, menthol or boric acid is all that is required to treat a typical case of *Miliaria rubra*. Topical antibiotics and topical steroids are required for complicated cases. There are no sequelae. Recurrences are common.

ACNE VULGARIS

Acne vulgaris (literally meaning common acne) is a chronic inflammatory disorder of sebaceous follicles, predominantly seen in adolescence. It affects 80% of the population in the age group of 11 to 30 years. Acne has a major impact on the quality of life (QOL).

Aetiopathogenesis

Acne is hormonal in origin. Acne results from a complex interplay of increased sebum production, ductal hypercornification, follicular colonisation with *Propionibacterium acnes*, and inflammation. Acne lesions begin with the microcomedo, a microscopic lesion not visible to the naked eye. With time, the follicle fills with lipids, bacteria and cell fragments. Ultimately, a clinically apparent lesion occurs, either a non-inflammatory lesion (open or closed comedo) or an inflammatory lesion. Comedogenesis is unique to acne and ductal hypercornification is a key step in it. There is hyper proliferation and abnormal cellular differentiation in the follicular infundibulum, resulting in accumulation of excess and sticky keratinocytes that turn into plugs (comedones). *Propionibacterium acnes*, a Gram-positive, rod-like bacterium, resides in sebaceous follicles and contributes to comedogenesis and inflammation in acne through production of lipases and proteases, through elaboration of cytokines (TNF-α, IL-1α, IL-8), and through activation of toll-like receptor 2 (TLR 2).

Clinical Features

Acne is readily recognised by its age of onset, anatomic distribution, and folliculocentric morphology. However, it displays considerable range and variation. Typically, it precedes puberty by a year or two, peaks between 14 and 16 years in females, and 17 and 19 years in males. Acne displays cephalocaudal evolution. The first lesions, usually comedones, develop on the forehead (pre-adolescent acne). At its peak, acne covers the entire face (adolescent acne), and in mature adults (25 years plus) it settles on the jaw area and the adjacent neck (persistent acne/adult acne). Acne is reportedly more common in males, 55% versus 45% for females, although the latter frequently seek consultation from dermatology clinics. Also, our female patients have more severe acne, often with added stigmata of cutaneous hyperandrogenism, namely, seborrhoea, hirsutism, and alopaecia.

Typically, face is the only site of involvement or is distinctly more involved. Less commonly, back is more involved (acne corporis) (**Figure 1**), and such cases represent greater severity. Acne corporis also involves the chest, shoulders and upper arms, and rarely, buttocks and thighs.

Acne is a polymorphic condition showing an array of comedones, inflammatory lesions and sequelae. Besides open comedones (blackheads) (**Figure 2**), and closed comedones (whiteheads) (**Figure 3**), there are macro-comedones (larger

Figure 1: Acne vulgaris on back. Erythematous conical papules.

Figure 2: Acne vulgaris. Numerous blackheads (open comedones) and a few inflamed nodules.

Figure 3: Acne vulgaris. Inflammatory papules and pustules, 'closed comedones' pitted and ice-pick scars.

than 1 mm). A diagnosis of acne in the absence of comedones is not tenable. However, 10% of acne patients may not show comedones at first clinic visit. Inflammatory lesions include macules, papules, pustules, papulopustules, nodules, pseudo cysts, and sinus tracts (**Figure 4**). Only larger inflammatory

Figure 4: Severe acne vulgaris. Several inflammatory nodules, cysts and sinuses.

lesions are painful or tender. Acne may be associated with itching. Sequelae include post-inflammatory pigmentation and scars. There are several grading systems. An easy to use acne grading system is described in **Table 1**.

Table 1: Grading of Acne

Grade 1: Mild acne Predominance of comedones	Comedones < 30 Papules < 10 No scarring
Grade 2: Moderate acne Predominance of papules	Comedones any number Papules > 10 Nodules < 3 Mild scarring ±
Grade 3: Severe acne Predominance of nodules/cysts	Comedones any number Papules any number Nodules/cysts > 3 Extensive scarring

Acne tends to aggravate in hot and humid weather, under stress, and by injudicious use of oils and oily skin care products. Premenstrual flares are common and indicate hormonal imbalance. In time, acne remits, usually before the age of 25 years. Increasingly, it may persist longer, in some instances beyond the age of 50 years. There are also individuals who develop acne for the first time after the age of 25 years (adult acne).

Diagnosis

Acne is diagnosed clinically. Laboratory tests are only done to evaluate for hormonal imbalance and to screen and monitor for certain treatments. Differential diagnosis includes acneiform drug eruptions, folliculitis, and rosacea.

Treatment

Acne treatment plans are based on severity, and presence of associated features such as cutaneous hyperandrogenism. Combination treatments are preferred. Available modalities and their respective mode of actions are listed in **Tables 2 and 3**. First line treatments for all forms of acne are topical retinoid and benzoyl peroxide. Moderate acne often requires systemic antibiotics. Severe acne should be treated with oral isotretinoin. Acne in the context of cutaneous hyperandrogenism requires antiandrogens. Topical agents should be applied on the entire susceptible area, for example, the entire face. Topical retinoids are photoreactive and are best applied at bedtime. Adapalene

is the least irritating topical retinoid and also has anti-inflammatory effect. Topical antibiotics should never be used as monotherapy for risk of bacterial resistance. Oral isotretinoin has potential for serious adverse effects and should only be administered under expert supervision. An algorithmic approach to management of acne is described in **Figure 5**.

Table 2: Topical Treatment Options in Acne

Predominantly anticomedonal
- Adapalene 0.1%
- Tretinoin 0.25% and 0.05%
- Tazarotene 0.05% and 0.1%
- Azelaic acid 10% and 20%

Predominantly antimicrobial
- Benzoyl peroxide 2.5% and 5%
- Clindamycin 1%
- Erythromycin 4%, clarithromycin 2%

Combinations
- Adapalene/clindamycin
- Benzoyl peroxide/erythromycin

Table 3: Systemic Treatment Options in Acne

Antibiotics (antimicrobial, anti-inflammatory)
- Tetracycline 500 mg bid
- Doxycycline 100 mg od
- Minocycline 100 mg od

Retinoids (sebosuppressive, anti-comedonal, anti-inflammatory, anti-microbial)
- Vitamin A 50,000 units bid
- Isotretinoin 0.5 to 1.0 mg/kg

Anti-androgens (sebosuppressive, anti-comedonal)
- Combination OCP (cyproterone acetate 2 mg + ethinyl oestradiol 35 µg)
- Combination OCP (drospirenone 3 mg + ethinyl oestradiol 30 µg)
- Spironolactone 25 to 50 mg bid

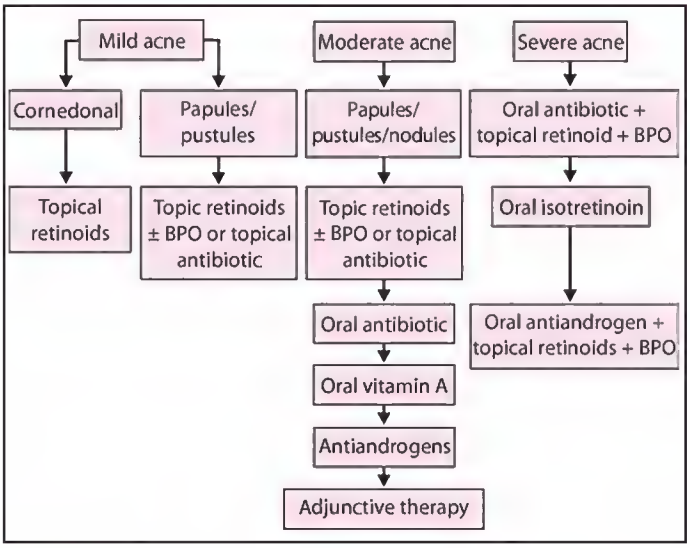

Figure 5: Acne treatment algorithm.

BPO= Benzoyl peroxide.

DRUG-INDUCED ACNE

Acne can be triggered or aggravated by androgens, progestogens, anabolic steroids, topical and oral corticosteroids, halogens, isoniazid, diphenylhydantoin, phenytoin, thiouracil, cyclosporine A, disulfiram, lithium, vitamin B12, and PUVA therapy. Steroid acne refers to the sudden onset of an asymptomatic, monomorphic, papular or pustular eruption on the upper torso in a post-pubertal individual, with or without previous acne, who has received systemic steroids. It does not scar and tends to resolve spontaneously or with mild topical acne medications after the steroids have been withdrawn.

ROSACEA

Rosacea is a chronic, waxing and waning, vascular reaction pattern, involving the central area of the face, occurring in mature adults. It is characterised by episodic flushing, erythema, telangiectasia, recurrent papules and pustules.

Aetiopathogenesis

Hypotheses include potential roles for vascular abnormalities, environmental factors, and micro-organisms such as *Demodex folliculorum* and *Helicobacter pylori*. Steroid rosacea refers to a rosacea-like clinical state, induced by prolonged use of topical steroids.

Clinical Features

Four clinical patterns are recognised: Erythemato-telangiectatic, papulopustular, phymatous, and ocular. Rosacea typically involves the central face viz. glabella, nose, cheeks and chin. Besides central location, later onset, and flushing, rosacea is distinguished from acne by the absence of comedones. However, acne and rosacea may co-occur (acne rosacea). Ocular changes are irritation, lacrimation, blepharitis, episcleritis, keratitis, corneal vascularisation, and iritis. Rhinophyma describes a sequel where the hypertrophied nose shows craggy, bulbous swelling with prominent follicular ostia filled with keratinous debris.

Treatment

Metronidazole 0.75% gel and/or oral antibiotics are the first-line treatments. Doxycycline 100 mg once daily; minocycline 100 mg daily; or clarithromycin 250 mg twice daily or 500 mg once daily, for 4 to 12 weeks are all effective. However, the condition tends to relapse.

ALOPAECIA AREATA

Human skin bears approximately 5 million hair follicles of which around 100,000 hair follicles are located on the scalp. The hair grow in a cyclical manner and exhibit four phases: Growth (anagen), regression (catagen), resting (telogen), and shedding (exogen). Hair disorders may result from defects in hair cycle, or hair growth (excess—hirsutism; sparse—hypotrichoses), and from hair follicle destruction by per follicular inflammation (Lichen planus, Lupus erythematosus).

Definition

Alopaecia areata (AA) is the most notable example of non-scarring, non-patterned alopaecia, characterised by sudden/rapid appearance of circumscribed, circular/ oval bald patches in hair bearing areas especially the scalp (**Figure 6**). The alopaecia results from arrest of hair follicles in late anagen phase.

Epidemiology

The prevalence in general population is 0.1% to 0.2%; life-time risk for developing AA is 1.7%, and it comprises 0.7% to 3% of all patients seen by dermatologists. A positive family history has been recorded in 10 to 20%. AA can occur at any age but the highest susceptibility has been observed in the age group 15 to 29 years.

Figure 6: Alopaecia areata. Circumscribed patchy alopaecia with no inflammation or scarring.

Aetiopathogenesis

AA is postulated to be a T-cell mediated autoimmune disease directed against hair follicles in late-anagen phase. AA is believed to be a polygenic condition with environmental and life-style factors acting as triggers and causing aggravation. AA is associated with atopy, type 1 diabetes mellitus, autoimmune thyroid disease, autoimmune polyendocrinopathy syndrome, vitiligo, pernicious anaemia, inflammatory bowel disease and Down's syndrome.

Clinical Features

Alopaecia areata is common in both men and women. A solitary patch is the initial presentation in 80%, and spontaneous re-growth in 3 to 6 months is the rule. The natural course is variable and unpredictable. Recurrences are common and, with each recurrent episode, the severity tends to increase and probability of spontaneous re-growth diminish. The presence of 'exclamation mark hair' at the margin of the alopaecia is indicative of activity. Re-growth in AA patches commences from the centre and progresses centrifugally. AA patches are typically skin coloured and asymptomatic.

Based on distribution and severity, several clinical patterns are recognised, namely, focal, reticular, ophiasis (band-like hair loss in the occipital and temporal scalp), sisaipho (predilection for parietal scalp mimicking androgenetic alopaecia), totalis (loss of all scalp hair), and universalis (loss of all scalp and body hair). Nail involvement, mostly as pitting, has been noted in 6.8 to 49.4%. AA significantly impacts the quality of life.

Diagnosis and Prognosis

AA is a clinically distinctive disease. The prognosis is variable, being good in mild disease and initial episodes. However, recurrent disease, severe disease (particularly ophiasis, totalis and universalis), early age at onset, nail involvement, and co-morbidities such as atopy, are adverse prognostic signs.

Treatment

A wide range of therapeutic options are available for management of AA. First choice modalities include topical steroids, intralesional steroids (triamcinolone acetonide 2.5 to 5 mg/ml), and 5% minoxidil lotion. For active/spreading AA systemic therapy with levamisole (50 to 150 mg on two consecutive days each week for 3 to 6 months) and/or prednisolone as oral minipulse (0.5 mg/kg dose on two consecutive mornings each week) are popular in our country. Aggressive systemic steroids, as daily dosing for limited periods, may be justifiable for severe and psychologically disabling disease. Systemic steroids are therapeutically very effective but relapses are a rule when they are withdrawn.

NAIL CHANGES

Nails, another skin appendage, are subject to abnormalities both internally as well as by disorders of the skin. Understanding the biology and anatomy of the nail allows the treating physician to ascertain the location of pathology and treat accordingly. The nail unit comprises of the proximal and lateral nail folds, nail matrix, nail bed, and hyponychium (**Figures 7 and 8**). Described

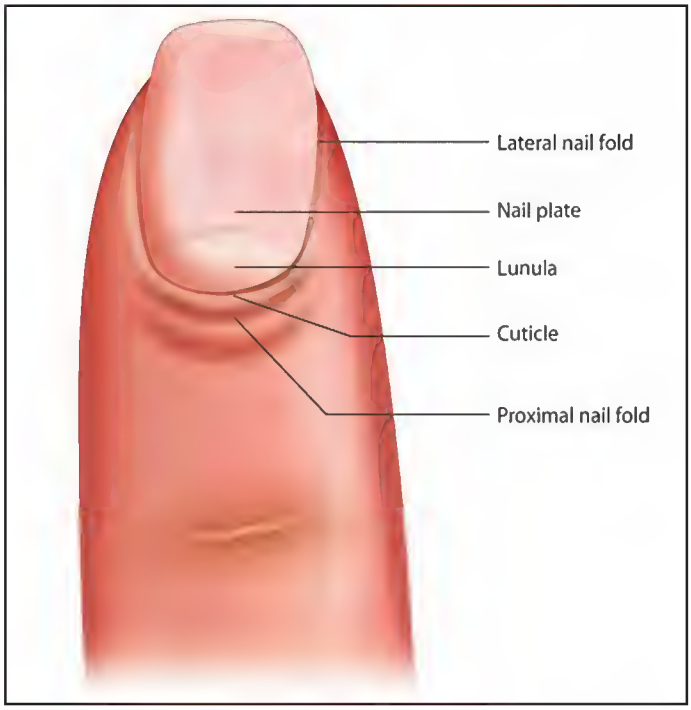

Figure 7: Diagramatic presentation of nail structure.

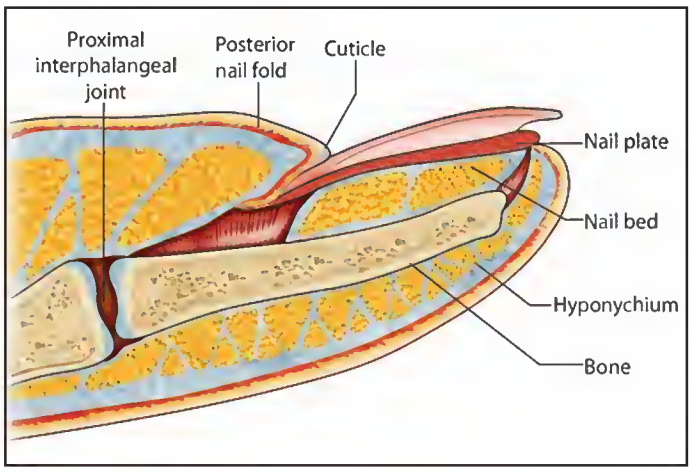

Figure 8: Nail unit in cross-section.

below are few of the common nail signs affecting the nail plate, nail bed, and nail folds.

Koilonychia

It is spooning of the nails, where the lateral edges of the nail plate are elevated above a depressed centre. Endocrinological diseases such as hypothyroidism and iron deficiency anaemia are the main causes way.

Pitting

Pitting occurs in response to a defect in the nail matrix, mainly the proximal matrix. They are shallow depressions in the surface of the nail and can be regular, irregular, large, or small depending on the duration and extent of pathology. Most common causes of pitting are psoriasis, alopaecia areata and eczematous conditions.

Clubbing

It is a over-curvature of the nail, with or without hypertrophy of the soft tissues and cyanosis. Clubbing is characterised by an increase in the angle (> 180°) between the proximal nail fold and nail plate, and it is mostly seen in cardiovascular, gastrointestinal and familial disorders.

Beau's Lines

A growth disruption in the nail matrix results in horizontal (transverse) depressions in the nail plate (**Figure 9**). Any systemic disease or event that is severe enough to cause disturbance of nail growth can result in Beau's lines.

Figure 9: Beau's lines. Transverse depressions in the nail plate.

Paronychia

Paronychia means inflammation of the nail folds. It is categorised into acute and chronic. Acute form is one of the most common infections of the hand, with *Staphylococcus aureus*, Streptococci and *Pseudomonas* being the likely pathogens. Chronic paronychia is caused by repeated trauma to the nail folds either physical (excessive manicuring) or chemical (water, contact irritants).

Tinea Unguium

The infection of the nail unit with dermatophytic fungi is known as *Tinea unguium*. Dermatophytes are keratinolytic fungi and normally invade keratins of skin, hair and nails, most common being *Trichophyton rubrum* and *T. mentagrophytes* (**Figure 10**). Toenails are infected 25 times more than the finger nails.

Figure 10: Distal onychomycosis showing yellow-brown discolouration.

11.11 Cutaneous Responses to Physical Factors

S Criton

Sun is the perennial source of energy and it sustains life on earth. Though it has beneficial effects, at times sunlight can cause harmful effects to man. This may range from trivial transient pigmentation to lethal cutaneous as well as systemic malignancies.

Sunlight has many components such as gamma rays, X-rays, ultraviolet rays, infrared light and radio waves. Common harmful effects of sunlight are due to ultraviolet rays. The ultraviolet rays have three components such as ultraviolet A (320 nm to 400 nm), ultraviolet B (290 nm to 320 nm) and ultraviolet C (200 nm to 290 nm). When light falls on skin some are reflected and some are absorbed. The penetration into skin is dependent on the wave length (the longer wavelengths penetrate more). As the rays penetrate, part of it is absorbed by chromophores, part is transmitted and part is reflected back. Once the energy is absorbed, the chromophores become excited and form photoproducts. These photoproducts are responsible for the skin changes.

CUTANEOUS EFFECTS OF ULTRAVIOLET EXPOSURE

The cutaneous effects of ultraviolet ray, exposure may be divided into early and late effects. The early effects are inflammation, tanning, hyperplasia, immunological changes, vitamin D synthesis and photo onycholysis. The late effects of ultraviolet exposure include pseudoporphyria, photoageing, photocarcinogenesis.

Skin Phototypes

Fitzpatrick developed the concept of skin types based on the person's responses to sunlight. Based on this, the skin is typed as Type I through VI. Persons with types I and II usually burn more easily. The types V and VI individuals tan easily and have least propensity to develop skin cancers. Type III individuals have moderate susceptibility to sun burn and good tanning ability; whereas type IV skin has low sun burn susceptibility but very good tanning potential.

MECHANICAL INJURY

Mechanical injuries are common on human skin due to pressure and shearing force. This may occur as a consequence of occupation, recreational activity or due to deformities. Constant friction produces callosities, corns and calluses. It can also lead to bullae. Corns are circumscribed areas of hard skin in the shape of a nodule commonly seen over the dorsal surface of toes. Calluses are more diffuse. Pressure ulcer is due to localised area of ischaemia and necrosis following prolonged compression of soft tissues over a bony prominence. Suction can also produce 'suction blister', which is a mechanical injury due to negative pressure.

'Computer palms' and 'mouse fingers' are emerging injuries due to mechanical stress to palms and fingers. Pressure, shear, moisture and friction are attributed factors causing these injuries. 'Spectacle frame acanthoma' is another entity developed following pressure and friction of the spectacle and moisture at the site where spectacle is coming into contract.

Vibration can cause vibratory angioedema and hand-arm vibration syndrome. Vibratory angioedema is a form of physical angioedema which disappears when the stimulus is withdrawn. In 'hand-arm vibratory syndrome', initially there is tingling and numbness. As the disease progresses, anaesthesia occurs. This is followed by blanching. As the disease progresses further, there is reduction in touch sensation and difficulty in doing fine work. The condition may be improved with use of nefedipine and α-andrenoreceptor antagonist.

THERMAL INJURIES

Thermal injuries include burn, electric injury and lightening injury. The spectrum of burn may be trivial and inconsequential to very severe leading to death. The type, depth, extent, age of the patient, associated illness, time elapsed between burn and treatment and general status of the patient either singly or in combination determine the outcome of burn. While treating the patient with burn cardiac status, renal status, the infection and coagulation abnormalities are monitored and corrected appropriately. Once the acute phase is over, long-term complications such as scarring and contracture are addressed.

Electricity can produce burns. This may be divided into high tension and low tension burns. With high tension injury, there will be injuries at the entry site as well as at the exit point. The management of electric burn include general supportive care and specific wound management.

When lightening strikes, focal entry and exit wounds are lacking in many. In some at the site of entry, there may be superficial streaking burns, known as 'lightening figures', and at the exit site there may be a charred defect.

COLD INJURIES

Cold environment is harmful to human body. Inherently body has developed protective mechanisms from cold injuries. When body is exposed to cold, a number of responses occur such as cutanenous vasoconstriction, increase in viscosity of blood, change in platelet adhesiveness, diminished conduction velocity in cutaneous nerves and slowing of dissociation of oxyhaemoglobin to haemoglobin. These factors will help the body to maintain its core temperature. Prolonged cutaneous vasoconstriction leads to ischaemia and later necrosis. This is prevented by subsequent vasodilatation which is known as *'hunting reaction of Lewis'*.

Disease of Cold Injury

The type and gravity of cold injuries depend on various factors such as absolute temperature, duration of exposure, individual susceptibility and altitude at which injury occurs. The factors controlling individual susceptibility are physical injury, body mass, physical fitness level, fatigue, sickness, trauma, peripheral circulation status as well as clothing and age of the patient.

Habits like alcohol consumption, smoking and use of psychotropic drugs will add onto cold injuries.

Classification of Cold Injury

The cold injuries may be broadly divided into freezing and nonfreezing injuries.

Frostbite

Frostbite is a type of cold injury caused by acute freezing of tissues on exposure to extreme degrees of cold. Frostbite has four phases such as pre freeze (vasospastic) phase, freeze thaw phase, stasis phase and ischaemic phase.

Frostbite usually affects fingers, toes, nose or cheeks. Depending on the tissue involved it may be graded into first through fourth degree. The first degree frost bite presents with blanched anaesthetic skin. In second degree, there will be oedema and blister formation. In third degree, the bullae become haemorrhagic, while in fourth degree, there will be necrosis.

Treatment

The principle in the management of frostbite is rapid rewarming and avoidance of further trauma. Rapid rewarming is done by immersion in water at 40 to 42° C for 20 minutes. The damaged part should be elevated and blisters should be left intact. Liberal use of analgesics are recommended for relief of pain. Early administration of heparin and infusion of low molecular weight dextran are suggested as effective modalities. Oxpentifylline and hyperbaric oxygen therapy are other recommendations.

Trench Foot (Immersion Foot)

Trench foot results by prolonged exposure to low temperature without freezing.

Clinical features

It start as numbness and tingling. The skin becomes erythematous initially but later it becomes pale and mottled. If the condition persists there may be pain, ulceration and sometimes gangrene.

Treatment

Rewarming the area and other supportive measures like rest to the part, analgesics, and antibiotic. The part should not be massaged, rubbed and exposed to extreme heat.

Pernio (Chilblains)

Chilblain is characterised by localised, tender, inflammatory, erythematous, pruritic lesions which blister or ulcerate. The predisposing factors to chilblains include genetic susceptibility, inadequate nutrition, focal sepsis, hormonal changes and systemic diseases such as dysproteinaemia, myelodysplastic disease and anorexia.

Clinical features

The characteristic lesions are blue-red oedematous, sharply bordered nodules. They are distributed on dorsal aspect of fingers and toes, shins, inner aspect of knees and thighs, heels, nose, ears or occasionally on breasts. Some of the lesions may ulcerate. On warming they become pruritic and later painful. The lesions may persist for 3 weeks or rarely more.

Treatment

The various drugs used are calcium channel blockers viz. nifedipine and diltiazem, vasodilators such as nicotinic acid esters as well as pentoxyfylline.

Acrocyanosis

Acrocynosis is a persistent cyanotic or erythrocyanotic-discolouration of skin with mottled pigmentation. It mainly affects the hands; feet and face are also affected in some.

Acrocyanosis may be idiopathic phenomenon or secondary to some diseases and drugs. The diseases causing acrocyanosis include autoimmune disorders, neoplastic diseases, eating disorders, neurological disorders, psychiatric illnesses and chronic arsenic poisoning.

There is no effective treatment for idiopathic condition. But if it is secondary to diseases, appropriate treatment may help to improve.

Livedo Reticularis

Livedo reticularis is a mottled cyanotic discolouration of the skin with network pattern, which is accentuated with cold. It may be physiological, idiopathic or secondary to intravascular obstruction or vessel wall diseases.

Cold Urticaria

This is characterised by development of wheals on rewarming at the site of localised cooling. It may be *acquired cold urticaria* or *familial cold urticaria*. In acquired variety there may be wheals with constitutional features on exposure to cold; while familial cold urticaria is an autosomal dominant condition. The diagnosis of cold urticaria may be made with 'ice cube test'. This may be negative in familial cold urticaria.

Cold panniculitis

In children on exposure to cold, there will be erythematous, tender subcutaneous nodules which persist for 2 to 3 weeks.

Winter Xerosis

Patients may present with itching during winter. The itching may be generalised; it may be more over legs. Predisposing factors include atopic dermatitis, ichthyosis, old age, hypothyroidism and excessive washing with soap.

Photodermatoses: Abnormal Cutaneous Effects of Ultraviolet Radiation Exposure

Photodermatoses can be divided into four categories such as (1) acquired idiopathic photodermatosis, e.g. polymorphic light eruption; (2) DNA – repair defective photodermatoses, e.g. Xeroderma pigmentosum; (3) photosensitisation by exogenous or endogenous drugs or chemicals, e.g. sulphonylureas, porphyrias; and (4) photoexacerbated dermatoses, e.g. lupus erythematosus.

Acquired idiopathic photodermatoses include polymorphic light eruption (PLE), actinic prurigo, hydroavacciniforme, chronic actinic dermatitis and solar urticaria.

Polymorphic (Polymorphous) Light Eruption (PLE)

This is a common form of idiopathic photodermatoses characterised by itching and polymorphous skin lesions such as papules, vesicles, plaques, papulovesicles, and erythema multiforme-like lesions. Though the lesions are polymorphic, in a given individual, they are monomorphic. The lesions are distributed in sun exposed areas of the body.

The treatment includes sun protection, topical steroid and antimalarials. The disease has a good prognosis.

Actinic Prurigo

A seasonal dermatitis characterised by itching, nodular and eczematous lesions over legs. It may begin at any age. The face and distal limbs are commonly affected. Treatment is mainly photoprotection. Systemic thalidomide is found to be useful.

Chronic Actinic Dermatitis

This is a syndrome encompassing photosensitive eczema, photosensitivity dermatitis, actinic reticuloid and persistent light reaction. The disease is reported world wide and affects chiefly the elderly. It presents as papules and plaques on a normal or erythematous skin over sun exposed areas. The disease may persist for a long time and in some there may be transformation to lymphoma.

The treatment includes avoidance or reduction of sun exposure and photoprotection. Systemic steroid, cyclosporine and azathioprine may be used in the treatment with some benefit. Very resistant cases PUVA (Psoralen and UVA) or NB UVB (Narrow Band UVB) may be useful.

Solar Urticaria

Solar urticaria (SU) is characterised by the appearance of wheals on exposure to sunlight. It may be primary or secondary. Solar urticaria is considered as Type I hypersensitivity reaction; while secondary solar urticaria is due to drug photosensitivity, cutaneous porphyria or lupus erythematosus.

Drug and Chemical Induced Photosensitivity

This may mimic sunburn. A number of patterns may help to suspect this entity such as pricking and burning sensation, immediate erythema on exposure to sun, oedema and urticaria, hyperpigmentation, exaggerated sunburn, telangiectasia and angioma, blisters, increased skin fragility and delayed erythema. Drugs such as sulphonamides, sulphonylureas, phenothiazines, furocoumarins, fragnances, sun screens, NSAIDs are considered important in causing drug-induced photosensitivity.

CLINICAL EVALUATION OF THE PATIENT WITH SUSPECTED CUTANEOUS PHOTOSENSITIVITY

While evaluating the patient with photosensitivity, the following points are noted: the age, sex, occupation, recreational activity, prior history of photosensitivity, family history of photosensitivity, history of seasonal changes, interval between exposure and onset of symptoms, history of medication for the disease or any other diseases, application of topical agents, the pattern of dress and aggravating and/or relieving factors.

The morphology of lesion and site of involvement are important diagnostic clues. The characteristic lesions are patches or papules. Pinhead sized hypopigmented papules may suggest PLE. Blisters with scarring may be of porphyria. Persistent excoriated papules over sun-exposed areas are suggestive of actinic prurigo; eczematous lesions may be due to chronic actinic dermatitis. Wheals on exposure to sun may suggest solar urticaria.

The sites of involvement such as malar area, and tip and bridge of nose, anterolateral forearm, rim of ears, 'V' area of chest, sides of neck and dorsum of hands may suggest photodermatitis (these are common sun-exposed areas). In photodermatitis some areas are not usually involved such as submental area, behind the pinna, sun protected areas, web space of fingers are some among them. Sparing of these areas in the dermatitis in question may also help to make a diagnosis of photodermatitis.

Laboratory investigations may help to establish the underlying cause of photodermatitis, e.g. estimation of porphyrin, antinuclear antibodies in lupus erythematosus. Photo testing and photopatch testing are some useful tools in evaluation of photodermatitis.

11.12 Genodermatoses

Vibhu Mendiratta

DEFINITION

Genodermatoses are a group of diseases which are transmitted genetically from parents to children. Genodermatoses have well-defined cutaneous features whose recognition plays a key role in its diagnosis and management.

AETIOPATHOGENESIS

The disorders arise due to defect or alteration in a single or multiple genes (polygenic disorders), or these may also arise due to alterations in chromosomal structure. Factors that may give rise to genetic defects include mutagens such as radiation, drugs, cytotoxic agents, chemicals, ultraviolet (UV) light, and viral infections. Single gene disorders have a clear mode of transmission which may be autosomal dominant, recessive, X-linked recessive or dominant. The genetic defect may affect specific protein which may be keratin, DNA or enzymes required for various metabolic processes. Some common genodermatoses, namely neurofibromatosis, tuberous sclerosis, icthyosis, palmoplantar keratoderma, xeroderma pigmentosum shall be outlined in detail.

NEUROFIBROMATOSIS (SYN. VON RECKLINGHAUSEN'S DISEASE)

Epidemiology

It is one of the most commonly encountered genetic disorder which affects both men and women equally. The prevalence is estimated to be 1 case per 3,000.

Aetiopathogenesis

An autosomal dominant disorder with a defect on the long arm of the chromososme 17. Children of one affected parent have a 50% chance of getting the disease. Severity in the affected individuals is variable, some have all the features, while others are only mildly affected.

Clinical Features

Neurofibromas are skin coloured, soft, fleshy, nodules distributed on various areas. Some neurofibromas are subcutaneous lumps (**Figure 1**). Neurofibromas increase in number with age. Plexiform neurofibroma are soft, doughy, subcutaneous swelling having a bag of worm feeling and run along nerves. Presence of multiple, brownish macules (*Café au lait* macules) and tiny specks of brownish macules in the axilla (axillary freckling) constitute some diagnostic features (**Figure 2**). There are multiple bony abnormalities in the form of scoliosis, *spina bifida*. Examination of the eyes shows Lisch nodules which are brownish iris hamartomas (**Figure 3**). Neurofibromatosis (NF-1) has bony abnormalities like scoliosis, *spina bifida*. Phaeochromocytoma, precocious puberty, tumours of the central nervous system (CNS), seizures and mental retardation may be associated. Neurofibromatosis type 2 has bilateral acoustic neuromas of the vestibulocochlear nerve leading to hearing loss. The diagnostic criteria are enlisted in **Table 1**.

Figure 1: Multiple nodules (neurofibromas) on face.

Figure 2: Multiple *café au lait* macules and freckling in neurofibromatosis.

Complications

Pressure effects on nerves, seizures, malignant change in neurofibroma.

Treatment

Single plexiform neurofibromas can be removed with the help of laser or excision. Genetic counselling should be held for the patient.

Figure 3: Iris hamartomas on the surface of iris.

Table 1: Diagnostic Criteria for Neurofibromatosis Based on the Clinical Criteria

1. Two or more neurofibromas on the skin or under the skin or one plexiform neurofibroma
2. Freckling of the groin or the axilla
3. *Café au lait* spots. Six or more measuring 5 mm in greatest diameter in pre-pubertal individuals and over 15 mm in greatest diameter in post-pubertal individuals
4. Skeletal abnormalities, such as sphenoid dysplasia or thinning of the cortex of the long bones of the body
5. Lisch nodules (iris hamartomas, freckling in the iris)
6. Tumours on the optic nerve also known as an optic glioma
7. A first-degree relative with a diagnosis of neurofibromatosis-1

TUBEROUS SCLEROSIS (SYN. BOURNEVILLES DISEASE)

Definition

Tuberous sclerosis is a genetic disorder with an autosomal dominant pattern of inheritance, and variable penetrance. Two-thirds of tuberous sclerosis (TSC) cases result from sporadic genetic mutations. Hence, there may not always be presence of an affected member in the family.

Epidemiology

Tuberous sclerosis occurs in all races, genders and ethnic groups. The prevalence is estimated to be between 10 to 13 cases per 100,000.

Clinical Features

The physical manifestations of tuberous sclerosis are due to formation of hamartomas. Hamartomas are present in the brain (in the form of cortical tubers). Characteristic cutaneous findings appear as multiple, brown, soft, grouped papules present in the perinasal area and cheeks in a butterfly distribution (**Figure 4**). These are called facial angiofibromas (misnamed as adenoma sebaceum). Their number increases with age. Subependymal nodules in the brain are diagnostic. Patient often presents with seizures at an early age, developmental delay and behavioural problems. About 50% of patients with tuberous sclerosis (TSC) have learning difficulties. Between 60 and 80% of the patients have tumours (angiomyolipomas) in kidneys, lung cysts, and cardiac rhabdomyomas. Ungual or subungual fibromas, (known as Koenen's tumours) are small fleshy tumours that grow around and under the toenails or fingernails and may need to be surgically removed if they enlarge or cause bleeding. Hypomelanotic macules ('ash leaf spots') are white- or light-coloured patches on skin that may appear anywhere on the body. These are usually the only visible sign of tuberous sclerosis at birth. Shagreen patches are areas of thick leathery skin which is dimpled like an orange peel and is usually found on the lower back or nape of the neck (**Figure 5**). *Café au lait* macules can be seen.

Figure 4: Multiple, brown small, grouped, fleshy papules around nose (angiofibromas) in tuberous sclerosis.

Figure 5: Shagreen patch and ash leaf macules on the back in tuberous sclerosis.

Approach to the Diagnosis of Tuberous Sclerosis

1. Taking a personal and family history
2. Examining the skin under Wood's lamp
3. Cranial imaging with non-enhanced CT or preferably MRI (for cortical tubers and subependymal nodules)
4. Renal ultrasound (angiomyolipoma or cysts)
5. An echocardiogram in infants (rhabdomyoma)
6. Fundoscopy (retinal nodular hamartomas or achromic patch).

Management

Management is symptomatic. Seizures require anti-epileptic drugs. Mental retardation should be managed in the developmental clinics. Facial angiofibromas can be removed with the help of electrosurgery or lasers.

Prognosis

The prognosis for individuals with tuberous sclerosis depends on the severity of symptoms. Leading causes of death include renal disease, brain tumour, lung cysts and status epilepticus.

ICTHYOSIS

Definition

The ichthyosiform dermatoses are a diverse group of hereditary skin disorders characterised by the accumulation of 'fish-like' scales resulting from abnormal epidermal cell kinetics. Severity of individual types ranges from mild to life-threatening icthyosis. Based on the mode of inheritance icthyosis can be autosomal dominant which includes: Icthyosis vulgaris, X-linked icthyosis (seen in boys only) and autosomal recessive icthyosis which includes the lamellar icthyosis and icthyosiform erythroderma. Recessive forms of icthyosis tend to be more severe than the dominant types.

Epidemiology

Icthyosis vulgaris is the most common type of icthyosis affecting around 1 in 250 people. Non-bullous icthyosiform erythroderma, bullous icthyosis and lamellar icthyosis are more severe forms but are uncommon.

Aetiopathogenesis

Icthyosis arise as a result of mutation in the gene regulating the keratin synthesis.

Clinical Features

All icthyosiform dermatoses present with dry, scaly skin which shows fish-like or plate-like scales in variable pattern of distribution. Icthyosis vulgaris begins in the first year of life and shows dry, scaly skin over the extensor aspects of the arms and legs. The scales are larger over the lower extremities and presence of mild keratoderma or (thickening of the skin over the palms and soles) is noted. The dryness becomes worse during winters and improves in summers and humid weather. Some patients also bear a tendency to develop atopic dermatitis.

X-linked icthyosis affects boys only. The scales are dirty brown in colour and affect both the extensor and flexural surfaces of the extremities with prominent involvement of the neck and trunk (**Figure 6**). Severe icthyosis exhibit widespread scaling, scales are more diffuse and distributed over both the extensor and flexures of the body. Scales are larger and plate-like (**Figure 7**). Associated features, such as thickening of skin of palms and soles, nail changes, eye abnormalities like ectropion, reduced sweating and redness of skin are some of the other associated features.

Figure 6: X-linked icthyosis showing dirty dark brown, big fish like scales on extremities.

Figure 7: Large, dark scale in lamellar icthyosis.

Differential Diagnosis

Drug induced icthyosis, icthyosis secondary to lymphomas.

Diagnosis

Distribution of scales, colour and severity of scaling offer important clues to the diagnosis. A family history is very useful. In some cases, a skin biopsy is done to help confirm the diagnosis. In some cases, genetic testing and prenatal testing may be helpful in making the diagnosis.

Treatment

Treatment for icthyosis includes application of creams and emollients in the form of petroleum jelly and vegetable oils for hydrating the skin. Oral retinoids are used for severe icthyosis. Exposure to sunlight may improve or worsen the condition. Systemic complications need symptomatic and supportive treatment.

Prognosis

Autosomal dominant icthyosis improves with age and the severity lessens with time. Weather also affects the severity and icthyosis improves in summers.

XERODERMA PIGMENTOSUM

Definition

Xeroderma pigmentosum or XP, is an autosomal recessive disorder of DNA repair.

Epidemiology

It is a very rare disorder. Affects both men and women. Parents already with a child with XP have a 1 in 4 chance of having another child with XP.

Pathogenesis

There is a genetic defect in the repair of DNA damaged by UV light. The most common defect in XP is an autosomal recessive genetic defect in which nucleotide excision repair (NER) enzymes are mutated. Patients with XP are at a higher risk of developing skin cancers such as the basal cell carcinoma.

Clinical Features

Disease presents early in life in the infantile period (around 3 to 6 months) with the history that the child cries on exposure to

the light. Skin turns erythematous on exposure to sun and there may be photophobia. Development of freckles and lentiginosis on the exposed area of the body, such as the extensor aspect of arms, face and the neck are early signs. With the passage of time actinic keratoses, seborrhoeic keratosis, keratitis, corneal ulcers and pre-malignant lesion appear on the skin and the conjunctiva (**Figure 8**). The skin appears dry and pigmented. Later by adulthood squamous cell carcinoma, basal cell carcinoma, and malignant melanoma may form, and constitute the common causes of death.

Figure 8: Multiple actinic keratoses, lentiginosis and conjunctival erythema in xeroderma pigmentosum.

Diagnosis

Diagnosis is based on the recognition of symptoms and skin signs of photosensitivity, dry, pigmented skin with multiple freckles, lentiginosis, pre-malignant and malignant skin lesions. There may be presence of affected members in the family. Identification of the severity of the enzyme defect is based upon demonstration of defective excision repair of DNA bases on exposure to the ultraviolet light.

Management

Patients should be counselled strictly to avoid sun light by wearing hats, goggles and full sleeved garments. Potent, broad spectrum sun screens should be advised. Oral retinoids have been used as chemopreventive agents against the development of skin cancers. Patients should be examined regulary in the clinic and any suspicious, noduloulcerative lesion should be biopsied to exclude the possibility of malignant transformation.

Prognosis

Prognosis is poor in severe cases. Early preventive measures in the form of strict avoidance of sun exposure might delay the development of skin cancers.

EPIDERMOLYSIS BULLOSA

Definition

It is a mechanobullous disorder which is caused by an inherited defect in the keratin formation and is characterised by the presence of multiple blisters and erosions over the trauma prone areas of the body.

Epidemiology

It occurs in a frequency of 1 in 50,000. Epidermolysis bullosa is more common in communities where consanguineous marriages are common. It is common in South India.

Clinical Features

Epidermolysis bullosa presents at or soon after birth. Depending on the keratin defect and the depth of bulla formation there can be divided into three types: (i) E. bullosa (simplex), (ii) junctional; and (iii) dermal or dystropic variant. Simplex varieties are more common, milder and show improvement in the severity of blistering with time. Junctional and the dystrophic variants are more severe and show mucosal blisters, erosions and deformities in the form of contractures. The disease is characterised by the formation of blisters on gentle rubbing or on minimal skin trauma especially over the trauma prone sites such as the buttocks, elbows, hand, feet, arms and legs (**Figure 9**). The blisters rupture to form erosions and crusted lesions which may be slow to heal and get infected. Severe variants with mucosal blistering interfere with feeding. There may be blisters in the pharynx, larynx, eyes and the genital mucosa. There may be contractures and mitten like deformities of hands in the severe variants (**Figure 10**). Pyloric stenosis and development of squamous cell carcinoma are some of the other associated complications.

Diagnosis

Diagnosis is made on the basis of presence of early, spontaneous blistering of skin on trauma prone sites and a positive family history. Confirmation of the diagnosis is by performing electron microscopy on skin biopsy obtained from the blister.

Treatment

The disease requires a multi-dimensional, multi-speciality approach. Treatment is symptomatic with care of the eroded skin using potassium permanganate compresses (1:8000)

Figure 9: Leg contracture and mitten like deformities in epidermolysis bullosa.

Figure 10: Erosions on neck, hands in a newborn in epidermolysis bullosa.

dilution and application of topical antibiotics like mupirocin cream to prevent superimposed infections. Prolonged walking and tight foot wear should be avoided to prevent blisters over feet in localised cases. Severe blistering involving the mucosae and skin can be improved by administering systemic steroids or other immunosuppressive agents, such as cyclophosphamide or cyclosporine. Reconstructive surgery is required for deformities.

Prognosis

Epidermolysis bullosa is a lifelong disease which does not have a cure. Epidermolysis bullosa simplex has the best prognosis as the disease tends to improve a little with age. Limb deformities, oesophageal stenosis, malnutrition, squamous cell carcinoma are some of the complications which develop sometime during the course of the disease and the latter may be an important cause of death.

PALMOPLANTAR KERATODERMA

Definition

Palmoplantar keratoderma are a group of heterogenous disorders some of which are inherited defects due to mutations in the enzymes involved in the synthesis of keratin. They can be autosomal dominant or autosomal recessive.

Epidemiology

These are uncommon.

Clinical Features

The onset of keratoderma is usually seen in childhood. Skin over palms and soles becomes hard, thick, dry and hyperkeratotic. There may be fissures and cuts in the skin (**Figures 11 and 12**). Sometime, the keratoderma may show involvement of the dorsum of hand and feet with areas of thickened skin. The condition is usually asymptomatic but it may interfere with daily activities. Severe variants show abnormal teeth and thickening of nails also.

Figure 11: Diffuse thickening of skin over soles with fissures in hereditary palmoplantar keratoderma.

Figure 12: Keratoderma over palms.

Diagnosis

Skin biopsy and presence of familial occurrence of the disease help in differentiating it from other acquired causes such as psoriasis, hyperkeratotic eczema.

Treatment

Liberal application of emollients are advised along with specific agents in the form of high concentrations of salicylic acid (3% to 12%) depending on the severity of thickening. Oral retinoids are also employed for severe cases.

11.13 Skin in Connective Tissue Diseases

Sandipan Dhar

This group of diseases is characterised by inflammation of connective tissues in various parts of the body. These are also labelled as 'Collagen Vascular Diseases'. However, there is little evidence that collagen is primarily involved in causation of these diseases. Most of the entities have multisystem involvement and are characterised by distinct histopathological features and positivity of a number of immunological tests in the blood, known as 'collagen profile'. Various connective tissue diseases with significant cutaneous involvements are shown in **Table 1**.

Table 1: Various Types of Connective Tissue Diseases with Significant Cutaneous Involvement

Lupus erythematosus
Systemic lupus erythematosus
Discoid lupus erythematosus
Subacute lupus erythematosus
Scleroderma
Progressive systemic sclerosis
Morphea or localised scleroderma
Scleredema
Lichen sclerosus *et atrophicus*
Dermatomyositis
Mixed connective tissue disease

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

Lupus erythematosus encompasses a group of disorders characterised by chronic inflammatory vasculopathy involving the skin and almost all the systems of the body. Skin involvement is the most common clinical manifestation after joint inflammation and is found in up to 70% of patients during the course of the disease and about 25% patients present with cutaneous lesions for the first time.

Clinical Features

The most frequent cutaneous manifestations of SLE are malar rash (58%), photosensitivity (45%), discoid rash (10%), livedo reticularis (14%), and subacute cutaneous lesions (6%). The malar rash presents over the butterfly area of the face as an erythematous, mildly scaly patch involving the cheeks and bridge of the nose (**Figure 1**). The lesions are quite photosensitive and continued exposure to ultraviolet light leads to increased synthesis of antinuclear antibodies (ANAs) in the circulation.

Mucous membrane lesions in the form of gingivitis, mucosal ulceration and haemorrhage are also seen in this form of the disease.

Diagnosis

Serologic tests are quite useful not only in the diagnosis but also in evaluation of the disease severity and its systemic involvement. Various serologic tests carried-out are antinuclear antibody (ANA), deoxyribonucleic acid, dsDNA, antihistone antibody. ANA titre of more than 1:160 is quite suggestive of active SLE. A positive anti-dsDNA is confirmatory of SLE. 'Lupus band test' requires direct immunofluorescence testing of skin biopsy sample from the affected skin, exposed unaffected skin and covered skin.

Figure 1: Systemic lupus erythematosus scaly patch involving the cheeks and bridge of the nose.

Treatment

Oral corticosteroids are the mainstay of treatment. The dose of steroid is decided according to the severity of the disease, i.e. organ system involvement. The usual starting dose is 30 to 40 mg of prednisolone per day. Steroid dosage is then tapered slowly over a period of 3 to 6 months as per activity of the disease. To prevent osteoporosis, oral vitamin D and calcium supplementation are given as a routine to all patients. Various immunosuppressives used as steroid-sparing agents are azathioprine, cyclophosphamide, methotrexate, chlorambucil, etc. Newer agents used for this are mycophenolate mofetil, tumour necrosis factor (TNF) inhibitors, etc. Use of a good sunscreen is mandatory throughout the day in all patients with lupus erythematosus.

Prognosis

The prognosis of SLE has improved drammatically over the past few decades because of availability of systemic corticosteroids and cytotoxic drugs.

DISCOID LUPUS ERYTHEMATOSUS (DLE)

Epidemiology

It is thought to be seven-fold commoner than SLE and is generally seen between 20 to 40 years of age. Females are more commonly affected with a female to male ratio of 3:1.

Clinical Features

The discoid lesions of DLE are characterised by well-circumscribed, erythematosus, indurated plaques with adherent

scales, patulous follicular openings and telangiectasia (**Figure 2**). The lesions, when heal, produce atrophy, scarring, hyperpigmentation and/or depigmentation. The lesions are most commonly found over the face (**Figure 3**), head (**Figure 4**) and neck. However, the involvement of chest, upper arm, back, buttock, thighs, legs are not infrequent. Lips are often affected by DLE and sometimes lichen planus and lupus erythematosus may coexist over lips, mostly lower lip and known as LE-LP overlap syndrome.

Figure 2: Typical discoid lesion of systemic lupus erythematosus on back of patient.

Figure 3: Discoid lupus erythematosus lesion on the face.

Figure 4: Discoid lupus erythematosus lesion on the scalp.

Diagnosis

Diagnosis of DLE is confirmed by histopathological examination of the skin.

Treatment

For few isolated lesions of DLE, topical moderately potent to potent corticosteroids are used for a period of 3 to 6 weeks. For disseminated lesions, oral chloroquine or hydroxychloroquine is given for a period of 3 to 6 months depending upon the response. Prior eye examination and cardiac check-up including electrocardiogram (ECG) are to be carried out in each patient. Other drugs used with variable success are dapsone and clofazimine. When present over photoexposed areas, regular use of a sunscreen lotion is a must.

Prognosis

Up to 25% to 40% of DLE patients remit spontaneously; 20% with generalised DLE and 5% with localised DLE go onto develop SLE.

SUBACUTE LUPUS ERYTHEMATOSUS

Subacute lupus erythematosus presents as annular/polycyclic lesions or psoriasiform lesions mostly over the trunk and upper extremities.

SCLERODERMA

Scleroderma is a chronic disease of unknown aetiology that affects the microvasculature and loose connective tissues and is characterised by fibrosis of the skin and internal organs. Various diseases of importance under this heading are progressive systemic sclerosis, localised scleroderma/morphea and scleroderma.

Progressive Systemic Sclerosis (PSS)

It is a generalised disease of the skin, lungs, heart, gastrointestinal tract, joints and kidneys. The diagnosis of PSS is made on the basis of some criteria as shown in **Table 2**.

Table 2: Diagnostic Criteria for Progressive Systemic Sclerosis

Major Criteria
Sclerodermatous alterations
Raynaud's phenomenon
Minor Criteria
Capillary microscopy changes
Vascular changes
Gastrointestinal involvement
Renal involvement
Cardiac involvement
Muscle involvement
Joint/tendon involvement
Serology

Clinical Features

The skin changes are characterised by diffuse and progressive induration and hardening of the skin. Often the process starts over the face and acral areas (acrosclerosis). The face looks hide-bound and expressionless with pinched nose, pursed mouth and mat-like telangiectasiae (**Figure 5**). Often there are pigmentary changes over the face and neck in the form of hyperpigmentation and depigmentation (pepper-salt pigmentation) (**Figure 6**). Changes over the fingers show

Figure 5: Typical facies in progressive systemic sclerosis.

Figure 6: Pepper-salt pigmentation in progressive systemic sclerosis.

Figure 7: Sclerodactyly and pitted scars on fingertips.

sclerodactyly or sausage shaped fingers with taut skin over the fingers and thimble pitted scars over fingertips (**Figure 7**). Raynaud's phenomenon is almost a constant feature in cases of PSS. On exposure to cold, patients complain of pain, burning, pallor, cyanosis, tingling and hyperhidrosis. It commonly affects fingers and toes. At the early stage of the disease, patients often complain of arthralgia and limited joint mobility. Patients often complain of weight loss, fatigue, reflux and dyspepsia, muscle weakness and dyspnoea. Pulmonary involvement is a major

Figure 8: Sclerodactyly and telangiectasia.

cause of mortality and more than 50% of the patients with PSS show restrictive lung changes. A variant of scleroderma is known as CREST syndrome which is an acronym for calcinosis, Raynaud's phenomenon, oesophageal hypomotility, sclerodactyly and telangiectasia (**Figure 8**).

Diagnosis

Histopathological examination of the skin and detection of anti scl-70 (anti DNA topoisomerase) and anti-centromere antibodies are most important and useful tests.

Treatment

Treatment of PSS entails a host of systemic care. General measures include avoidance of factors leading to vasospasm (tension, fatigue, stress, cold weather, smoking) and minimising trauma to the hands. For Raynaud's phenomenon, nifedipine or pentoxphylline is used. For arthritis, nonsteroidal, anti-inflammatory drugs (NSAIDs) are used and omeprazole/pantoprazole is used for reflux oesophagitis. In the early oedematous stage of the disease, oral corticosteroids are useful. Prednisolone is given in a dose of 30 to 40 mg/day for 2 to 3 weeks followed by definitive therapy of the disease. D-penicillamine has been found to be useful in some patients. Methotrexate and cyclosporine have also been used with variable success for long-term control of the disease.

Prognosis

The prognosis of PSS is variable and depends on the involvement of organ system(s) and rate of progression of the disease. The cause of death is usually cardiac or respiratory failure. It usually follows a relatively benign course and in such cases anti-centromere antibody is positive.

Pregnancy and Systemic Sclerosis

Systemic sclerosis is considered to be a high risk factor for pregnancy because of higher chances of miscarriage, premature birth and other complications.

MORPHOEA (LOCALISED SCLERODERMA)

Morphoea is a localised type of scleroderma characterised by localised induration and hyperpigmentation of skin.

Clinical Features

It can be subdivided into five types, e.g. plaque, generalised, linear, guttate and deep, according to clinical presentation and depth of tissue involvement. In case of 'guttate morphea', the lesions

are 1 to 3 mm sized indurated papules. In 'linear scleroderma' there may be involvement of the face and/or forehead manifesting as Parry-Romberg syndrome and *'en coup de sabre'*. Linear scleroderma involving frontal and frontoparietal regions of the scalp is called *'en coup de sabre'*. It presents as a depressed sclerotic groove over the frontal/frontoparietal region of the scalp, usually unilateral. The groove may extend downwards to involve cheek, nose, upper lip, and at times mouth, gum, chin or neck. Rarely, the localised scleroderma may involve the subcutaneous tissue, muscle and bone and is known as 'disabling pansclerotic morphea'. Sometimes, the morphea lesions may have overlying lichen sclerosus *et atrophicus* (LSA) lesions.

Plaque-type morphea presents as one or few hyperpigmented indurated papules of 0.5 to 15 cm diameter. The areas usually affected are back, buttock, abdomen, thigh and rarely the face (**Figure 9**). The lesions resolve with hyperpigmentation and sometimes atrophy (**Figure 10**).

Diagnosis

Skin biopsy helps in diagnosis of morphea and localised scleroderma of all types. ANA positivity occurs in approximately 25% to 65% of cases with linear scleroderma and generalised morphea. Rheumatoid factors are positive in 25% to 40% cases and eosinophilia is seen in a good number of cases. Recently, anti-topoisomerase II antibodies have been detected in 76% of patients with localised scleroderma and in 85% of cases of generalised morphea. These antibodies, in contrast to anti-topoisomearse I/scl-70 antibodies have been found in 14% of the patients with systemic scleroderma.

Treatment

Treatment of morphea and linear scleroderma is not very rewarding. Topical and intralesional corticosteroids help in resolution of the lesions. Topical calciprotriol has been shown to help resolution of the lesions particularly when used under occlusion and at early stage of the disease. For generalised morphea and linear scleroderma, oral corticosteroids are given initially for 2 to 3 weeks followed by methotrexate for a period of 3 to 6 months which may help resolution of the lesions. Other therapeutic options are oral calcitriol, cyclosporine and D-penicillamine. These treatment modalities are, however, chosen for very selective patients. Physiotherapy and corrective surgeries are adjunctive treatment modalities.

Figure 9: Plaque-type hyperpigmented lesions on back.

Figure 10: Plaque-type hyperpigmented lesions on the back.

Prognosis

Plaque type of morphoea tends to improve within 3 to 5 years. However, the residual hyperpigmentation and hypo-pigmentation and occasional atrophy may persist for long periods of time. Lesions of linear scleroderma also tend to improve with time. However, the residual atrophy and pigmentary changes may remain for indefinite period of time.

SCLEREDEMA

Scleredema is a rare disorder that manifest as large area of induration of skin and subcutaneous tissue that must be distinguished for more commonly occurring scleroderma. The condition most commonly occurs in adult diabetics (scleredema *adultorum of Buschke*). However, children often suffer from this disorder usually after an episode of streptococcal upper respiratory tract infection. The skin changes often start over the neck and spread in a cephalocaudal direction to involve the upper trunk and occasionally the face and arms. It manifests as slow and insidious onset of non-pitting oedema and induration. Usually, the patients are asymptomatic, but in some patients a prodrome of fever and malaise may precede the skin changes by 2 to 4 weeks. The condition is by and large benign, but involvement of skeletal and cardiac muscles have been reported. The pathogenesis of scleredema is unknown. The condition usually resolves spontaneously over a variable period of a few months to 2 years or so.

LICHEN SCLEROSUS ET ATROPHICUS

Lichen sclerosus *et atrophicus* (LSA) is a disease of unknown aetiology which is mostly seen in females, although, males are also affected.

Clinical Features

The disease is characterised by sharply defined small pink to ivory coloured papules which coalesce to form plaques of variable sizes (**Figure 11**). As the lesions progress, follicular plugging and atrophy becomes more prominent (**Figure 12**). The lesions are asymptomatic and can develop on any part of the body. Lesions often tend to develop over the sites of trauma, irritation and surgical scars (Koebner's phenomenon).

Figure 11: Lichen sclerosus *et atrophicus* showing plaques of variable sizes.

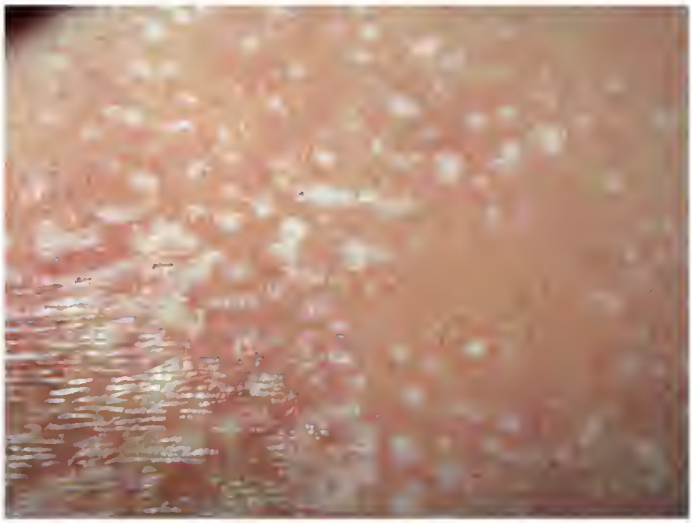

Figure 12: Lichen sclerosus *et atrophicus* showing follicular plugging and atrophy.

The lesions of LSA may top the lesions of plaque-type of morphea. Lesions often develop over the genital areas both in females and males. In females, the lesions of LSA lead to the development of kraurosis vulvae. Here the lesions are distributed over the genital and perianal area in an hourglass configuration or figure of eight pattern (**Figure 13**). The lesions are symptomatic and produce pruritus, burning sensation and bleeding from vulvar and perianal area on urination and defaecation. There may be vaginal discharge, purpuric lesions, blistering and excoriation over labia minora and clitoris. In males, the lesions are known as 'balanitis xerotica obliterans' (BXO).

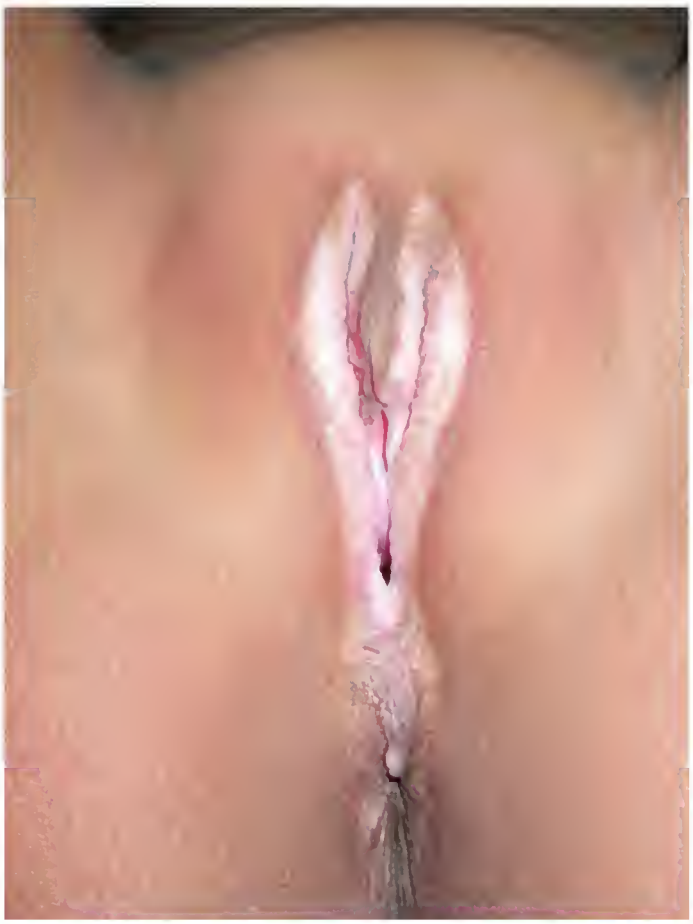

Figure 13: LSA showing lesions over the genital and perianal area.

Diagnosis

Skin biopsy and histopathological examination clinches the diagnosis as the condition has some unique histopathological features.

Treatment

Topical corticosteroids are the treatment of choice. Moderately potent to superpotent topical corticosteroids used for a period of 6 to 8 weeks help to resolve the lesions. Topical tacrolimus (0.1%) and premecrolimus (1%) have recently been found to be quite helpful. Surgical options like circumcision, plastic reconstruction and corrective surgeries may be required along with medical therapy to improve the quality of life of the patients.

Prognosis

Some of the lesions may improve spontaneously, particularly the lesions over the skin. Lesions over the genitalia, however, show little tendency to resolve spontaneously. Instead, ulceration, urethral stricture, anal and vaginal stenosis may occur. In females, carcinoma may develop over longstanding vulvar LSA.

DERMATOMYOSITIS

It is an idiopathic inflammatory myopathy of striated muscles along with the characteristic cutaneous findings, hence it has got both cutaneous and muscular components. Disease has got racial predilection. Females are affected twice as commonly as males. Though it can occur at any age but two peaks are seen, one between 5 to 10 years and another is 50 years of age.

Aetiopathogenesis

The exact cause of dermatomyositis is unknown, but certain factors have been implicated like genetic factor linked to human leucocyte antigen (HLA) DR3, DR5, DR7. Infectious agents like coxsackievirus, parvovirus, echovirus, HTLV-1, human immunodeficiency virus (HIV), toxoplasma and borrelia can be a trigger factor. Various drugs like hydroxyurea, penicillamine, statins, quinidine and phenylbutazone, etc. can cause dermatomyositis.

Clinical Features

Various types of dermatomyositis are enumerated in **Table 3**.

Table 3: Various Clinical Types of Dermatomyositis

Dermatomyositis
Polymyositis
Dermatomyositis associated with malignancy
Dermatomyositis associated with connective tissue disorders
Juvenile dermatomyositis

The pathognomonic cutaneous features are heliotrope rash (periorbital confluent macular mauve or violaceous erythema) and Gottron's papules (papules having violaceous hue overlying the dorsolateral aspect of interphalangeal or metacorpophalangeal joints). Other cutaneous features are malar erythema, poikiloderma (variegated telangiectasia along with atrophy and hyperpigmentation) (**Figure 14**), periungual and cuticular changes (cuticular hypertrophy with haemorrhagic infarcts) and mechanics hands (fingertip erythema and scaling). Calcinosis cutis are also seen, which are firm yellow or flesh coloured nodules extruding calcium through the skin though seen only in 4% of children and adolescents (**Figure 15**).

Figure 14: Dermatomyositis on the face of a child.

Muscle findings are proximal muscles weakness like difficulty in rising from chair or bed, climbing the stairs, combing hair, difficulty in swallowing; but walking may be normal as distal muscles are unaffected. Systemic features which include joint swelling associated with pulmonary and gastrointestinal involvement make the prognosis worse. It should be differentiated from lupus erythematosus, MCTD, steroid myopathy, cutaneous vasculitis, etc.

Diagnosis

Diagnosis is basically clinical and can be made from the skin changes. Muscle enzymes are abnormal during the course of dermatomyositis except in the amyotrophic variety. Most sensitive enzyme is CPK (creatine phosphokinase). Apart from this, aldolase, AST, LDH, may also be abnormal. Magnetic resonance imaging (MRI) is a useful tool as it not only shows the presence of inflammatory myopathy but also helps to differentiate it from steroid myopathy. It can also serve as a guide in selecting the muscle biopsy site.

Figure 15: Calcinosis cutis showing extruding calcium.

Treatment

It includes general measures, treatment of involved skin, affected muscles, and treatment of complications. General measures include bed rest for severe muscle inflammation, programmed physical therapy to avoid contractures and joint complications. Goal of pharmacotherapy is to reduce morbidity and to prevent complications. Mainstay of the treatment are systemic corticosteroids. It has been observed that most patients develop corticosteroid-induced myopathy. Therefore, it is prudent to use immunosuppressive agents like methotrexate, azathioprine and cytotoxic agents (mycophenolate mofetil) as steroid sparing agents. Apart from these, intravenous immunoglobulin for at least 6 months has proved beneficial. Rituximab is another effective option.

Therapy for cutaneous lesions is difficult. Education, avoidance of sun and broad-spectrum sunscreens are helpful in photosensitive patients. For the treatment of calcinosis cutis, calcium channel blockers (diltiazem) shows gradual resolution.

Prognosis

The disease may spontaneously remit in the juvenile variety of cases, but relapses can be seen. Prognosis also depends upon the degree of systemic involvement. In adults, it is mandatory to search for underlying malignancy, successful treatment of which can reduce the mortality to a greater extent. Majority of the patients survive but may develop residual weakness and disability.

11.14 Skin in Systemic Diseases

Uday Khopkar

Skin is a mirror of health and disease and reflects almost all systemic disturbances. The skin is available for examination to any physician who cares to pay attention to it.

CUTANEOUS SYMPTOMS AND SIGNS OF INTERNAL DISEASES

Pruritus

Pruritus (itching) in the absence of skin lesions can be a symptom of internal disease and may even be a presenting manifestation of it. Patients with infective hepatitis or evolving renal disease may occasionally present with generalised pruritus without any skin rash. Generalised dry itchy skin may be a feature of Hodgkin's lymphoma. Pruritus in a case of polycythaemia gets worse after bath.

Exanthem and Enanthem

Skin rashes (exanthem) and mucosal rashes (enanthem) are well recognised since ages as signs of systemic viral and occasionally bacterial infections. Chickenpox, smallpox, measles, rubella, hand, foot and mouth disease have characteristic morphology and distribution of their rashes. The confluent rash of dengue fever gives an appearance of 'islands of normal skin in a sea of red'; is late to appear in the course of disease and may be missed due to its asymptomatic nature.

Purpura

Thrombocytopaenia and disorders of coagulation result in non-inflammatory purpura (petechiae, purpura, ecchymosis, haematoma), damage to blood vessels in small vessel vasculitis results in inflammatory purpura (palpable purpura). Palpable purpura is seen as red oedematous papules, which fail to blanch on diascopy.

Ischaemic Necrosis and Ulcers

Cutaneous infarcts may occur due to vascular occlusion resulting from a variety of internal diseases like diabetes, atherosclerosis, Berger's disease, vasculitis, collagen vascular diseases, disseminated intravascular coagulation, coumarin necrosis, antiphospholipid antibody syndrome or calciphylaxis. Cutaneous ulcers may be a manifestation of diverse conditions like sickle cell disease or ulcerative colitis, Crohn's disease or even septicaemia or fungaemia. While taking care of the immediate consequences of such lesions, it is important to detect and correct the underlying cause.

Skin Nodules

Nodules on the skin may occur due to plethora of internal causes like erythema nodosum, erythema nodosum-leprosum, panniculitis, metastasis of internal malignancy, lymphomas, sarcoidosis or systemic infections like cryptococcosis, penicilliosis, histoplasmosis, leishmaniasis, bacillary angiomatosis or cysticercosis.

Papular Lesions

Systemic infections like cryptococcosis, miliary tuberculosis, neoplastic conditions like leukaemia and histiocytosis X may present with papular lesions. Tuberculids like papulonecrotic-tuberculid and lichen scrofulosorum present as papular rashes due to hypersensitivity to tubercular antigen.

SYSTEMIC DISEASES AND THEIR SKIN MANIFESTATIONS

For the purpose of this discussion, internal diseases that manifest onto the skin may be grouped into: HIV infections; internal malignancies; multisystem diseases; individual organ diseases; specific skin signs of diseases affecting individual organs; and non-specific signs of organ failure (**Table 1**).

Human Immunodeficiency Virus (HIV) Infection

With a very high prevalence of HIV infection in India, familiarity with cutaneous manifestations of HIV infection has become a necessity for all physicians.

Since HIV infection is sexually transmitted in most instances, other sexually transmitted infections like herpes simplex, condyloma-acuminata, syphilis and chancroid tend to occur more frequently in the HIV-infected. These infections are also more severe in terms of extent, morphology, speed of progression, time to healing and complications. Details of various cutaneous manifestations are covered in the chapter on 'Sexually Transmitted Infections and HIV'.

Skin in Multisystemic Diseases

Several multisystem diseases involve the skin in a variety of ways. Frequently many of these manifestations are subtle or asymptomatic and are therefore not complained of by the patient. Seeking these actively will certainly add an edge to the clinical acumen of a physician. Lupus erythematosus in its localised form (discoid lupus erythematosus, **Figure 1**) and systemic form [systemic lupus erythematosus (SLE), **Figures 2 to 4**], systemic sclerosis (**Figures 5 and 6**), dermatomyositis (**Figures 7 and 8**) and sarcoidosis (**Figure 9**) are some of the prominent diseases in this category of multisystem diseases.

Cutaneous Markers of Internal Malignancies

Apart from cutaneous metastases and their side-effects like lymphoedema, internal malignancy may manifest onto the skin through the immune suppression (candidiasis) or malnourishment (dry skin) associated with advanced malignancies. Besides, internal neoplasms in genetic diseases may be associated with skin signs.

It is common for lymphoproliferative diseases like lymphomas and leukaemias to manifest onto the skin at some stage of the disease. Moreover, several skin signs presage development of internal malignancies. Some of these may result from the effects of hormones secreted by the tumour while still others occur through hitherto undiscovered mechanisms (paraneoplastic dermatoses). Some of the skin manifestations of internal malignancies are tabulated in **Table 2**.

Table 1: Examples of Skin Manifestations of Systemic Infections

Bacterial infections	
Bacterial endocarditis	Palmar erythema and nodules
Anthrax	Malignant pustule over face
Tuberculosis	
Miliary tuberculosis	Brown-red papules
Scrofuloderma	Nodules and sinuses overlying involved organs
Tuberculids	Demonstrable tuberculous focus, no acid fast bacili (AFB) in skin lesions, strong Mantoux test and tuberculoid granuloma on biopsy
Erythema induratum	Tender nodules and ulcers over calves of young ladies
Papulonecrotic tuberculid	Papulopustular lesions healing with scarring
Lichen scrofulosorum	Grouped follicular micropapules
Erythema nodosum	Tender, erythematous nodules and plaques over shins
Septicaemia	
Septic vasculitis	Palpable purpura, haemorrhagic vesicles, skin infarcts
Disseminated intravascular coagulation	Skin infarcts and gangrene of digits
Purpura fulminans	Large skin infarcts lead to deep punched out ulcers
Meningococcaemia	Palpable purpura, haemorrhagic vesicles over limbs
Pseudomonas septicaemia	Necrotic ulcers with yellow-green discharge (ecthyma gangrenosum)
Viral infections	
Viraemia due to many viruses	Maculopapular or papulovesicular exanthem and enanthem
Hepatitis B	Cutaneous vasculitis
Spirochetal infections	
Secondary syphilis	Symmetric non-pruritic scaly rash
Leptospirosis	Rash over shins
Borreliosis	Erythema chronicum migrans expanding rings over limbs
Fungaemia	
Cryptococcosis	Papules, nodules and ulcers over face and limbs
Histoplasmosis	Nodules and ulcers over mucosae and mucocutaneous junctions
Parasitic infestations	
Post-kala-azar dermal leishmaniasis	Generalised symmetric hypopigmented macules, nodules and diffuse erythema of face
Cysticercosis	Asymptomatic subcutaneous nodules over trunk

Figure 1: Disseminated discoid lupus erythematosus. Erythematous dyspigmented plaques.

Figure 2: Discoid lupus erythematosus. Extensive confluent discoid lesions.

Figure 3: Systemic lupus erythematosus. Malar rash with erythema and oedema over lips and upper chest.

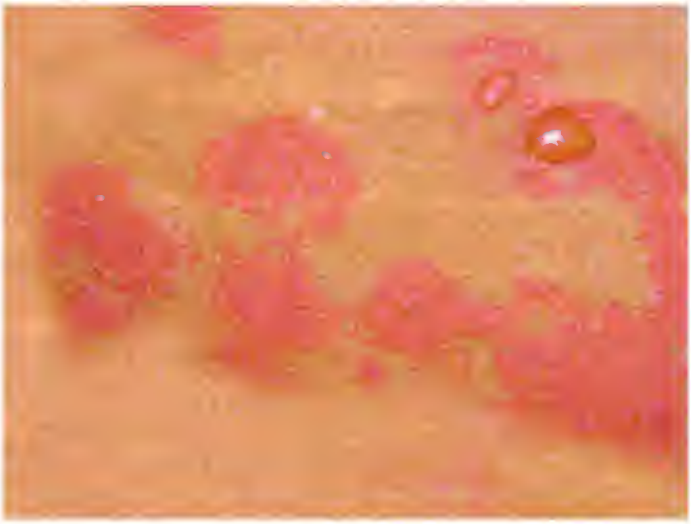

Figure 4: Bullous lupus erythematosus. Vesiculobullous lesions on erythematous base.

Figure 7: Dermatomyositis. Diffuse violaceous erythema of face with affection of upper eyelid.

Figure 5: Systemic sclerosis. Re-pigmenting vitiligo like patches over hidebound skin.

Figure 8: Gottron's papules. Erythematous lichenoid papules in dermatomyositis.

Figure 6: Systemic sclerosis. Acrosclerosis with scarring and resorption of tips of digits.

Figure 9: Sarcoidosis. Reddish brown shiny plaque.

Table 2: Skin Changes Associated with Internal Malignancies

Direct effects of malignant neoplasms	
Carcinomas	Cutaneous metastases
Haematological malignancies	Specific skin infiltrates
Visceral malignancy	Infiltration or ulceration of contiguous skin
Effects of infiltration	Sclerosis, lymphoedema, lymphangiectasia
Effects of debility	Candidiasis, herpes zoster, dry, lusterless skin and hair, hyperpigmentation, xerosis
Genodermatoses with associated internal malignancy	
Gardner's syndrome	Cutaneous lipoma and osteomas are pointers of colonic polyposis and malignancy in future
Neurofibromatosis	Phaeochromocytoma, gliomas, haematological malignancies
Peutz-Jeghers syndrome	Lentigines on lips associated colonic polyps with predisposition for malignancy
Paraneoplastic signs of internal malignancy	
Acanthosis nigricans	Brown-back velvety plaques over neck and flexures
Acute febrile neutrophilic dermatosis (Sweet's syndrome)	Tender, red plaques over limbs and face in a middle-aged lady
Acquired ichthyosis	Dry fish-like skin most commonly in Hodgkin's lymphoma
Clubbing	Severe grades of clubbing with lung carcinoma
Dermatomyositis	Up to 10% cases have associated with internal malignancy
Erythema gyratum repens	Concentric rings of erythema and scaling over trunk
Hypertrophic osteoarthropathy	Subperiosteal new bone formation
Migratory thrombophlebitis	Highly malignant lesion with metastases
Myeloma-associated amyloidosis	Skin nodules and purpura
States associated with endocrine neoplasms	
Addisonian pigmentation	Adrenal corticotropin hormone (ACTH) secreting neoplasms
Hirsutism	Coarse hair in females in male distribution
Androgenetic alopaecia in females	Virilising tumours
Necrolytic migratory erythema	Expanding rings of erythema and vesiculation with glucagonoma
Carcinoid tumours	Flushing of face and upper trunk

Skin in Diseases Affecting Individual Systems or Organs

The skin is involved in this group of diseases in two ways. The more common skin manifestations are those that are caused due to individual organ failure and are therefore not part of a specific aetiopathologic entity. Hence, the dryness of skin seen in renal failure is not specific for any of the causes of renal failure and is therefore not helpful to reach an aetiopathologic diagnosis. On the other hand, cutaneous inflammatory lesions in a case of Crohn's disease are specific for the condition and are helpful to reach the diagnosis.

Endocrine Disorders

With the probable exception of keratinocytes almost every component of the skin is influenced by the endocrine system. Hence, careful examination of the skin is an integral part of the workup in endocrinology. Hyper- or hypofunction of individual endocrine gland is accompanied by several skin alterations that provide clues to the diagnosis. Some of these are enumerated in **Table 3**. Additionally common autoimmune skin diseases like vitiligo, alopaecia areata or lichen planus may occur together with autoimmune endocrine disorders.

Acanthosis nigricans

This important marker of endocrine disease is characterised by symmetrical velvety hyperpigmented plaques in neck and flexures (**Figure 10**). Acanthosis nigricans has been classified into the five following types: hereditary, pseudoacanthosis nigricans, benign, drug-induced and malignant. The last two types are rare. The hereditary benign type is dominantly transmitted, presents during childhood and is not associated with any internal malignancy or endocrine disorder.

Acanthosis nigricans is most commonly seen in obese persons who may have subclinical insulin resistance. The skin changes are reversible on weight reduction. The benign type occurs in association with various endocrine disorders or syndromes. They include acromegaly, Cushing's disease, hypothyroidism, insulin-resistant diabetes mellitus, Addison's disease, Stein-Leventhal syndrome, etc. The triad of hyperandrogenism, insulin-resistance and acanthosis nigricans in women is known as HAIR-AN syndrome. Correction of endocrine abnormalities may slowly revers the skin changes.

Cardiocutaneous Diseases

Although it is not common for heart diseases to be associated with skin lesions several multisystem diseases frequently manifest with cardiac and cutaneous findings. These include SLE, rheumatic fever, dermatomyositis, systemic sclerosis, rheumatoid arthritis, behçet's disease, periarteritis nodosa, Reiter's disease and sarcoidosis. Bacterial endocarditis may present with splinter haemorrhages in the nails or palmar erythema or nodules. In addition, several specific cardiocutaneous associations have been identified. These are listed in **Table 4**.

Skin Changes in Gastrointestinal Diseases

Several gastrointestinal symptoms or syndromes have specific dermatologic associations (**Table 5**, **Figure 11**). In addition to these, pancreatic and liver diseases frequently manifest themselves onto the skin. Moreover, some common skin diseases are associated with asymptomatic but significant gastrointestinal affection. Prominent amongst them are dermatogenic enteropathy, dermatitis herpetiformis and pyoderma gangrenosum. Dermatogenic enteropathy indicates

Table 3: Endocrine Disorders and the Skin

Pancreas	
Diabetes mellitus	(Please refer to the chapter on Metabolic and Nutritional Disorders of the Skin)
Glucagonoma	Necrolytic migratory erythema (expanding rings of superficial vesicopustules and scaly papules over face, trunk or flexures)
Pancreatitis	Cutaneous haemorrhage, enzymatic panniculitis
Pancreatic carcinoma	Migratory thrombophlebitis
Pituitary	
Acromegaly	Skin is coarse, leathery, oily and dark, hypertrichosis, cutis verticis gyrata and acanthosis nigricans are other features
ACTH secreting tumours	Cutaneous features of Cushing's syndrome and addisonian pigmentation
Hypopituitarism	Lack of axillary and pubic hair, pallor of skin and nipple
Thyroid	
Myxoedema	Skin of the face and acral areas is thick and boggy (non-pitting oedema)
Hypothyroidism	Skin is dry, cool and pale yellow (due to carotenaemia), hairs are dull, coarse and brittle, loss of lateral third of eyebrows, nails are thin, striated and brittle
Graves' disease	Pretibial myxoedema (waxy papules or plaques with 'peau de orange' look) may affect hands and feet, thyroid acropachy (drumstick clubbing)
Hyperthyroidism	Skin is flushed, moist and smooth, velvety to touch, hair are thin and friable and alopaecia is common, nails are soft, friable or show koilonychia or onycholysis, generalised pruritus
Adrenal cortex	
Cushing's syndrome	Skin is thin, fragile with purpura and striae, redistribution of body fat leads to truncal obesity, moon facies, buffalo hump and thin limbs. Acne, hirsutism and acanthosis nigricans are other features
Addison's disease (primary hypoadrenalism only)	Generalised diffuse brown-black pigmentation of skin and mucosae with accentuation over exposed areas (face, hands, forearms), flexures (axillae, groins), bony prominences (knuckles, knees, elbows), normally pigmented areas (palmar creases, nipples, genitalia, pre-existing melanocytic nevi), frictional areas (e.g. beltline), mucosae (blue black colour esp. over oral mucosa), pigmented bands on nails
Sex hormones excess	
Defeminising and virilising syndromes	Hirsutism and male pattern alopaecia, thick, oily, hyperhidrotic skin with acne and acanthosis nigricans
Deficiency	
Hypogonadism (pituitary)	Features hypopituitarism, juvenile scalp hair pattern in adult males
Hypogonadism	Absence of sparsity of axillary and pubic hair in males or female type body hair distribution in male.

Table 4: Cardiocutaneous Diseases

Heritable diseases	
Progeria (childhood and adulthood)	Atherosclerosis with premature ageing of skin
Neurofibromatosis	Hypertension due to pheochromocytoma with coarctation of aorta
Marfan's syndrome	Striae with valve disease or aneurysm of aorta
Pseudoxanthoma elasticum	Yellowish papules over neck and flexures with hypertension, peripheral vascular disease
Infective diseases	
Bacterial endocarditis	Palmar erythema, septic vasculitis, Osler's nodes, Janeway lesions, subungual splinter haemorrhages
Lyme disease	Myocarditis and erythema chronicum migrans in *Borrelia burgdorferi* infection
Syphilis	Aortic aneurysms, penile scar, gumma
Viral and rickettsial infections	Myocarditis and maculopapular or haemorrhagic rash
Connective tissue disorders	
Systemic lupus erythematosus	"Libman-Sack" endocarditis, pericardial effusion, congenital heart blocks in neonatal lupus erythematosus
Scleroderma	Conduction blocks, cardiomyopathy
Metabolic diseases	
Hyperlipidaemias	Tuberous and planar xanthomas in coronary artery disease due to hypercholesterolaemia
Amyloidosis	Cardiomyopathy and skin infiltration and purpura
Haemochromatosis	Cardiomyopathy with hyperpigmentation
Fabry's disease	Generalised angiokeratomas with hypertension and ischaemic heart disease

malabsorption associated with extensive skin disease like exfoliative dermatitis. The intestinal villi are atrophic and general indicators of malabsorption are present Gluten-sensitive enteropathy occurs in association with dermatitis herpetiformis though this is probably uncommon in Indian patients with dermatitis herpetiformis. Skin ulcers in pyoderma gangrenosum are sometimes associated with inflammatory bowel disease.

Hepatic Diseases and the Skin

Chronic liver disease manifests itself on the skin with many signs. Icterus is associated with yellowish discolouration of skin and pruritus. Spider angiomas occur over the face, neck and upper trunk in hepatic failure. The nails become clubbed and white and the palms show erythema and Dupytren's contracture. The face turns red initially and later dark and the skin becomes thin with telangiectasia (paper-money skin) and purpura. There is gynaecomastia and loss of axillary and pubic hair. Prominent veins around the umbilicus (caput medusae) and over chest are a sign of portal hypertension. Viral hepatitis may act as a trigger for autoimmune phenomena in the skin like leucocytoclastic vasculitis.

Cutaneous Manifestations of Renal Diseases

Renal failure due to any cause leads to dry, pruritic, scaly skin with a tendency to develop purpura or ecchymoses on minor trauma. Besides, the skin is pale yellow due to associated anaemia and

Table 5: Gastrointestinal Diseases and the Skin

Diarrhoea	
Gluten-sensitive enteropathy	Dermatitis herpetiformis
Ulcerative colitis	Pyoderma gangrenosum, aphthae, pyoderma vegetans, pyostomatitis, erythema nodosum
Crohn's disease	Pyoderma gangrenosum, perianal fistule, mucocutaneous granulomas, erythema nodosum
Mastocytosis	Urticaria pigmentosa
Pellagra	Photodermatitis over neck, hands and forearms, glossitis, erythema of other mucosae
Gastrointestinal bleeding	
Henoch-Schönlein purpura	Palpable purpura
Hereditary haemorrhagic telangiectasia (Osler-Weber-Rendu)	Spider-like angiomas of skin and mucosa
Pseudoxanthoma elasticum	Small, soft, yellowish papules over neck and axillae
Gastrointestinal polyposis	
Peutz-Jeghers syndrome	Acral and periorificial lentigines
Gardener's syndrome	Lipomas, sebaceous cysts, osteomas
Gastrointestinal neoplasms	
Glucagonoma	Necrolytic migratory erythema
Pancreatic adenocarcinoma	Migratory thrombophlebitis
Carcinoid syndrome	Flushing of face, upper torso, pseudoscleroderma
Metastatic carcinoma	Umbilical nodule due to metastasis of stomach carcinoma
Malabsorption	Diffuse hyperpigmentation, dry scaly skin, lusterless fragile hair, thin brittle nails, pruritus, acquired ichthyosis
Pancreatitis	Enzymatic panniculitis: purpura over periumbilical region (Cullen's sign) or flanks (Grey Turner's sign). Hyperlipemic xanthomatosis is associated with pancreatitis
Skin lesions in liver cell failure	Icterus, paper-money skin, spider angiomas, palmar erythema, hyperpigmentation, white nails, gynecomastia, loss of axillary and pubic hair, caput medusae if poral hypertension

pitting oedema as well as accumulation of urochrome or carotene pigments. High blood urea levels may reflect onto the skin by deposition of urea crystals on the nose and malar area forming 'uraemic frost'. Other non-specific indicators of renal failure include acquired perforating dermatoses like perforating folliculitis or Kyrle's disease and loss of hair from limbs, all of which result from persistent rubbing and scratching of the skin. Secondary hyperparathyroidism due to renal failure is probably responsible for persistent pruritus in some cases. Calcinosis cutis and pseudoporphyria cutanea tarda are other non-specific signs of renal failure. Half and half nails in chronic renal failure show brown red discolouration of their distal half. Occasionally, skin and kidneys may be affected by the same pathological process. Some of these instances are enlisted in **Table 6**.

Haematological Disorders and the Skin

Many haematologic diseases display skin lesions at some stage of the disease evolution (**Figure 12**). Some of them like those of T-cell lymphoma or systemic mastocytosis are of diagnostic importance whereas others like purpura in leukaemia are not

Figure 10: Acanthosis nigricans. Velvety hyperpigmented plaque.

Figure 11: Peutz-Jeghers syndrome. Lentigines on lips and face.

Table 6: Renocutaneous Diseases

Hereditary diseases	
Fabry's disease	Angiokeratomas, sphingolipid deposits in kidneys
Sickle cell disease	Leg ulcers and pigmentation
Tuberous sclerosis	Shagreen plaque, adenoma sebaceum, ash-leaf macules
Metabolic disorders	
Gout	Cutaneous and subcutaneous yellowish nodules (tophi) that contain urate crystals
Primary and myeloma associated amyloidosis	Papules, nodules, purpura

specific for the disease (**Table 7**). Occasionally, skin diseases may be associated with haematologic disturbances. Amongst these are anaemia induced by persistent exfoliative dermatitis or, leucocytosis seen in generalised pustular psoriasis or Sweet's syndrome.

Respiratory Diseases and the Skin

Most of the multisystem diseases like SLE or sarcoidosis or vasculitides display both skin and respiratory system involvement. Tuberculosis of lungs or other organs may be occasionally associated with skin lesions (**Table 1**). The skin may be directly affected due to tuberculous infection or may show features of hypersensitivity to circulating tuberculous antigens. The latter condition is termed as a tuberculid to distinguish it from actual tuberculous infection.

Skin Lesions in Diseases of Bones and Joints

Most of the multisystem diseases including collagen vascular diseases are associated with arthritis or arthralgias. Besides

Figure 12: Digital gangrene in antiphospholipid antibody syndrome.

those, about 5% psoriatics have arthritis whereas about 5% of patients with arthritis have psoriasis. Type II lepra reaction in lepromatous leprosy may occasionally present with arthritis. Erythema nodosum, hepatitis B, secondary syphilis, Lyme disease and Sweet's syndrome are other instances where skin rashes are accompanied by joint pains.

Keen observation of skin lesions frequently provides a decisive clue to diagnosis of an internal disease. Hence, familiarity with

Table 7: Skin Manifestations of Some Haematologic Disorders

Erythrocyte disorders and haemoglobinopathies	
Iron deficiency anaemia	Koilonychia, atrophic glossitis, alopaecia
Pernicious anaemia	Addisonian hyperpigmentation, vitiligo, glossitis, cheilitis
Haemolytic anaemia	Sickle cell anaemia, thalassaemia—Leg ulcers
Polycythaemia	Pruritus or flushing after bathing, erythermalgia, urticaria
Meth/sulph/carboxy haemoglobinaemia	Violet or brown discolouration of skin, especially face and hands
Porphyrias	Photosensitivity and skin fragility
Leucocyte disorders	
Leukaemia	Chloromas are greenish blue nodules in acute myeloblastic leukaemia. Leukaemia cutis (papules, nodules or plaques) are specific lesions. Non-specific lesions include purpura, Sweet's syndrome, pyoderma gangrenosum, eczematous eruptions or pruritus. Moreover, opportunistic infections like candidiasis, herpes zoster, molluscum contagiosum or cryptococcosis occur
Chediak-Higashi syndrome	Pigment dilution of skin and hair
Platelet disorders	Livedo reticularis, chilblain-like lesions, leg ulcers, gangrene
Consumptive coagulopathy	Skin infarcts, gangrene
Lymphocyte diseases	
Cutaneous T-cell lymphoma (Sézary syndrome)	Scaly, poikilodermic patches or plaques and infiltrated erythematous nodules, ulcers or erythroderma
B-cell lymphoma	Secondary cutaneous infiltrates (nodules or plaques) occur in late stages.
Plasma cell disease	
Multiple myeloma	Skin nodules.
Myeloma-associated systemic amyloidosis	Macroglossia, indurated purpuric, nodules or plaques
Mast cell disease	Mastocytosis sysndrome (diarrhoea, abdominal pain), urticaria pigmentosa (hyperpigmented itchy plaques with positive Darier's sign)
Cryoglobulinaemia	Cold urticaria, Raynaud's phenomenon or skin lesions resembling vasculitis
Antiphospholipid syndrome and macro or hyperglobulinaemia	Raynaud's phenomenon, livedo reticularis, purpura, skin infarcts, gangrene

skin signs of systemic diseases will work as an asset to the clinical acumen of a physician.

Neurocutaneous Disorders

The integumentary system and the nervous system are both derived from the ectoderm. Hence, it is not surprising that many nervous system disorders are associated with skin changes. Some of these neurocutaneous disorders also involve eyes and are called as phacomatosis that include genodermatoses like neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, phacomatosis pigmentovascularis, etc. Skin manifestations are obvious pointers to the correct diagnosis in this group. Other conditions where skin and nervous system may be affected simultaneously include autoimmune disorders and infections (Table 8).

Nutritional Deficiencies

Protein energy malnutrition (PEM)

Children with PEM show numerous skin changes. Kwashiorkor presents with dry, scaly skin (flaky paint dermatosis) that is oedematous and tends to crack with criss-cross fissures (crazy pavement dermatosis). The face is swollen and pale with dry skin. In marasmus, the skin is dry, thin and wrinkled. There is near-absence of subcutaneous fat with lax skin giving a wizened 'old man' look to the face. The hair are thinner and lighter in colour, sometimes with variation in colour of hair along their length (flag sign).

Phrynoderma

The skin of the elbows and knees becomes rough (toad skin) due to follicular keratoses. The conical keratotic papules with central plug are also seen over buttocks, lateral aspects of thighs and arms. Deficiency of vitamin A and essential fatty acids is causative. Night blindness and conjunctival and corneal xerosis may be associated.

Pellagra

Deficiency of niacin leads to pellagra. Most common predisposing factor for pellagra in the Indian setting is alcohol abuse, expecially in the absence of protein supplementation. However, niacin deficiency may also occur in people on a staple diet of maize or jowar. Rarely pellagra like lesions occur due to drugs (INH, ethionamide). Photosensitivity leading to brownish red erythematous patches and sharply circumscribed plaques over sunexposed areas characterise the condition. Forearms and neck are preferentially affected. Sharply outlined brownish plaques around the neck lead to the typical 'Casal's necklace'. Less frequently, bony prominences, flexures and frictional areas get affected. The tongue is smooth and red.

Riboflavin deficiency

Riboflavin causes oral, ocular and cutaneous changes. The oral mucosa is red and the tongue magenta red and smooth. The nose, eyebrows and other seborrheic areas of face show yellowish powdery scales (seborrhoea). Riboflavin deficiency commonly co-exists with pellagra in the setting of alcohol abuse.

Table 8: Neurocutaneous Disorders

Genetic disorders or nevoid anomalies	
Neurofibromatosis	Neurofibromas, Café au lait macules, iris hamartoma, gliomas, vestibular neuromas
Tuberous sclerosis	Adenoma sebaceum, ash-leaf macule, shagreen patch, mental retardation, epilepsy, cortical tubers
Cerebriform congenital	Over scalp with leptomeningeal melanocytosis melanocytic naevus
Sturge-Weber syndrome	Port wine stain, retinal and intracranial vascular malformation
Infections	
Tuberculosis	Miliary tuberculosis involving skin and nervous system
Cryptococcosis	Cryptococcal meningitis, umbilicated white papules over skin
Cytomegaloviruses (CMV) infections	Encephalitis - with perianal ulcers, CMV retinitis
Toxoplasmosis	Encephalitis and retinitis
Syphilis	Meningovascular or parenchymal involvement, tabes dorsalis, cerebral form – General paralysis of the insane (GPI)
Bacterial infection of the dangerous area of face	Cavernous sinus thrombosis
Neurocysticercosis	Cutaneous cysts in neck area, seizures
CNS haemorrhage	
Severe thrombocytopaenia	Petechiae, subarachnoid or intra-cranial bleeding
Autoimmune	
Antiphospholipid antibody syndrome	Non-inflammatory palpable purpura, seizures, abortions, positive anti-phospholipid antibodies
Systemic lupus erythematosus	Cognitive dysfunctions, seizures, early stroke, malar rash
Periarteritis nodosa	Painful subcutaneous nodules along arteries, vasculitic ulcers, peripheral neuropathy
Wegener's granulomatosis	Medium sized vasculitis affecting skin, kidney, upper and lower respiratory tract, peripheral neuropathy
Behçet's disease	Oro-genital ulcers, arthritis, positive pathergy test, meningoencephalitis, brainstem involvement, cranial nerve palsies, cerebral venous sinus thrombosis

11.15 Leprosy

BK Girdhar

DEFINITION

Leprosy (Hansen's disease) is a chronic infectious disease caused by *Mycobacterium leprae*. The organism mainly affects the skin and the peripheral nerves.

EPIDEMIOLOGY

The case load has drastically come down with the worldwide application of multi-drug therapy. Though new patients continue to be detected, the recent (2007) prevalence rate across the globe is very small with all but four countries (Brazil, Democratic Republic of the Congo, Mozambique and Nepal) having achieved elimination, i.e. having prevalence less than one per 10,000 population. Within the India, seven states (Bihar, Chattisgarh, Jharkhand, Maharashtra, Orissa, Uttar Pradesh and West Bengal) continue to have higher prevalence of the disease and contribute two thirds of the patients.

AETIOLOGY AND BACTERIOLOGY

Leprosy is caused by *M. leprae*, a Gram-positive bacillus which is weekly acid-fast and stains bright red with carbol-fuschin.

TRANSMISSION

Man is the only natural host and reservoir of this infection, though a few animals caught in wild have been found to have the infection. It is mainly the untreated lepromatous patients who are infectious and spread the disease in the community. The route of exit of bacilli from the body is mainly from nose and mouth. Aerosol and close contact are important source of transmission. The organisms enter the healthy contacts either through microscopic breaches in the skin or more likely through upper respiratory tract, in particular the nasal mucosa.

PATHOGENESIS

The incubation period ranges from six months to more than 20 years (in most instances 2 to 5 years. In a small proportion of infected individuals (less than 1% to 5%), the disease develops due to impairment of specific cell-mediated immunity (CMI). The type of disease that the patient develops depends upon the degree of impairment of cellular immunity (**Figure 1**).

CLINICAL MANIFESTATIONS

Based on the outcome, determined by individual's specific cellular immunity, six defined types of leprosy have been classified.

Indeterminate Leprosy (IL)

This is the earliest diagnosable manifestation of the disease. The lesions are small, asymptomatic, vague macules, 1 to 3 in number and are hypopigmented, may be with mild redness (**Figure 2**). Some impairment of sensations may be found on careful testing for fine touch (with cotton wool or pointed paper) and temperature (hot and cold).

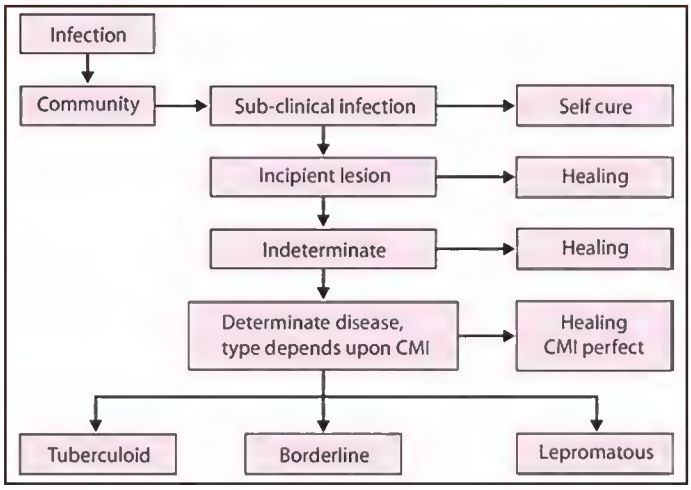

Figure 1: Pathogenesis of leprosy.

CMI = Cell-mediated immunity

Figure 2: Indeterminate leprosy: Small vague lesion on the elbow.

Tuberculoid Leprosy (TL)

This type of disease develops in those who have good CMI (**Figure 3**). Here the disease remains localised to one anatomical area with 1 to 3 patches which are usually medium to large in size and are well defined. Two types of lesions, one raised and red plaques and the other well-defined hypo-pigmented flat

macules are seen which have loss of hair, and impairment of sensations. Local or regional nerve thickening may be there. Skin smears are negative but lepromin test is strongly positive (**Table 1**).

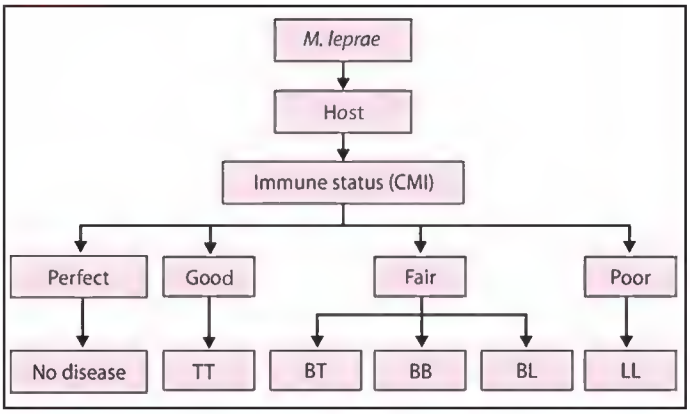

Figure 3: Conceptual representation of spectrum of leprosy.

CMI = Cell-mediated immunity; TT = Tuberculoid leprosy; BT = Borderline tuberculoid; BB = Mid borderline; BL = Borderline lepromatous; LL = Lepromatous leprosy.

(Reproduced with permission from L.K. Bhutani. Colour Atlas of Dermatology)

Lepromatous Leprosy (LL)

Lesions can be macules, plaques, and nodules which appear in generalised symmetrical fashion affecting the extensors more than the flexors (**Table 1**). Early lepromatous disease may present only as shine, due to smoothening of creases by infiltration, over the face and/or back. Papules and nodules appear on the ear, especially the rim of the external ear (**Figure 4**), forehead, cheeks and chin and on the extensors of the body. Lesions are symmetrically placed, small, ill-defined, smooth shiny and devoid of any sensory impairment.

Figure 4: Lepromatous leprosy. Infiltration with nodularity of the ear rim.

The eyebrows may be lost starting from the lateral side. In the absence of treatment, appearance of thicker infiltration in the form of nodules on the face may give the face a leonine look (**Figure 5**). Sheets of infiltration may appear on the distal parts of the extremities (**Figure 6**). There is peripheral anaesthesia of glove and stocking type (**Figure 7**).

Figure 5: Lepromatous leprosy. Leonine facies.

Figure 6: Lepromatous leprosy. Infiltration and shiny skin of hands.

In untreated cases, skin smears are positive in all sites, often with large number of organisms in all microscopic fields. In contrast to tuberculoid disease, lepromin test is uniformly negative.

Borderline Leprosy (BT, BB and BL)

This is a large group with variable and unstable immune system. Depending upon the closeness to the tuberculoid type, the patients are grouped as borderline tuberculoid (BT), while those with features more akin to the lepromatous form are designated as borderline lepromatous (BL). Patients with some manifestations of both the types are called mid borderline (BB). Lesions are relatively more localised, fewer, often larger with

Table 1: Clinical Features of Leprosy

Feature	Tuberculoid (TT)	Borderline tuberculoid (BT)	Mid borderline (BB)	Borderline lepromatous (BL)	Lepromatous (LL)
No. of lesions	1 to 3	Few	Many	Numerous	Innumerable
Distribution	Localised	Localised or distant, mostly regional	Widespread	Generalised asymmetrical	Generalised symmetrical
Size	Usually large	Usually large with satellites	All sizes	Mostly small	Small with sheets of infiltration
Margin/edge	Well-defined	Partly well-defined	Ill-defined, inner edge abrupt in annular lesions	Vague	Vague, infiltration
Surface	Dry, hair loss +	Dry, hair loss +	Some dry, some smooth	Mostly smooth	Smooth, shiny or oily
Sensations	Impaired or lost	Impaired, intact in satellite lesions	Impaired in some, intact in others	Mostly intact	Intact in lesions, peripheral anesthesia ±
Nerves thickening	Limited local and/or regional	Limited local and/or regional	Many regional or distant	Many, often symmetrical	Many, symmetrical
	Firm	Abscess ± Firm	Firm/normal	Normal/soft	Soft and smooth
Skin smears	Negative	Negative	May be positive in some lesions (+/++)	Positive, usually moderately	Positive, often highly
Lepromin	+++	+++	+/–	–	–

Figure 7: Lepromatous leprosy. Acquired ichthyosis and oedema feet.

Figure 8: Borderline tuberculoid leprosy. Well-defined erythmatous plaque with central clearing.

definite sensory impairment in patients toward the BT group (**Figure 8**) and progressively wide spread, more in number, smaller and vague with partial or no loss of sensations as one goes towards the BL type (**Figure 9**). Likewise the number of affected nerves increases and the nerves become softer with disease progression (**Table 1**).

Figure 9: Borderline lepromatous leprosy. Bilateral, small, vague erythmatous macules and plaques over the trunk.

Neuritic Leprosy (NL)

In NL there are no skin manifestations (apart from signs and symptoms of nerve damage) but only nerve thickening. There may be only one nerve thickening (mono-neuritis) or multiple nerves may be clinically involved (mono-neuritis multiplex).

ORGAN INVOLVEMENT

Organ involvement is mainly seen in patients with lepromatous type of disease.

Of the internal organs, liver and kidneys are commonly affected. Kidney involvement is common, especially in those who have had repeated attacks of type 2 erythema nodosum leprosum (ENL) reactions. Glomerulonephritis, interstitial nephritis, less commonly pylonephritis and amyloid deposits can occur resulting in proteinuria, cells and cast in the urine.

Testes being the cooler organ are frequently involved in lepromatous patients. The disease may *per se* produce testicular atrophy with loss of normal testicular sensations. Oligo/

Azoospermia and decreased testosterone levels may result in sterility and loss of libido. Acute painful orchitis may occur in some patients during reactions.

Lymphnodes may get mildly enlarged in a significant proportion of lepromatous patients.

Bone and muscle affection is seen in a small proportion of untreated lepromatous disease of many years. Specific involvement of the eyes due to bacillary spread with appearance of lepromas in the iris and cornea, resulting in insidiously appearing granulomatous uveitis and keratitis respectively, is not uncommon in patients with advanced lepromatous disease and can reduce vision partially or completely. In patients with type 2 (ENL) reaction, eyes may suddenly become painful and red. In the nose there is ulceration of the septal and turbinate mucosae, resulting in blood stained nasal discharge and crusting. Following repeated or prolonged ulceration, bone and cartilage may get affected and destroyed with consequent perforation of septum and collapse of nasal tip.

It is noteworthy that brain, spinal cord, heart, lungs and gastro-intestinal tract have not been observed to have any significant affection.

DISABILITY AND DEFORMITY

Disability means the diminished ability of a person to perform normal movements and do his/her normal work. Deformity is defined as any deviation of appearance of any part or parts of the body. Nerve damage is the main cause for the above. Deformities are called primary, if these are due to direct damage by the disease process, e.g. muscle paralysis, nasal deformity, eye damage, etc. (**Figures 10 and 11**). Secondary deformities are a consequence of sensory loss and thereby loss of tissue due to burns, trauma and secondary infection, e.g. post-burn blisters, ulcers, scars, contractures and loss of digits on hands, trophic ulcers on feet and corneal ulcers due to affection of trigeminal nerve (**Figures 12 and 13**). Disabilities occurring due to damage to various nerves are detailed in **Table 2**.

Table 2: Clinical Effects of Nerve Damage

Site	Nerves	Features
Face	Trigeminal	Loss of sensation over the face corneal anaesthesia if ophthalmic division affected
	Facial	Facial palsy. If only zygomatic branch affected – lag ophthalmos on the affected side
Hand	Ulnar	Loss of sensations and sweat over the little and medial half of ring finger. Clawing of little and ring finger initially and later of long and index fingers
	Median	Loss of sensations and sweat over the thumb, index, long and lateral half of ring fingers. Loss of abductor and opponence function of thumb and later its clawing
	Ulnar and median	Loss of sensations and sweat over whole of palm and medial half of dorsum of hand. Clawing of all fingers
	Radial	Sensory and sweating loss over lateral half of dorsum of hand. Wrist drop
Foot	Common peroneal	Loss of sensations and sweat over lower half of leg. If only superficial affected, sensory loss over dorsum of foot. Foot drop
	Posterior tibial	Loss of sensation and sweat over the sole of foot. Claw toes

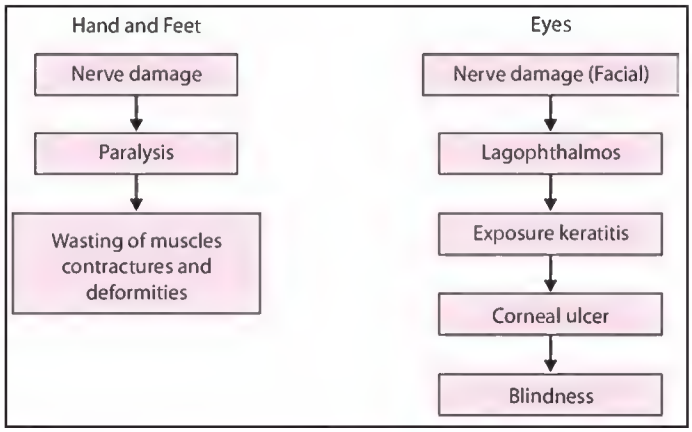

Figure 10: Development of primary disabilities.

Figure 11: Claw hand with trophic ulcers (post-burn blister, ulcers and scars).

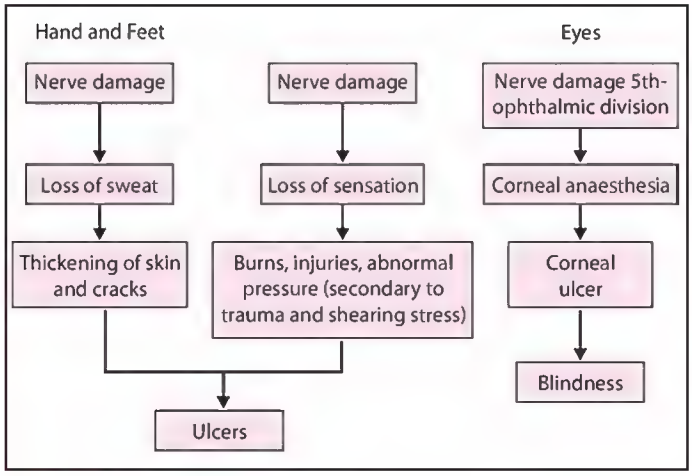

Figure 12: Development of secondary disabilities.

DIAGNOSIS OF LEPROSY

The diagnosis of leprosy is based on the following three cardinal signs: (i) hypopigmented or erythematous patch with definite impairment of sensations, (ii) involvement of peripheral nerve(s), demonstrated by palpable thickening of cutaneous (**Figure 14**) and/or regional nerve trunks and (iii) finding of acid-fast bacilli (AFB) in the skin smears from lesion. For the definite diagnosis either the first two or the third alone need to be present.

Figure 13: Trophic ulcers. Deep punched ulcers over the pressure points of fore feet.

Figure 14: Thickened greater auricular and transverse cervical nerves.

For testing pain, tip of fine ball-pen can be used. Thermal sensation can be tested using test tubes containing hot and cold water. Peripheral nerve trunks and local cutaneous nerves should be palpated for thickening, tenderness and consistency. Nerve function assessment includes, testing for sensations in the lesions and area supplied by the nerve and assessment of power in the muscles supplied by the nerve(s) (the voluntary muscle testing).

Bacteriological Examination (Skin Slit Smears)

This involve making a nick in the suspected lesion and taking a small amount of blood free dermal tissue on to a glass slide and staining the same for AFB using 5% sulphuric acid or 1% acid (hydrochloric acid) alcohol. Skin smears as above are taken from a number of sites including ear lobules and lesions. The stained slides are examined, under oil immersion for number of pink stained bacilli per field, averaging after examination of almost hundred microscopic fields. An average of at least four sites is the bacteriological index (BI). The BI reflects the quantum of bacillary load in the body. The BI, in log scale, is usually 4 to 6+ in untreated lepromatous patients, while it may be hard to find the bacilli towards the tuberculoid end.

Skin Biopsy

Histological examination is often required for confirmation of doubtful cases and for accurate classification of the disease.

Nerve Biopsy

This is required only in a very few cases, especially in those who do not have any skin signs.

Lepromin Test (Mitsuda/Dharmendra)

Lepromin test has no diagnostic value, particularly in endemic areas and where BCG vaccination is practised. Though important for assessing the degree of specific cellular immunity of the patients and useful for immunological classification, presently its role is limited to academics and research only.

Other Laboratory Tests for Diagnosis

Serological tests for leprosy (fluorescent antibody absorption test, PGL-1 antibody and monoclonal antibody based tests) are all positive in high proportion (92% to 100%) of highly bacillated lepromatous cases.

DIFFERENTIAL DIAGNOSIS

As mentioned, careful sensory testing and nerve examination in suspected cases confirms or rules out leprosy. However, in patients with hypopigmented patches/conditions like birth marks (especially, naevus achromicus), pityriasis alba, pityriasis versicolour, vitiligo, post-inflammatory hypopigmentation and lesions of post-kala-azar dermal leishmaniasis (PKDL) need to be differentiated. Nutritional deficiencies, alcoholism, diabetes and heavy metal effects should be considered in patients suspected to have leprosy. Entrapment neuropathies involving the main trunks of the limbs, including that of lateral cutaneous nerve of the thigh (resulting in meralgia paresthetica or Bernhardt's syndrome), and those of trigeminal and facial nerves may occasionally cause confusion in diagnosis.

REACTIONS IN LEPROSY

Occurrence of acute episodes in leprosy have been called reactions. Basically there is a rapid change in the host response with temporary increase in T-cell reactivity. In many patients, this is precipitated by intercurrent problems like stress, pregnancy, acute or chronic infections and anti-leprosy drugs.

Reactions occurring in borderline patients (called type 1 or reversal reactions) are mostly the result of increased cellular hypersensitivity and present as lesions becoming suddenly swollen, angry red and may even ulcerate (**Figure 15**). New lesion may suddenly appear. Nerves may become acutely painful, tender, swollen with increased nerve damage leading to motor deficit. Steroids constitute the main treatment.

In lepromatous and some BL patients, the reactions are on account of antigen-antibody (immune) complexes—either formed or deposited locally. This type of reaction is known as type 2 or ENL reaction. Patients have febrile episodes together with crops of painful red papules or plaques over the face, trunk and the extensors of the limbs (**Figure 16**). These episodes are often associated with acute neuritis, peripheral oedema, lymphadenitis, bone pains, arthritis, acute uveitis and/or orchitis. Swollen and necrotic lesions may also occur.

Figure 15: Borderline tuberculoid leprosy in type I reaction: Swollen, erythmatous and oedematous plaque.

Figure 16: Erythema nodosum leprosum (type II lepra reaction): Erythmatous tender plaques.

MANAGEMENT

Simultaneous administration of two or more drugs, called the multi-drug therapy (MDT) has been the recommended therapy since 1982 (**Table 3**). Dapsone, a sulphonamide derivative, continues to be basic drug. Clofazimine is mildly bactericidal. Having a different mode of action and anti-inflammatory properties has been recorded with this drug. The main component of MDT is rifampicin.

In addition to the above, several new compounds includes fluoroquinolones, in particular ofloxacin, sparfloxacin and moxifloxacin, minocycline.

Multi-Drug Therapy (MDT)

A combination of drugs is routinely advocated to prevent drug resistance. For the purpose of treatment, based on the quantum of the infecting organisms within the body of the patients, all leprosy patients are divided into pauci-bacillary and multi-bacillary groups. Earlier BI was taken as the guide, presently the number of skin lesions is the criteria for this classification. For field treatment, set guidelines have been provided by the World Health Organization (WHO) and adopted by the Government of India. The regimens are detailed in **Table 3**.

All other patients, lepromatous, borderline lepromatous (BL), mid-borderline (BB), borderline tuberculoid (BT) patients with more than 5 lesions are considered multi-bacillary. As expected, almost all of them show AFB positivity in skin smears, though to a variable extent. The MDT for multi-bacillary patients has been recommended for presently 12 months but the dwrofrai can be increased up to 18 months (**Table 3**).

Table 3: WHO Regimens for Leprosy

Group	Drugs	Doses (mg)			Regimens	Duration
		Adult	Children			
			6-14 (years)	0-5 (years)		
PB	Rifampicin	600	450	300	Once a month supervised	6 monthly pulses in maximum of 9 months
	Dapsone	100	50	25		
MB	Rifampicin	600	450	300	Once a month supervised	12 monthly pulses in a maximum of 18 months
	Clofazimine	300	150	100		
	Dapsone	100	50	25	Daily self-administered	
	Clofazimine	50	50 AD	50 BW		

mg = Milligram; PB = Pauci-bacillary; MB = Multi-bacillary; AD = Alternate days, BW = Twice a week

As in tuberculosis, it is mandatory that patients should be kept under surveillance following completion of regimens. This is not only to diagnose and provide care for reaction and/or nerve damage, that can occur even after completing the regimens but also to look for relapses, which are mostly late to appear. All pauci-bacillary patients, including single lesion cases, should be seen at least once a year for 2 years and all multi-bacillary patients should be followed up yearly for at least 5 years.

Management of Lepra Reactions

The type 1 reactions, which are the consequence of changes (more often increase) in cellular hypersensitivity, result in sudden increase in inflammation in skin and nerves in borderline patients. Oral corticosteroids are the mainstay for this type of reactions. An initial daily dose of 30 mg to 40 mg

prednisolone equivalent is sufficient in most cases. After 4 to 8 weeks when the condition improves, as evidenced by decrease in lesional redness and swelling, nerve pain and tenderness or improvement in sensory and motor recovery, the steroids are tapered gradually.

Type 2 (ENL) reactions are the result of local and systemic immune complex deposition or formation and are seen in lepromatous patients. As stated above, attempt should be made to identify and manage precipitating cause, if any, like concomitant infections, physical or psychological stress etc. Addressing the precipitating factors often relieves the patient of reactions. Patients having mild reactions, i.e. with only a countable few skin lesions (with or without mild fever), usually respond to rest, aspirin and/or chloroquine in 5 to 10 days. However, those with severe reactions, presenting with wide-spread skin lesions with fever, acute nerve problems, acute lymphadenitis, arthritis, periostitis, uveitis or orchitis need to be given steroids. Unlike type 1 reactions, here the steroids are required to be given in short courses and rapidly tapered off.

11.16 Sexually Transmitted Infections

Vinod K Sharma, Naresh Jain

Sexually transmitted diseases (STDs) represent a major public health problem causing acute illness, chronic disability and long- term consequences in men, women and children. STDs have a tremendous impact at individual and community level. STDs are responsible for significant proportion of maternal morbidity, ectopic pregnancy, infant illness and death, malignancies, infertility and increased transmission of HIV infection. Sexually transmitted infections (STIs) include all STDs and other infections that may not cause clinical disease of genitals but can be transmitted by sexual intercourse, e.g. hepatitis B, HIV, HTLV-1, etc. STDs most commonly affect people aged 15 to 44 years, the most economically productive group. The emergence of HIV has led to changes in the epidemiological patterns of various sexually transmitted bacterial and viral infections. The different aetiological agents for STDs, diseases caused and complications are listed in **Table 1** and incubation period of common STDs is summarised in **Table 2**.

Table 1: Sexually Transmitted Agents and Diseases

Agents	Disease or syndrome	Complications
Bacteria		
Neisseria gonorrhoeae	Urethritis, epididymitis, bartholinitis, cervicitis, endometritis, salpingitis, proctitis, pharyngitis	Infertility, ectopic pregnancy, chorioamnionitis, premature rupture of membranes, premature delivery, conjunctivitis, PID, disseminated gonococcal infection (DGI)
Chlamydia trachomatis (D-K)	Urethritis, epididymitis, bartholinitis, cervicitis, endometritis, salpingitis, proctitis, pharyngitis	Same as in N. gonorrhoeae, except DGI, Reiter's syndrome, pneumonia
Chlamydia trachomatis (L1, L2, L3)	Lymphogranuloma venereum	Esthiomene, ano-recto-genital syndrome, proctocolitis, skin rashes, pneumonia, hepatitis, meningoencephalitis
Treponema pallidum	Syphilis-primary and/or secondary, latent neurosyphilis, cardiovascular syphilis	Abortions, dementia, death
Haemophilus ducreyi chancroid	Phimosis, sclerosis, meatal stenosis	
Calymmatobacterium granulomatis	Donovanosis	Phimosis, sclerosis, SCC
Mycoplasma hominis	Non-gonococcal urethritis, cervicitis, salpingitis	PID, post-partum fever
Ureaplasma urealyticum	Non-gonococcal urethritis, cervicitis, salpingitis	Chorioamnionitis, low birth weight
Gardnerella vaginalis and others	Bacterial vaginosis	
Group B *β-haemolytic Streptococcus*	Neonatal sepsis, neonatal meningitis	
Viruses		
Herpes simplex virus 1, 2	Primary and recurrent genital herpes	Aseptic meningitis, neonatal herpes and associated mortality or neurological sequelae, spontaneous abortion, premature delivery
Human papilloma virus	Condyloma acuminata	Laryngeal papilloma in infants, squamous epithelial neoplasia of cervix, anus, vagina, vulva and penis
Hepatitis B virus	Acute, chronic and fulminant hepatitis B	Cirrhosis, hepatocellular carcinoma
Cytomegalovirus	Infectious mononucleosis	Congenital infection, birth defects, infant mortality, cognitive impairment (mental retardation, sensorineural deafness), variable manifestations in immunocompromised host
Molluscum contagiosum virus	Genital *molluscum contagiosum*	Infection, eczematoid dermatitis, erythema annulare centrifugum
Human immunodeficiency virus	AIDS and related conditions	Opportunistic infections, death
Human T-lymphotropic virus	T-cell leukaemia, lymphoma, tropical spastic paraparesis	Death
Protozoa		
Trichomonas vaginalis	Urethritis, balanitis, vaginitis	
Fungus		
Candida albicans	Vulvovaginitis, balanitis, balanoposthitis	
Ectoparasites		
Phthirus pubis	Pubic lice infestation	
Sarcoptes scabiei	Scabies	Norwegian scabies in immunocompromised host

Table 2: Incubation Period of Common STDs

STDs	Incubation Period (mean)
Primary chancre	9 to 90 days (21 days)
Chancroid	One to several weeks (5 to 8 days)
Donovanosis	9 to 50 days (17 days)
Lymphogranuloma venereum	5 to 30 days (10 days)
Herpes genitalis (primary)	5 to 7 days (5 days)
Genital warts	1 to 8 months (3 months)
Gonococcal urethritis	1 to 14 days (2 to 5 days)
Non-gonococcal urethritis	7 to 21 days (10 days)

Syphilis, herpes genitalis and anogenital warts are discussed in separate chapters.

CHANCROID

Aetiology

Chancroid is a sexually transmitted ulcerative disease associated with inguinal adenitis (bubo) caused by *Haemophilus ducreyi*, a Gram-negative, facultative anaerobic bacillus, arranged in chains of 2 to 4 giving the typical appearance of a *'school of fish or rail road track'. H. ducreyi* is a fastidious organism and culture is difficult.

Epidemiology

Chancroid is most common in many of the world's poorest regions, such as areas of Africa, Asia, and the Caribbean. The prevalence of chancroid is higher in lower socioeconomic groups.

Clinical Features

After an incubation period that ranges from 1 to 14 days, a small inflammatory papule surrounded by erythema develops on genitalia, which rapidly progress to pustules followed by ulceration. The ulcers are multiple, painful, sharply circumscribed with ragged undermined edge (**Figure 1**). The ulcer base is composed of granulation tissue that bleeds on manipulation. Characteristically, the base of the ulcer is non-indurated. The ulcers are located primarily on the prepuce, frenulum or glans penis in males and labia, fourchette and cervix in females. Unilateral painful inguinal adenitis (bubo) in 30% to 60% of the patients within 1 to 2 weeks of the development of ulcer. The nodes become enlarged, tender and then matted.

Diagnosis

Besides the clinical clues, the main tool for definite diagnosis for chancroid is bacterial culture of *H. ducreyi* and direct examination of *H. ducreyi* from the genital ulcer by Gram-stain. Polymerase chain reaction (PCR) and indirect immunofluorescence using monoclonal antibodies are recent techniques. Histopathological examination also helps in the diagnosis.

Treatment

Azithromycin 1 g orally in a single dose or ceftriaxone 250 mg intramuscularly in a single dose or ciprofloxacin 500 mg orally twice a day for 3 days or erythromycin base 500 mg orally three times a day for 7 days. Ciprofloxacin is contraindicated for pregnant and lactating women. Fluctuant bubo should be aspirated using a wide bore needle. In the presence of bubo, the antimicrobial agents may have to be continued for a longer period till the bubo heals. Sexual contacts within 10 days before the onset of patient's symptoms should be examined and treated, even in the absence of symptoms in view of the known asymptomatic carriage.

Follow-up

After starting the treatment, patients should be reviewed at day 3 and day 7.

DONOVANOSIS

Aetiology

Donovanosis (*granuloma inguinale*) is indolent, progressive, ulcerative and granulomatous skin disease caused by *Calymmatobacterium granulomatis*. The organism has an appearance similar to a safety pin.

Epidemiology

Donovanosis is endemic in tropical and subtropical regions. In India donovanosis is endemic along the East Coast, i.e. Orissa (7.5%), Andhra Pradesh (1.12%) and Tamil Nadu (4.7%).

Clinical Features

The incubation period may range from 3 days to 3 months. The primary lesion may be a skin-coloured to erythematous papule, which ulcerates to form well-defined granulomatous ulcer (**Figure 2**). The ulcer is usually painless, beefy-red in colour and bleeds easily on touch. In men, the penis, scrotum and glans are most commonly affected and in females, the labia minora, mons-veneris and fourchette are most common sites. True adenopathy is rare. The disease spreads by satellite inoculation and daughter lesions and thereby these spread slowly to the inguinal region where it can mimic a bubo (pseudobubo).

Figure 1: Chancroid-ulcer with ragged edges.

Figure 2: Donovanosis-fleshy ulcer.

During its progression it leads to the destruction of lymphatics resulting in lymphoedema and elephantiasis of the genitalia. Persistent untreated lesions over years can lead to malignant transformation.

Diagnosis

Besides history and clinical appearance, a touch or crush preparation stained with Wright's or Giemsa's stain from a punch biopsy specimen which shows deeply staining, bipolar, safety pin rods in the cytoplasm of macrophages (Donovan bodies). The culture of organism is difficult but PCR can help in the diagnosis.

Treatment

Doxycycline 100 mg orally twice a day for at least 3 weeks and until all lesions have completely healed. Azithromycin 1 g orally once per week or ciprofloxacin 750 mg orally twice a day or erythromycin base 500 mg orally four times a day or trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice a day are alternatives. Therapy should be continued for at least 3 weeks and until all lesions have completely healed. All sex partners (within 60 days of onset of patient's symptoms) should be examined and offered therapy.

Follow-up

Review is preferably monthly for first 3 months.

LYMPHOGRANULOMA VENEREUM

Aetiology

Lymphogranuloma venereum (LGV) is a sexually transmitted disease affecting primarily the lymphatic system, caused by *Chlamydia trachomatis* serovars L1, L2 and L3. *Chlamydia* are Gram-negative, intracellular, obligate parasites, measuring from 0.3 to 1.0 micron in size.

Epidemiology

LGV has a worldwide distribution but is endemic in India and South-East Asia.

Clinical Features

The incubation period is usually around a week (3 to 12 days). The portal of entry and the initial symptoms are determined by the nature of sexual act. The clinical features can be divided into primary stage, secondary (inguinal stage) and a tertiary stage (complications).

Primary Lesion

The primary lesion is 5 to 8 mm soft, erythematous, painless erosion that heals spontaneously in a few days.

Inguinal Syndrome (Bubo)

Secondary inguinal lymphadenopathy (bubo) begins 1 to 2 weeks after the primary lesion as discrete, movable, tender nodes that later coalesce to form a firm, fist-sized, elongated, immovable mass. Nodes are bilateral in one-third of cases. These may occur above and below Poupart's ligament, giving rise to the "groove" sign. Rupture of the lymph nodes leads to chronic sinus formation. At time of rupture of the bubo, patients might have constitutional symptoms.

Anogenital Rectal Syndrome

Early manifestation of this disease is mucoid rectal discharge following over weeks to months by fever, rectal pain and tenesmus. At this stage they have multiple superficial ulcers with irregular borders. As the disease progresses, crypt abscesses and fistulas are formed resulting in rectovaginal fistula, fistula in ano, etc. Ultimately they heal with fibrosis and lymphatic obstruction, resulting in rectal stricture and lymphoedema of the genitals (ram-horn penis, saxophone penis) leading to genital elephantiasis (esthiomene). Carcinoma of the rectum develops in 2% to 5% cases of rectal stricture due to LGV. The ano-rectal syndrome is more common in women.

Diagnosis

LGV can be confirmed by: (i) serological procedures like complement fixation test, counter immunoelectrophoresis, radio immunoprecipitation test, etc.; (ii) demonstration of chlamydial antigens by immunofluorescence; and (iii) isolation of *Chlamydia* by tissue culture.

Treatment

Treatment cures infection and prevents ongoing tissue damage. Buboes might require aspiration through intact skin or incision and drainage to prevent the formation of inguinal/femoral ulcerations.

Recommended regimen to doxycycline 100 mg orally twice a day for 21 days, or alternatively, erythromycin base 500 mg orally four times a day for 21 days.

Sexual contacts within the 60 days before the onset of patient's symptoms should be examined, tested for urethral or cervical chlamydial infection, and treated with standard *Chlamydia* regimen (azithromycin 1 g orally stat or doxycycline 100 mg orally twice a day for 7 days).

Follow-up

Patients should be followed clinically until signs and symptoms have resolved. Differential diagnosis of genital ulcer disease is discussed in **Table 3**.

URETHRITIS

Urethritis, inflammation of the urethra can be classified into two types—gonococcal and non-gonococcal urethritis. The former is caused by *Neisseria gonorrhoeae*, a Gram-negative intracellular diplococci and it measure 1 to 2 μ in size. The adjacent surface of the cocci is flattened and long axis of the bean-shaped organisms are parallel. They are cultured on Thayer-Martin medium. Non-gonococcal urethritis is caused by variety of organisms, *Chlamydia trachomatis* being the most common. Other organisms that are responsibile for non-gonococcal urethritis are *Ureaplasma urealyticum, Mycoplasma, Trichomonas vaginalis, Candida albicans,* HSV, etc.

Epidemiology

The disease is spread mainly by sexual activity. The commercial sex workers are the main source of infection in a developing country like India. Urethritis constitutes 14% to 20% of patients attending STD clinic in India.

Clinical Features

After a period of 2 to 10 days of exposure, the disease manifests as acute burning sensation of urethra with copious purulent discharge. Approximately 25% of males will develop gonorrhoea after a single exposure. Meatal erythema, dysuria,

Table 3: Clinical Features of Common Genital Ulcer Disease

Characteristics	Syphilis	Herpes	Chancroid	LGV	Donovanosis
Primary lesions	Papule	Vesicle	Pustule	Papule, pustule or vesicle	Papule
Number of lesions	Usually one but in 1/3 more than 1	Multiple and may coalesce	Usually multiple and may coalesce	Usually one	Variable
Diameter	5 to 15 mm	1 to 2 mm	Variable	2 to 10 mm	Variable
Edges	Sharply demarcated elevated, round or oval	Erythematous, polycyclic	Undermined, ragged, irregular	Elevated round or oval	Elevated, irregular
Depth	Superficial or deep	Superficial	Excavated	Superficial or deep	Elevated
Base	Smooth non-purulent covered with serious exudates	Erythematous	Purulent, bleeds easily	Variable	Red and velvety, bleeds readily
Induration	Button-like	None	Soft	Occassionally firm	Firm
Pain	Uncommon, but tender on firm pressure	Frequently tender	Usually very tender	Variable	Uncommon
Lympha-denopathy	Firm, non-tender, bilateral, and in 1/3 cases it may be tender	Firm, tender, often bilateral with initial episode	Tender, may suppurate, loculated, usually unilateral, occasional cord like lymphangitis	Tender, may suppurate, loculated usually unilateral	None, may be pseudobuboes
Recurrence	No	Yes, in 80%	No	No	No

Adapted from: Sharma VK, Kumar U. Sexually Transmitted Diseases; 2nd edition. New Delhi: Viva Books; 2009. Table 45.3; Page 771.

abnormal bleeding or increased discharge can be seen in females. In addition to urethritis, 1% of male patients develop other complications like tysonitis, periurethral abscess, Cowperitis, epididymorchitis and prostatitis. Disseminated form is seen in immunocompromised patients. Complications like pelvic inflammatory disease, bartholinitis, perihepatitis, and urethral strictures can develop.

Non-Gonococcal Urethritis

Non-gonococcal urethritis (NGU) can occur alone or more often (45%) in association with gonococcal urethritis. They present after a long incubation period of 3 weeks. The symptoms are mild and they have scanty mucopurulent/mucoid discharge. In females, untreated NGU can lead to pelvic inflammatory disease with its consequences.

Diagnosis

Gram stained preparation helps in the diagnosis and in distinguishing between gonococcal and non-gonococcal urethritis. A diagnosis of urethritis is made if there were more than 5 pus cells present per high power field (1 x 1000). In case of gonococcal urethritis, there are sheets of pus cells with Gram-negative intracellular dipococci. In case of non-gonococcal urethritis, there are only scanty pus cells with no intracellular Gram-negative diplococci.

Treatment

Uncomplicated gonococcal infections of the cervix, urethra, and rectum – ceftriaxone 125 mg IM in a single dose or cefixime 400 mg orally in a single dose or ciprofloxacin 500 mg orally in a single dose or ofloxacin 400 mg orally in a single dose or levofloxacin 250 mg orally in a single dose *plus* treatment for *Chlamydia*, if chlamydial infection is not ruled out (Cap. Doxycycline 100 mg bid for 7 days or tab. erythromycin 500 mg qid for 7 days).

HIV and STDs

Sexually transmitted diseases and HIV infection have a symbiotic relationship. Genital ulcer increases the acquisition of HIV infection 2 to 5 times. Because of large ulcerated area and the presence of inflammatory CD4+ cells, which act as receptors of HIV, the genital ulcers (**Figure 3**) provide an ideal route for transmission by shedding HIV virus. On the other hand, HIV infection by immunosuppression can lead to large, non-healing genital ulcers or treatment resistant genital ulcers. Clinical features and treatment of different STDs with HIV are summarised in **Tables 4 and 5**.

Table 4: Variations in Syphilis Presentation in Individuals with HIV Infection

Clinical finding	
Primary syphilis	Painless ulcer becomes painful due to superinfection, giant chancre, multiple ulcers (in up to 25%)
Secondary syphilis	Lues maligna — secondary syphilis with vasculitis manifested by fever, malaise, headache, nodules, indurated plaques with ulceration is more frequent
Latent and tertiary syphilis	Shorter latent period with rapid progression to tertiary disease within the first year of infection
Serological response to syphilis	VDRL and treponemal antibody test in blood and CSF may be false negative due to prozone phenomenon. Failure to drop VDRL titers by one year despite adequate treatment (serofast phenomenon)
Diagnosis	If VDRL is negative, dark field microscopy, biopsy of the lesion and direct fluorescent antibody staining of material from the lesion of polymerase chain reaction may be helpful
Treatment	Syphilis treatment is relatively unchanged in HIV co-infected patients, but regular follow-up is required because of increased rates of treatment failure

Adapted from: Kar HK. Sexually Transmitted Diseases; 2nd Edition. New Delhi: Viva Books; 2009. Table 11.2; Page 224.

Table 5: Variations in Other STDs Presentation in Individuals with HIV Infection

Chancroid	
Clinical findings	Genital ulcers tend to be larger and persist longer. Multiple inguinal buboes. Frequent occurrence of giant and phagedenic ulcer
Treatment	Treatment failure can occur with single-dose therapy with azithromycin and ceftriaxone, so erythromycin, 500 mg 6 hourly for 7 days is preferred
Herpes genitalis	
Clinical findings	As immunosuppression progresses,lesion may persist or progress to chronic enlarged painful non-healing ulcers with raised margin, ulcer may bleed
Treatment	Treatment might be extended if healing is incomplete after 7 to 10 days of therapy.For severe HSV disease, initiating therapy with acyclovir 5 to 10 mg/kg body weight IV every 8 hours might be necessary. Suppressive therapy includes acyclovir 400 to 800 mg bid or tid
Granuloma inguinale	
Clinical findings	Lesion may be larger,extensive,pseudobubo formation which may burst producing ulceration; slow response to the treatment
Treatment	Doxycycline 100 mg orally bid or erythromycin 500 mg orally qid for 2 to 3 weeks. If no improvement, add gentamicin 1 mg/kg intravenously
LGV	
Clinical findings	Acute inflammation with bilateral inguinal bubo which may burst into ulceration
Treatment	Same regimen (doxycycline, 100 mg orally bid or erythromycin, 500 mg orally qid for 21 days, but prolonged therapy may be required

Adapted from: Kar HK. Sexually Transmitted Diseases; 2nd edition. New Delhi: Viva Books; 2009. Table 11.3; Page 229.

SYNDROMIC APPROACH TO STD MANAGEMENT

The main motive under this approach is to diagnose and treat patients on the basis of groups of symptoms or signs

Figure 3: Non-healing ulcer of genital herpes in a HIV-positive patient.

(syndrome) rather than for a specific STD. A genital ulcer, which is a symptom of both chancroid and syphilis, is treated for both chancroid and syphilis in an area where both are prevalent. The urethritis is treated by covering for both gonococcal and chlamydial infection. The '4C's of syndromic approach are counselling, condom usage, compliance and contact tracing. The main drawback of syndromic approach is wastage of resources, use of multiple drugs and development of drug resistance. As laboratory tests are expensive, time consuming and not available at the primary level, the syndromic approach is validated. It also helps in prompt treatment of STD at primary health centre and reduce transmission of STDs including HIV infection.

11.17 Premalignant Conditions and Malignant Tumours of the Skin

Arun C Inamadar, Aparna Palit

INTRODUCTION

Premalignant and malignant skin lesions are commoner among white races. Malignancies like primary cutaneous melanoma are extremely rare among Indians.

Exposure to solar and artificial ultraviolet rays (UVRs) and contact with carcinogenic chemicals are few of the predisposing factors for development of cutaneous malignancies.

Genetic susceptibility to the development of skin malignancies is well known. High-frequency, low-penetrant genes are responsible for sporadic occurrence of skin cancers whereas rare, low-frequency, high-penetrant genes are associated with familial cancer predisposition syndromes. Immunosuppressed state [organ-transplant recipients and human immunodeficiency virus (HIV) infection] confers a susceptibility to non-melanoma skin cancers.

Common premalignant skin lesions are actinic keratosis and leucoplakia.

ACTINIC KERATOSIS

These are hyperkeratotic lesions with malignant potential occurring on photodamaged skin of elderly individuals.

Fair-skinned outdoor workers are common sufferers and occurrence is directly related to the degree of UVR exposure. The common sites are scalp, face and dorsa of hands. The lesions are multiple, asymptomatic, brownish macules or papules (1 mm to >2 cm) with rough, scaly surface. There may be pain and traumatic bleeding.

Histopathologically there are features of dysplasia. Many lesions may undergo spontaneous resolution or may progress (< 0.1%) to invasive squamous cell carcinoma (SCC). Management includes restricting outdoor activities, use of sunscreen and destruction of existing lesions with 5-fluorouracil (5-FU) cream, cryotherapy or photodynamic therapy.

LEUCOPLAKIA

Leucoplakia is a white patch or plaque on the mucous membrane which is not removable by rubbing, cannot be attributed to any specific underlying cause by its morphology and requires a diagnosis by exclusion (WHO). Some leucoplakias have premalignant potential and may slowly progress to malignancy (2 to 5%) over several years.

Various causes of leucoplakia have been presented in **Table 1**. It is common in elderly with an incidence rate of about 1%. Oral mucosa is the most common site, involving palate, tongue or floor of the mouth. Clinically the lesions are asymptomatic diffuse, speckled or striated, fixed white plaques with or without reddish reticulation on the surface (erythroplakia).

All lesions should be biopsied to rule-out dysplasia. Moderate to severe dysplasia indicate higher risk for malignancy. Such lesions should be managed by topical bleomycin (0.5%), surgical excision or laser ablation. Risk factors must be avoided.

Table 1: Causes of Leucoplakia

Aetiology	Types	Risk of malignancy
Infective origin	Chronic Candidal leucoplakia	Increased risk but malignancy uncommon
	Syphilitic leucoplakia (tertiary stage)	Rare condition, high malignant potential
	Oral hairy leucoplakia (Epstein Barr virus)	Malignancy not recorded
	Leucoplakia associated with chronic renal failure (Epstein-Barr virus)	Slow progression to SCC over decades
	Proliferative verrucous leucoplakia (Human Papilloma virus)	
Chronic irritation	Smoking Tobacco chewing Chewing of Betel leaves and areca nut Snuff-dipping	Higher risk, but rare
Idiopathic	—	—
Paraneoplastic (in association with internal malignancy)	May occur in association with visceral malignancies, specially those of upper aerodigestive tract.	—
In association with genetic disorders	Dyskeratosis congenita Olmsted syndrome	

MALIGNANT EPIDERMAL TUMOURS

Common malignancies of epidermal origin are SCC, basal cell carcinoma (BCC) and primary cutaneous melanoma. These skin tumours constitute part of some of the genodermatoses like Bloom's syndrome, xeroderma pigmentosum (XP), Gorlin's syndrome, Muir-Torre syndrome, Bazex's syndrome, etc.

Squamous Cell Carcinoma

Cutaneous SCC is the malignant proliferation of the epidermal keratinocytes.

Aetiopathogenesis

Exogenous risk factors for SCC include chronic exposure to UVR, carcinogenic chemicals like tar, arsenic and physical agents like ionising and thermal radiation. Latent infection with human papilloma virus is a factor precipitating SCC.

Clinical features

The sites of predilection are photodamaged areas of face and neck, burn scar, keloid, non-healing ulcer, existing pre-malignant lesions or any site with long-term infection (lupus vulgaris) or inflammation. It starts as indurated areas or irregular, raised, painless nodules on such lesions. It enlarges rapidly with variegated/ulcerated surface, bleeding easily. In late stage, the lesion becomes cauliflower-like (**Figure 1**) and malodorous.

Figure 1: Cauliflower like fungating lesion of squamous cell carcinoma.

There are regional and distant lymphadenopathies. Visceral metastasis occurs through lymphatics.

Clinical variants

Intraepidermal, *in situ* SCC with a small potential for invasiveness are Bowen's disease and erythroplasia of Queyrat on genitalia. In India (Kashmir), prolonged contact with Khangri (pot with coal fire) in winter season is one of the precipitating factors causing SCC on abdominal wall (Khangri cancer). SCC that arises from chronically scarred skin is known as Marjolin ulcer.

Key diagnostic points

Histopathologically, the lesions may be well-differentiated (individual cell keratinisation and horny pearls), or poorly differentiated (anaplastic keratinocytes invading the dermis; "windblown" appearance).

Differential diagnosis

Early lesions of SCC may be mistaken with actinic keratosis or BCC.

Treatment

Treatment include topical 5-FU, photodynamic therapy, Mohs micrographic surgery, surgical excision with wide margin (high-risk lesions <1 cm and any lesion >2 cm), radiotherapy, chemotherapy or combination of these.

Basal Cell Carcinoma

BCC is the most common cutaneous malignancy worldwide, accounting for about 90% of malignant tumours. Commonly known as rodent ulcer, it arises from basal cells of the epidermis. It is locally invasive and metastasises very rarely.

Aetiopathogenesis

Predisposing factors include exposure to UVR [mostly ultraviolet B or medium wave (UVB)], occupational contact with tar, pitch and ingestion of arsenic. UV-induced mutations in the *TP53* tumour-suppressor gene (chromosome 17p), have been implicated in some cases of BCC. Multiple, early onset BCC may be seen in familial cancer syndromes.

Clinical features

It occurs in the elderly, fair-skinned individuals, predominantly in the periorbital region (lower eyelid 70%, followed by inner canthus, upper eyelid and outer canthus). The initial lesion is a small, raised, translucent, pearly papule with or without pigmentation and prominent blood vessels. These are slow growing with a rolled-out border, gradually destroying the underlying tissue (**Figure 2**). Neglected, advanced lesions may invade eye, underlying lacrimal duct and sinuses, facial and skull bones and even meninges, known as 'ulcus terebrans' (penetrating ulcer).

Figure 2: Large lesion of basal cell carcinoma with rolled-out border and distortion of inner canthus of eye.

Clinical variants

Various morphological patterns of BCC include:

- Noduloulcerative (most common)
- Cystic
- Morphoeic (cicatricial)
- Superficial spreading (multicentric)
- Pigmented.

Key diagnostic point

Histopathological picture includes islands of dark blue basal cells with peripheral palisading, invading the dermis. Mitotic figures and apoptotic bodies are seen in plenty.

Differential diagnosis

The lesions have to be distinguished from keratoacanthoma, early SCC, seborrhoeic keratosis and melanoma.

Treatment

Different treatment modalities for BCC are topical imiquimod (5%) cream, 5-FU, interferon-α, surgical excision, Mohs micrographic surgery, radiotheraphy, cryotherapy, curettage, cautery and photodynamic therapy. There are chances of recurrence or appearance of new lesions.

Cutaneous Malignant Melanoma

This is a malignant tumour of epidermal melanocytes resulting from UVR exposure in genetically susceptible individuals. This malignancy occurs exclusively among white races. There is a gradual increase in melanoma in Australia, New Zealand and different parts of United States. Primary cutaneous melanoma is extremely rare in Indian skin.

Aetiopathogenesis

Intermittent, unaccustomed or recreational solar exposures are the risk factors for cutaneous melanoma rather than chronic exposure. Other risk factors include positive family history (2%), presence of multiple benign melanocytic naevi and past history

of melanoma. Mutation of the tumour suppressor gene *CDKN2A* (chromosome 9p21) is found in 10 to 30% patients, particularly in familial cases. Mutation of *CDK4*, melanocortin 1 receptor (*MC1R*) gene (chromosome 17) polymorphism and presence of oncogene *BRAF* are other susceptibility factors.

Clinical variants

- Superficial spreading melanoma (most common),
- Nodular melanoma (rapid growth, poor prognosis)
- Lentigo maligna melanoma (Hutchinson's lentigo)
- Acral lentiginous melanoma (Darker races)
- Subungual melanoma
- Mucosal melanoma
- Secondary melanoma without detectable primary site.

Clinical features

Common body sites involved are the trunk in men and lower legs in women. This malignancy affects younger people than other cutaneous carcinomas. Head and neck melanoma may result from cumulative solar exposure in older people.

In nodular melanoma, melanin pigment may be sparse. Lentigo maligna melanoma is very slow-growing, occurring on the face of elderly patients as brownish-black, irregular, flat lesions. Acral lentiginous melanoma occurs on palms and soles as a central raised area surrounded by a pigmented macule. Subungual melanoma is commonly misdiagnosed as other benign conditions and definitive diagnosis is usually late.

Key diagnostic points

A naevus with erratic behaviour (increased size, change in shape/colour) is suspicious. The 'ugly duckling' sign, as proposed by some French authors is that 'a naevus different from its 'brother' naevi can be a melanoma'. Suspected lesions should be biopsied with 1 to 2 mm of surrounding clinically normal skin. Histopathologically, invasion of the dermis by malignant melanocytes is the diagnostic feature.

There are systems to aid clinical diagnosis of melanoma; the American ABCDE (A = asymmetry, B = irregular border, C = irregular colour, D = diameter >1 cm, E = evolution) and Glasgow seven-point check-list are commonly used. The latter includes 3 major and 4 minor features as follows:

Major features:

- Change in size
- Change in shape
- Change in colour.

Minor features:

- Diameter more than 5 mm
- Inflammation
- Oozing/bleeding
- Mild itching/altered sensation.

In adult patients, presence of one major feature is an indication of removal of the lesion, and additional minor features are additive to the clinical suspicion.

Pathological prognostic guides include depth of invasion of tumour cells as expressed by the:

- Breslow's tumour thickness (distance between granular layer and the deepest invasive area of primary lesion in mm).
- Clark's levels (five levels, starting from *in situ* to invasion into fat, indicating extent of penetration of primary lesion).

Several prognostic factors in cutaneous melanoma have been presented in **Table 2**.

Table 2: Prognostic Factors in Primary Cutaneous Melanoma

Factors	Prognosis
Clinical	
Age	Increasing age, worse prognosis
Gender	Female, better prognosis
Location of tumour	Proximal extremity lesions have better prognosis than trunk lesions. Those on head, neck and acral location have worst prognosis
Histopathological	
Cell type	Presence of amelanotic cells, signet ring cells, naevoid cells and small cells indicate worse prognosis Spindle cells have better prognosis
Cellular atypia	Marked cellular atypia worsens prognosis
Angiotropism, vascular invasion and neurotropism	Presence of any of these factors worsens prognosis
Ulceration	Worsens prognosis
Mitotic figures	Increased mitotic figures, worse prognosis
Tumour vascularity	Increased vascularity, worsens prognosis
Breslow's tumour thickness	Increasing thickness, worse prognosis
Clark's level	Increasing level, worse prognosis
Radial and vertical growth phase	Vertical growth is worse than radial growth
Tumour volume	Higher tumour volume, worse prognosis

Differential diagnosis

Benign melanocytic naevi in young adults and seborrhoeic and actinic keratosis in older age group are to be differentiated from melanoma.

Treatment

Tumour node metastasis (TNM) staging system is followed to make decisions on treatment.

Management includes surgical excision, sentinel lymph node biopsy in case of thicker primary lesion and adjuvant chemotherapy/radiotherapy in the advanced stage of disease. Primary preventive measures include awareness campaigns regarding sun protection and identification of early lesions.

Several vaccines for melanoma are in the process of development. These are used in affected melanoma patients instead of prophylactic use. Interferon α 2b and anti-CTLA-4 antibody (iplimumab, ticlimumab) are under trial for the treatment of melanoma.

2. Quinn AG, Perkins W. Non-melanoma skin cancer and other epidermal skin tumours. In: Burns T, Breathnach S, Cox N, Griffiths C, editors; *Rook's Textbook of Dermatology*, Vol-3; 8th Ed. Oxford: Wiley-Blackwell; 2010: p-52.

11.18 Therapy of Dermatological Diseases

MK Singhi

Dermatology, as with all fields of medicine, is continuously evolving. Introduction of newer drugs, surgical procedures and lasers have revolutionised the treatment of various skin diseases. Dermatological therapies can be divided in three parts:

1. Topical therapy
2. Systemic therapy
3. Surgery

TOPICAL THERAPY

Topical therapy remains the mainstay for the treatment of most of skin diseases. Treatment by topical methods lead to intimate contact between the drug and skin and the risk of systemic side-effects is minimised. In topical therapy the drug is first incorporated into a vehicle before application. A clinician must know the appropriate vehicle that should be used for a particular dermatosis. **Table 1** gives the vehicles used in dermatology.

Wet Therapy

Wet dressings and baths are used to clean the wounds and for dressing purposes. A wide variety of solutions are used for these purposes, viz. aluminium acetate lotion, Burow's solution, Eusol, and potassium permagnate solution.

TOPICAL STEROIDS

Topical steroids are the most widely used therapeutic agents for the treatment of inflammatory skin disease (**Table 2**).

Mechanism of Action

Topical corticosteroids (TCS) are known to act in four ways:

Anti-inflammatory and immunosuppressive effects

TCS reduce the recruitment of neutrophils and monocytes in the affected area and inhibit phagocytosis. They also inhibit capillary proliferation, fibroblast proliferation, collagen deposition. They also cause inhibition of phospholipase A_2 and thereby decreasing the formation of prostaglandins and leukotrienes and hence decreasing the inflammatory process.

Antimitotic effects

TCS affect cell differentiation and have been found to be antimitotic to several tissues.

Table 1: The Various Vehicles and their Use

	Ointments	Creams	Gels	Lotions
Composition	Water in oil emulsion	Oil in water emulsion	Semisolid emulsion in alcohol base	Powder in water (sometimes oil)
Potency	Strong	Moderate	Strong	Low
Hydration property	Hydrating	Some hydration	Drying	Drying
Sensitisation risk	Very low	High	High	High
Irritation risk	Low	Low	High	Moderate
Used on body sites	Non-intertriginous	All sites	Hairy areas	Intertriginous, scalp
Stage of dermatitis treated	Chronic	Acute to subacute	Acute to subacute	Acute

Table 2: Potency of Topical Corticosteroids (TCS) and Considerations for their Use

Potency	Type of dermatoses	Amount of TCS and duration of usage	Location of dermatoses	Usage in children	State of epidermis
Superpotent Clobetasol Halobetasol	Dermatosis resistant to high potency TCS	Use TCS for short duration and avoid extensive application (>50 gm/week)	Do not use on atrophogenic area such as face, axillae, groins and submammary area	Avoid use in children <12 years of age	Best for thick, lichenified or hypertrophic skin, avoid with thin skin
High potency Halcinonide Betamethasone Mometasone Methylprednisolone	Severe	Use TCS for short duration and avoid extensive application (>50 gm/week)	Do not use on atrophogenic area such as face, axillae, groins and submammary area	Avoid use in children <12 years of age	Best for thick, lichenified or hypertrophic skin, avoid with thin skin
Medium potency Hydrocortisone butyrate Triamcinolone acetonide Fluocinolone	Moderate	Used for extensive use in adults	Best on trunk and extremities	Do not use for extended periods (1 to 2 weeks only)	Use for short duration on thin skin, less effective on thick skin
Low potency Desonide Hydrocortisone	Steroid sensitive	Used for treatment of large areas and for long-term use	Best choice for atrophogenic area	Best for infants and children	Best for thin skin, not effective on thick skin

Vasoconstrictor effect

TCS inhibit histamine, bradykinin and prostaglandins and potentiate norepinephrine leading to vasoconstriction. This vasoconstriction potentiates anti-inflammatory effect.

Effects on mast cells and immediate reactivity

TCS on prolonged use decrease the histamine content of the mast cells. Histamine levels did not decline until after 3 weeks of treatment.

Indications of Topical Corticosteroids

- Dermatitis and papulosquamous disorders such as atopic dermatitis, lichen planus, lichen simplex chronicus, psoriasis.
- Bullous dermatoses such as bullous pemphigoid, pemphigus foliaceous.
- Behcet's syndrome, vitiligo, sarcoidosis, alopaecia areata.

Adverse Effects of Topical Corticosteroids

Systemic

- Suppression of hypothalamic-pituitary-adrenal axis
- Cushing syndrome
- Growth retardation in children

Local

Epidermal atrophy- shiny, wrinkled skin with hypopigmentation, telangiectasia, striae, purpura.

Hypertrichosis, contact dermatitis, folliculitis, increased susceptibility to infections, perioral dermatitis, rosacea, acne, delayed wound healing, glaucoma, cataracts.

TOPICAL ANTIBACTERIALS IN DERMATOLOGY

Topical antibiotics are divided into two categories – drugs used for wound care and drugs used for acne and rosacea. Topical use helps to achieve high local drug concentration with minimal systemic absorption, thereby reducing adverse effects.

Drugs used for wound care include bacitracin, neomycin, gentamicin, silver sulphadiazine, mupirocin, fusidic acid and nadifloxacin. They are used for wound care, skin infections such as impetigo, folliculitis, burns, leg ulcers, bruises and lacerations.

Topical drugs used for acne and rosacea include benzoyl peroxide, clindamycin, erythromycin, clarithromycin, metronidazole, azelaic acid. Benzoyl peroxide (BP) is non-specific oxidising agent, is bactericidal for *Propionibacterium acnes* and decreases inflammation of acne lesions. Combination therapy of BP with topical antibiotic is more effective and decreases antibiotic resistance. BP may cause erythema, burning, peeling and dryness and may cause bleaching of hair and clothes. Metronidazole is indicated in the treatment of rosacea.

ANTIFUNGALS

Various antifungals used in dermatology, their mechanism of action and spectrum are listed in **Table 3**.

TOPICAL AND INTRALESIONAL ANTIVIRALS

Antiviral drugs used in dermatology are divided into three main categories-viricidal drugs, immunoenhancing drugs and cytodestructive drugs. The major drugs in these categories are listed in **Table 4**.

TOPICAL RETINOIDS

Retinoids are a group of compounds that have biological activity as that of vitamin A. Topical retinoids currently used in india are tabulated in **Table 5**.

SYSTEMIC CORTICOSTEROIDS

Systemic corticosteroids are synthetic derivatives of the natural steroid, cortisol, which is produced by the adrenal glands. They are called 'systemic' steroids if taken by mouth or given by injection as opposed to topical corticosteroids, which are applied directly to the skin (**Table 6**).

Mechanism of Action

Corticosteroids bind to the receptor on the cell membrane, translocate to the nucleus and act as agonist or antagonist to multiple genes. They inhibit NFκB and AP-1 genes leading to decreased production of multiple cytokines such as IL-1, TNF,

Table 3: Antifungals and their Route of Administration

Drugs	Mechanism of action	Spectrum
Polyenes Nystatin (topical)	Binds to cell membrane sterols and causes change in cell permeability and cell leakage	Yeasts *(Candida)*
Azoles Topical: miconazole, clotrimazole, oxiconazole, sertaconazole Topical and oral: ketoconazole, flucanazole, itraconazole	Inhibits lanosterol demethylase leading to inhibition of ergosterol synthesis	Dermatophytes, *Candida, M. furfur*
Allylamines Terbinafine (oral and topical), Naftifine (topical)	Inhibit squalene epoxidase leading to inhibition of ergosterol synthesis	Dermatophytes, *Candida* (only Terbinafine)
Benzylamines Butenafine (topical)	Inhibit squalene epoxidase leading to inhibition of sterol synthesis	Dermatophytes, *Candida* (weak activity)
Griseofulvin (oral)		Dermatophytes, mainly *tinea capitis*
Ciclopirox olamine (topical)	Interferes with membrane transport of essential molecular precursors, cell membrane integrity and cell respiratory process	Dermatophytes, *Candida, M. furfur*
Selenium sulphide (topical)	Cytostatic effect on epidermal cells leading to shedding of fungi	Used for treatment of tinea versi-colour and *seborrhoeic capitis*

Table 4: Antiviral Drugs

Group	Drugs	Mechanism of action	Spectrum	Clinical uses	Adverse effects
Viricidal	Acyclovir	Inhibits viral DNA polymerase	HSV-1, HSV-2, VZV	Herpes genitalis and Herpes labialis	Mild pain, burning, stinging
	Cidofovir (under research for topical use)	Inhibits viral DNA synthesis	HSV, MCV, HPV	Herpes genitalis and Herpes labialis, codyloma acuminate, verruca vulgaris, Molluscum contagiosum	Headache, nausea, rash, pain, ulceration, paraesthesia
Immunoenhancing	Imiquimod	Immunomodulator, inducer of IL, TNF, IFN	HPV, HSV, MCV	External genital and perianal warts	Erythema, erosions, oedema, burning, stinging, rash, flu like symptoms
Cytodestructive	Podophyllin	Antimitotic, arrests cells in metaphase		Condyloma acuminate	Erythema, erosions, burning, contraindicated in pregnancy
	Trichloroacetic acid	Causes hydrolysis of cellular proteins leading to cell death		Genital warts, molluscum contagiosum	Local pain, ulceration
	Salicylic acid	Keratolytic		Warts located on hands and feet	Nausea, vomiting, tinnitus, delirium

Table 5: Retinoids

Retinoid	Mechanism of action	Therapeutic effects	Clinical uses	Adverse effects
Tretinoin Isotretinoin	Affects cellular differentiation and proliferation, normalises follicular epithelial differentiation	Comedolysis, epidermal thickening, dermal regeneration, pigment lightening	Acne vulgaris, fine wrinkle, mottled hyperpigmentation	Irritation, erythema, desquamation, pruritis, burning, worsening of psoriasis (tazoretene)
Adapelene	normalises follicular epithelial differentiation	Comedolysis	Acne vulgaris	
Tazarotene	Modulates the expression of genes that regulate cell differentiation, proliferation and inflammation	Normalises proliferation and differentiation of cells in psoriasis, comedolysis	Psoriasis (< 20% of body surface), Acne vulgaris	

Table 6: Classification of Systemic Corticosteroids

Drug	Equivalent dose (mg)	Glucocorticoid potency	Mineralocorticoid potency
Short acting			
Cortisone	25	0.8	2+
Hydrocortisone	20	1	2+
Intermediate acting			
Prednisone	5	4	1+
Prednisolone	5	4	1+
Methylprednisolone	4	5	0
Triamcinolone	4	5	0
Long acting			
Dexamethasone	0.75	20 to 30	0
Betamethasone	0.75	20 to 30	0

cause lymphocyte and eosinophil apoptosis, alter signal transduction by inhibiting phospholipase A_2 leading to decreased production of various prostaglandins, leucotrienes and other inflammatory mediators. They also have inhibitory effect on various white blood cells subsets leading to decreased cellular and humoural immunity. Corticosteroids also cause vasoconstriction, decreased angiogenesis and decreased vascular permeability.

Indications

Systemic corticosteroids are indicated in various bullous dermatoses, autoimmune connective tissue disease, vasculitis, contact dermatitis, papulosquamous disease such as lichen planus and neutrophilic dermatoses.

Contraindications

Absolute contraindications are systemic fungal infection, herpes simplex keratitis. Relative contraindications are hypertension, CHF, depression, previous pyschosis, active TB, diabetes, osteoporosis, pregnancy, cataract, glaucoma and gastric ulcer disease.

Side Effects

Hypothalamic-pituitary adrenal (HPA) axis suppression, addisonian crisis, Cushing's syndrome, hyperglycaemia, increased appetite, hypertension, CHF, hypokalaemia, hypertriglyceridaemia, hypocalcaemia, osteoporosis, avascular nacrosis of head of femur, peptic ulcer disease, cataract, glaucoma, infections, pyschosis, depression, myopathy, pseudotumour cerebri and peripheral neuropathy.

ANTIHISTAMINICS IN DERMATOLOGY

Antihistaminics represent the standard approach for the management of various allergic disorders. They block the effects of the histamine by blocking the H_1 receptors. Major group of antihistaminics are listed below in **Table 7**.

Mechanism of Action

These drugs competitively block the action of histamine at the level of H_1 receptors. They block histamine induced

Table 7: Group of Antihistaminics

First generation antihistaminics

Highly sedative—Diphenhydramine, Promethazine, Hydroxyzine

Moderately sedative—Pheniramine, Cyproheptadine, Meclizine, Buclizine

Mild sedative—Chlorpheniramine, Dimethindene, Mebhydrolin, Cyclizine, Clematine

Second generation antihistaminics

Terfenadine, Fexofenadine, Astemizole, Loratidine, Cetirizine, Mizolastine, Ebastine

Tricyclic antihistaminics

Doxepin

bronchoconstriction, smooth muscle contraction and triple response-wheal, flare and itch. Type I hypersensitivity reactions are suppressed. Urticaria, itching and angioedema are controlled. Many H_1 blockers antagonise muscarinic effects of acetylcholine.

Side Effects

First generation H_1 antihistaminics cross the blood-brain barrier (BBB) and cause sedation, impaired cognitive function, drowsiness. Anticholinergic activity leads to dryness of mouth, urinary hesitancy, blurring of vision, constipation. Tachycardias and dysrhythmias may occur. Second generation antihistaminics have significantly less CNS depressant property and no cholinergic side effects.

Drug Interaction

Erythromycin, clarithromycin, ketoconazole, itraconazole, HIV-1 protease inhibitors, selective serotonin reuptake inhibitors (SSRI) inhibitors increase the risk of torsades de pointes when used along with terfenadine or astemizole.

Uses

Treatment of allergic disorders such as itching, urticaria, hay fever, dermographism, pruritides.

ANTI-MALARIALS IN DERMATOLOGY

Hydroxychloroquine and chloroquine are anti-malarial medications used in the treatment of dermatological disorders. The exact mechanism by which chloroquine acts is not known they are believed to act by their effects on light filtration, immunosuppressive actions, anti-inflammatory actions and DNA binding.

Dose

Hydroxychloroquine: 200 to 400 mg per day, maximum 6.5 g per day

Chloroquine: 250 to 500 mg per day, maximum 4.0 g per day.

Indications

DLE, SLE, photosensitivity disorders pleomorhic light eruptions (PLE) and Porphyria cuternea tarda (PCT), lepra reaction type II. Hydroxychloroquine is used much more frequently than chloroquine, as chloroquine is more likely to cause irreversible retinal damage.

Adverse Effects

Visual disturbances include halos, blurred vision, photophobia, corneal deposits, retinopathy, agranulocytosis, pancytopaenia, nausea, vomiting, diarrhoea, irritability, mood swing, headache, vertigo, tinnitus, pyschosis, bleaching of hair, bluish grey pigmentation of skin, exacerbation of psoriasis, morbilliform rash.

Contraindications

Relative contraindications are pregnancy and lactation, hepatic dysfunction, neurological defects, psoriasis, visual field defects, psychosis, blood disorder, myasthenia gravis, intermittent porphyria or variegate porphyria, Glucose-6-phosphate dehydrogenase deficiency.

SYSTEMIC RETINOIDS

The retinoids are a class of chemical compounds that are related chemically to vitamin A. Systemic retinoids are divided into three groups: First generation (isotretinoin, tretinoin), second generation (etretinate, acitretin) and third generation (bexarotene). Isotretinoin and acitretin are available in India.

Mechanism of Action

Retinoids exert their effect by activating nuclear receptors and regulating gene transcription. Isotretinoin causes inhibition of sebaceous gland differentiation, proliferation, reduce the size of sebaceous gland and suppression of sebum production. It also causes normalisation of follicular epithelial desquamation. Etretinate and acitretin exert antipsoriatic effects by inducing cellular differentiation, antiproliferation, antikeratinisation and anti-inflammation. Bexarotene regulates cellular differentiation and proliferation.

Indications

Psoriasis (acitretin): Erythrodermic psoriasis, pustular psoriasis, severe plaque psoriasis and recalcitrant psoriasis, acne vulgaris (isotretinoin), Mycosis fungoides (bexarotene), other indications are Gram-negative folliculitis, rosacea, hidradenitis suppurativa, Darier's disease, pityriasis rubra pilaris and lichen planus.

Dose

Dose of isotretinoin is 0.5 to 2 mg per kg per day and that of acitretin is 25 to 50 mg per day.

Adverse Effects

Systemic retinoids have potentially serious side-effects. They are highly teratogenic and may cause retinoic acid embryopathy and spontaneous abortions. Women of childbearing age should practice complete contraception during and one month after therapy with isotretinoin and acitretin. Systemic retinoids also cause xerosis, palmoplantar desquamation, telogen effluvium, paronychia, dry eyes, cheilitis, epistaxis, headache. They also cause hypercholesterolaemia, premature epiphyseal closure, myopathy and pseudotumour cerebri and depression. Bexarotene may in addition cause leucopaenia, hypothyroidism and agranulocytosis.

CYTOTOXIC DRUGS

The common cytotoxic drugs used in dermatology are listed in **Table 8**.

SURGICAL PROCEDURES IN DERMATOLOGY

Cryotherapy

Cryotherapy is a commonly used in-office procedure for the treatment of a variety of benign and malignant lesions. The

Table 8: Cytotoxic Drugs

Drug	Mechanism of action	Indication	Side-effects	Contraindication	Dose	Note
Methotrexate	Inhibits dihydrofolate reductase,causes inhibition of cell division in S phase of cell cycle	Psoriasis (pustular, erythrodermic, extensive plaque psoriasis,psoriatic arthritis), Sezary syndrome	Hepatotoxicity, pancytopaenia, malignancy (lymphoma),acute pneumonitis, nausea,anorexia, alopaecia, fatigue	Absolute: Pregnancy and lactation. Relative:alcoholism patient,hepatic disease.	0.3 mg/ kg/week in divided doses	Folic acid 5 mg daily reduces of incidence pancytopaenia and GI side effects
Azathioprine	Active metabolite is 6-thioguanine which inhibits DNA and RNA synthesis leading to decreased T- and B-cell function	Photodermatosis, pemphigus and bullous pemphigoid, contact dermatitis, atopic dermatitis, SLE, connective tissue disease	Malignancy (lymphoma), pancytopaenia, infections, hypersensitivity syndrome, nausea, vomiting	Pregnancy	Up to 2 to 2.5 mg/kg/day	Use cautiously with concomitant allopurinol use
Cyclopho-sphamide	Active metabolite is aldophosphamide and phosphamide mustard. Cell cycle nonspecific. Inhibits B- and T-cell function	Mycosis fungoides, pemphigus, pemphigoid, histiocytosis, vasculitis	Haemorrhagic cystitis, dysuria, urgency, pancytopaenia, increased risk of lymphoma and bladder carcinoma, hair fall, nausea, hepatotoxicity	Absolute: pregnancy and lactation, bone marrow depression Relative: impaired hepatic or renal function	1 to 3 mg/ kg/day	Take plenty of fluids. Mesna decreases the risk of haemorrhagic cystitis
Cyclosporine	Inhibits calcineurin leading to decreased production of IL-2 which causes decreased T-cell proliferation. Also causes decreased production of pro-inflammatory cytokines	Psoriasis, lichen planus, bullous dermatosis, trichosis, connective tissue disease, atopic dermatitis	Renal dysfunction, hypertension, tremors, headache, hyper-gingivial hyperplasia, myalgia,hyperkalaemia, hyperuricaemia, hyperlipidaemia	Uncontrolled hypertension, decreased renal function	2.5 to 5 mg/ kg/day	

mechanism of destruction in cryotherapy is necrosis, which results from the freezing and thawing of cells. Treated areas re-epithelialise. Liquid nitrogen is preferred to other common refrigerants because of its lower boiling point, ease of use and relative safety.

Indications

Benign lesions such as acne, acne Keloidalis, cherry angiomas, keloids, lentigenes, molluscum contagiosum, seborrhoeic keratosis, skin tags, warts and xanthomas.

Premalignant and malignant lesions such as actinic cheilitis, Bowen's disease, leucoplakia, basal and squamous cell carcinoma, and Kaposi's sarcoma.

Complications

1. Acute complications include headache, pain, oedema and blister formation.
2. Delayed complications include haemorrhage, infection and excessive granulation tissue formation.
3. Prolonged-temporary complications include milia, hyperpigmentation and altered sensory nerve function.
4. Permanent complications include alopaecia, atrophy, keloids, scarring, hypopigmentation and ectropion formation.

Relative contraindications to cryotherapy include cold intolerance, cold urticaria, cryoglobulinaemia, history of pyoderma gangrenosum and Raynaud's disease.

Absolute contraindications include the use of cryotherapy near the eye margins.

ELECTROCAUTERY

Electrocauterisation is the process of destroying tissue using heat conduction from a metal probe heated by electric current. Since the heat does not penetrate deeper then papillary dermis, electrocautery is best used for very superficial lesions such as flat seborrhoeic keratosis or acrochordons.

DERMABRASION

Dermabrasion involves resurfacing the skin, from the epidermis, through the papillary dermis, maximum up to the junction of upper and mid reticular dermis either manually, with electrical abraders or CO_2 laser. The wound is allowed to heal by secondary intention, so as to achieve levelling effect, making the scar less conspicuous. The common indications for dermabrasion are acne scars and other facial scars, stable vitiligo, hypertrophic lichen planus, lichen simplex chronicus hypertropicus, actinic keratosis, fine wrinkles, tattoo removal and various tumours.

Adverse effects

Pain, oedema, crusting, hyperpigmentation/hypopigmentation, keloids and hypertrophic scars.

LASERS IN DERMATOLOGY

LASER stands for light amplification by the stimulated emission of radiation. The various types of skin disorders treated by lasers along with type of laser are indicated below:

1. Vascular lesions—vascular malformations, telangiectasias, haemangiomas (Pulsed dye laser).
2. Pigmented lesions—birth marks, Freckles (PDL, Q switched ND-YAG, Q switched Ruby).
3. Hair removal (800 diode, 1,064 long pulsed ND-YAG, IPL).
4. Keloids, hypertrophic scars, warts, seborrhoeic keratosis (CO_2 laser).

DERMAL FILLERS

Although soft-tissue augmentation is not a new cosmetic procedure, the discovery of new materials, suitable for injection into subcutaneous tissue and more refined techniques has enabled many defects to be corrected very well. The materials commonly used for augmentation are silicone, bovine collagen, autologous fat, hyaluronic acid, fibrel, new fill, etc.

Indications

Furrows, wrinkles, depressed scars, lip augmentation and shaping, profile defects of the face.

HAIR TRANSPLANTATION

Hair transplantation is a surgical technique that involves moving skin containing hair follicles from one part of the body (the donor site) to bald or balding parts (the recipient site). It is primarily used to treat male pattern baldness. It is also used to restore eyelashes, eyebrows, and beard hair, and to fill in scars caused by accidents and surgery. The various methods of hair transplantation consist of punch grafts, mini-and micrografts, single hair grafts and follicular unit grafts. Punch grafting causes fibrosis and paddy field appearance and is generally not preferred now a days. Follicular unit grafts give natural and fuller look and is considered to be the best method of hair transplantation.

12.1 Basic Considerations in Cardiology

Upendra Kaul, Aijaz H Mansoor

CARDIAC ANATOMY

Location

Heart is an irregularly conical hollow muscular organ, lying obliquely in the middle mediastinum. Right atrium (RA) forms the right heart border, left ventricle (LV) mainly forms the left border and the inferior border is formed mainly by the right ventricle (RV). Anterior surface is mostly formed by the RV, while the inferior surface consists of the right and left ventricles. The posterior surface is quadrilateral, formed mainly by the left atrium (LA). The base is oriented superiorly while the apex points leftward, anteriorly, and slightly inferiorly (levocardia). The heart is retrosternal, two-thirds to the left of the centreline.

The left heart border is formed from above downward by a part of descending thoracic aorta (aortic knuckle on chest radiograph), the pulmonary artery, the left atrial appendage and the LV. The right heart border, mostly retrosternal, is formed by RA with contribution from the venae cavae. The LV apex generally forms the true apex of the heart.

Measurements

The adult heart weighs approximately 325 ± 75 g in men and 275 ± 75 g in women. It measures about 5 inches from base to apex and is 3 inches in width.

The Pericardium

The heart and the origins of the great arteries are enclosed in the conical fibrous pericardium. Within this inelastic fibrous layer lies the serous pericardium. The visceral layer closely adheres to the heart, the parietal layer lines the fibrous pericardium. Between the two layers is a potential space (pericardial space) that contains 10 to 25 cc of fluid. The pericardium maintains the position of the heart within the mediastinum, lubricates the cardiac surfaces and forms a barrier against infection.

The Cardiac Chambers

The RA is a capacitance chamber that receives blood superiorly from the superior vena cava (SVC) and inferiorly from the inferior vena cava (IVC), and its Eustachian valve directs blood flow towards the fossa ovalis. The coronary sinus returns blood from the heart itself and its orifice is partially guarded by the Thebesian valve. Chiari net describes large and fenestrated Thebesian and Eustachian valves. The Thebesian veins directly drain cardiac blood into the heart via multiple orifices. Running almost vertically between the venae cavae is a 'C'-shaped muscular ridge (Crista terminalis) that separates the smooth-walled posterior RA (derived from sinus venosus) from the rough-walled anterior portion, which is prolonged into the triangular auricular appendage. Tendon of Todaro is a fibrous band located between the valves of the IVC and coronary sinus. Between the tendon of Todaro and the tricuspid annulus, is the triangle of Koch; the apex of this triangle overlies the AV node and bundle of His.

The RV is the most anterior heart chamber. Its free wall is about one-third the thickness of the LV. The RV consists of an inlet portion, a trabeculated apical portion and a smooth outflow tract (infundibulum or conus portion). The RV walls show a lattice-work of muscle fibres (trabeculae carneae). The RV contains three papillary muscles, from which extend chordae tendineae, attaching to the leaflet edges. The moderator band is an intracavitary muscle bridge connecting the RV free wall and the distal interventricular septum. It conveys the right bundle branch to the ventricular muscle.

The LA forms the left upper and posterior chamber of the heart. It is a cuboidal structure and receives four pulmonary veins. It is smaller than RA, has thicker walls (3 mm) and higher pressure. Internally it is smooth-walled and does not contain pectinate muscles except in the left atrial appendage. The LA appendage overlies the left circumflex artery and is smaller, longer, windsock shaped structure.

The LV is a high pressure chamber, thicker than the RV (2 to 3 times). Structurally, it contains the inflow tract, the apical zone and the left ventricular outflow tract (LVOT). The ventricular heart muscle is tri-layered (epicardium, myocardium and endocardium). The outer two-thirds of the myocardium has compact muscle layers that twist and spiral from apex to base during contraction. The LV contains two papillary muscles (anterolateral and posteromedial) from which chordae tendineae arise and attach to mitral valve leaflet edges. The chordae check leaflet excursion and prevent valve prolapse. False chordae do not attach to the mitral valve but attach to septum or free wall.

Cardiac Valves

Tricuspid valve is the largest, having three leaflets (anterior, posterior and septal). The mitral valve is funnel shaped (**Figure 1**),

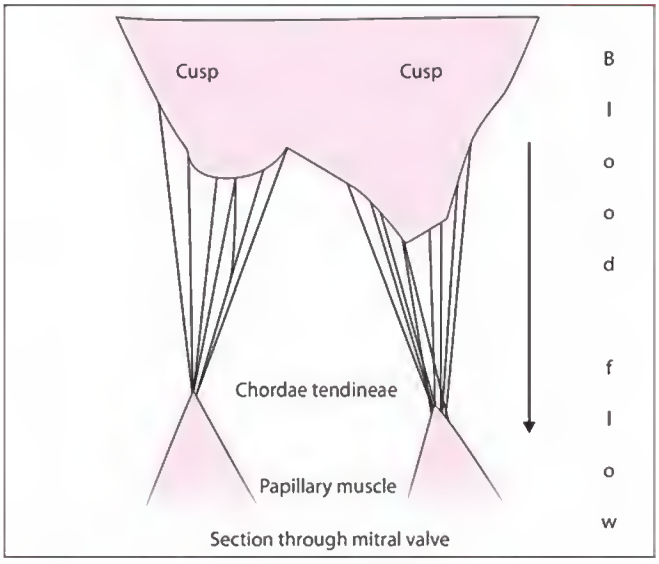

Figure 1: Schematic section through the mitral valve.

with two leaflets forming the apex and protruding into the LV. The posterior leaflet is crescent shaped, longer, narrower and attaches to over two-thirds of the annulus. It has three scallops. The anterior mitral valve is semicircular or oval shaped. The mitral chordae do not have insertions into the septum.

The aortic valve, the thicker and stronger of the semilunar valves (**Figures 2A and B**), consists of annulus, three cusps and a commissure. Approximately 2% of aortic valves are bicuspid. The nodules of Arantius are small fibrous mounds at the centre of the free edge of each cusp. Aortic valve has no tensor apparatus. Behind each cusp the wall bulges outward to form sinus of Valsalva. The aortic cusps are named as right, left and non-coronary (posterior); the right and left sinuses give rise to the corresponding right and left coronary arteries. Pulmonary valve is a mirror image of the aortic valve with similar but thinner cusps.

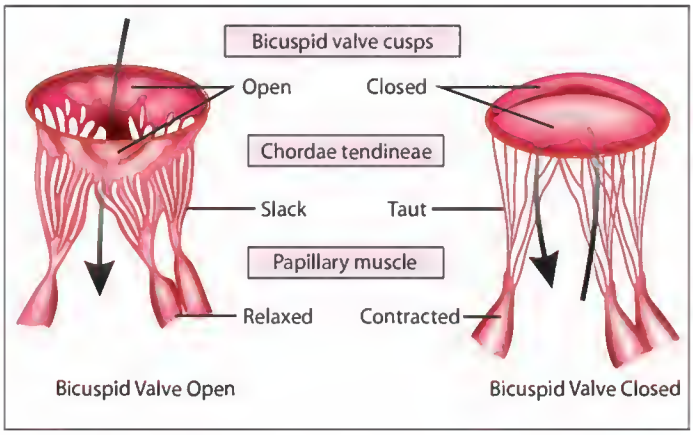

Figure 2A: Tensor apparatus of semilunar valve.

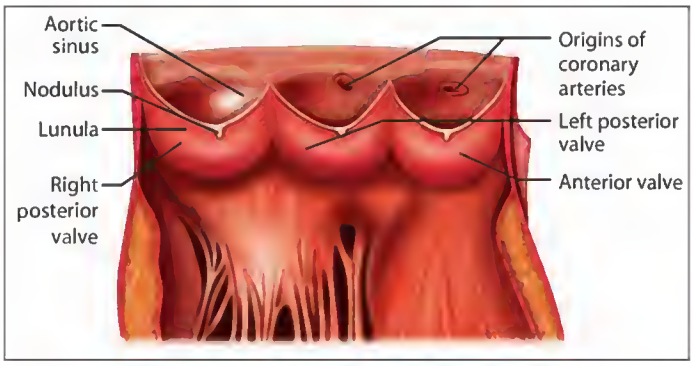

Figure 2B: Aorta cut open to reveal the aortic valve.

At the base of the heart, the fibrous cardiac skeleton encircles the four cardiac valves (annuli, fibrous trigones, intervalvular fibrosa and conus ligament). The fibrous scaffold is firmly anchored to the ventricle. It electrically insulates atria from the ventricles, supports the cardiac valves and provides a firm foundation against which the ventricles may contract.

CORONARY CIRCULATION

The coronaries are the first branches arising from the aorta (**Figure 3**). The right coronary artery (RCA) is located in the right atrioventricular groove and bifurcates at the crux into the posterior descending artery (PDA) and posterior left ventricle branches (PLBs). A dominant RCA provides the PDA and the PLBs; A co-dominant RCA provides the PDA, but the left

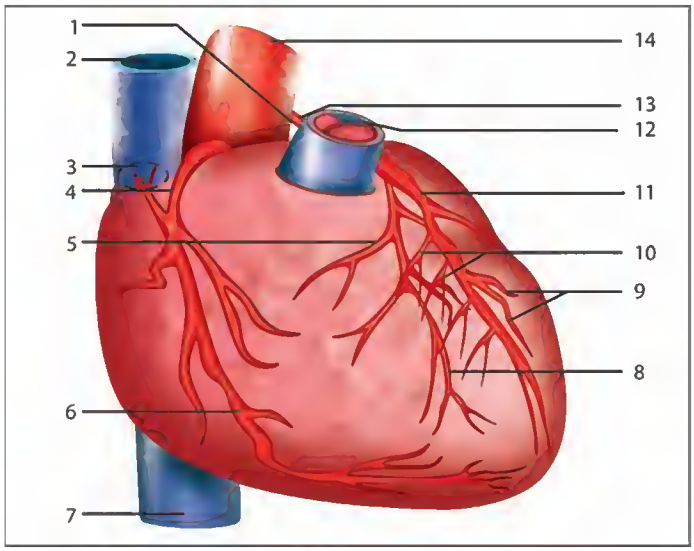

Figure 3: Coronary arteries and their branches.

1 = Left coronary artery; 2 = Superior vena cava; 3 = Sino-atrial node; 4 = Right coronary artery; 5 = Circumflex artery; 6 = Posterior descending artery; 7 = Inferior vena cava; 8 = Obtuse marginal; 9 = Diagonal branches; 10 = Septal perforator; 11 = Left anterior descending artery; 12 = Pulmonary artery and valve; 13 = Left main coronary artery; 14 = Aorta.

circumflex artery supplies the PLBs. A non-dominant RCA is small and does not reach the crux. The RCA dominates in three fourths of cases.

The left main trunk is 1 to 4 cm in length and bifurcates into the left anterior descending artery (LAD) and the left circumflex artery (LCX). In 30% cases, a third branch arises between the two (ramus intermedius). The LAD supplies blood to the ventricular septum (through four to seven septal perforators) and the anterolateral wall (through one to three diagonal branches). The LCX supplies the lateral wall of LV and LA.

The venous system of the heart consists of coronary sinus, cardiac veins and the Thebesian veins. The bulk of the venous drainage of the heart is carried out by veins accompanying coronary arteries and which drain into the RA via coronary sinus. The rest of the blood drains via venae cordae minimae directly into the cardiac cavity.

The electrocardiogram (ECG) can fairly well localise areas of ischaemia or infarction supplied by individual coronary arteries. The coronary blood flow is maintained remarkably constant over a wide range of blood pressures. Any increase in myocardial oxygen demand must be met by increased coronary blood flow.

THE CONDUCTION SYSTEM

It consists of the sino-atrial node (SA node), the atrio-ventricular (AV) node, the bundle of His, the right and left bundle branches and the Purkinje fibres (**Figure 4**). The heart beat is initiated in the SA node (the heart pacemaker), situated in the upper part of the crista terminalis (just to the right of the SVC-RA junction). It spreads down via the AV node into the ventricles. The RCA supplies the SA node (65% cases) and the AV node (80% cases). The nerve supply of the heart is derived from the vagus (cardio-inhibitory) and the cervical and upper thoracic sympathetic ganglia (cardio-accelerator). The transplanted heart is completely denervated and responds only to circulating substances and not to impulses of the autonomic system.

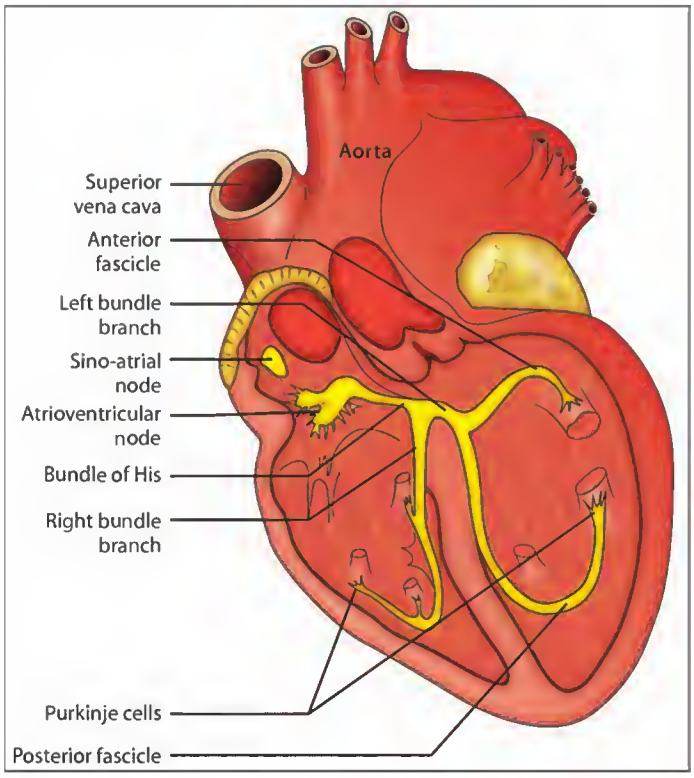

Figure 4: Conduction system of the heart.

CARDIOVASCULAR PHYSIOLOGY

The Circulation

The RA receives deoxygenated blood from the SVC and IVC, and discharges blood to the RV, which in turn pumps it into the pulmonary artery. Blood passes through the pulmonary arterial and alveolar capillary bed where it is oxygenated, then drains via four pulmonary veins into the LA. This in turn fills the LV, which delivers blood into the aorta (**Figure 5**). During ventricular contraction (systole), the tricuspid valve in the right heart and the mitral valve in the left heart close and the pulmonary and aortic valves open. In diastole, the pulmonary and aortic valves close and the two AV valves open. Collectively, these atrial and ventricular events constitute the cardiac cycle of filling and ejection of blood from one heart beat to the next (**Figure 6**).

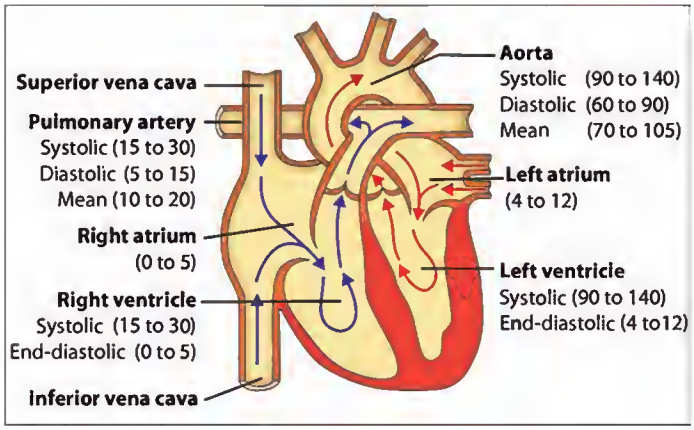

Figure 5: Direction of blood flow through the heart. The blue arrows show deoxygenated blood moving through the right heart to the lungs. The red arrows show oxygenated blood moving from the lungs to the systemic circulation. The normal pressures are shown for each chamber in mm Hg.

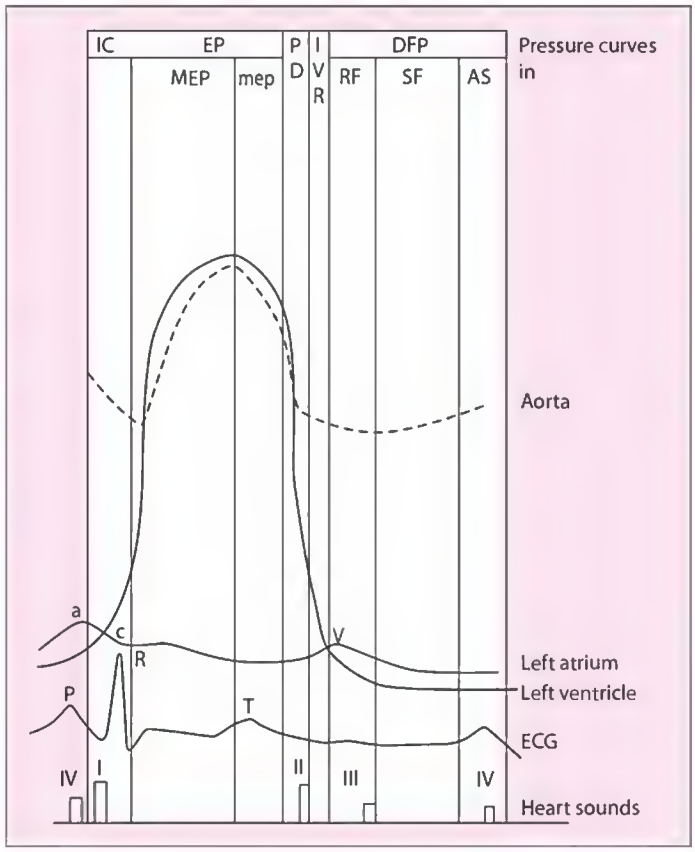

Figure 6: The cardiac cycle.

EP = Ejection period; DFP = Diastolic filling period; IC = Isovolumic contraction; MEP = Maximum ejection phase; mep = Minimum ejection phase; PD = Protodiastole; IVR = Isovolumic relaxation phase; RF = Rapid filling; SF = Slow filling; AS = Atrial systole.

The Determinants of Cardiac Output

Ejection fraction is the percentage of ventricular volume ejected by the ventricle per beat whereas cardiac output is the volume of blood pumped by ventricle per minute. Cardiac output is a paramount physiological variable that is adjusted as per body requirements. It is a product of stroke volume and heart rate. Influences on stroke volume will impact cardiac output, and stroke volume can be altered by changes in preload, contractility, and afterload. Preload is the haemodynamic load (stretch) on the myocardial wall fibres at end-diastole. Clinically, the end-diastolic volume (EDV) is the best measure of LV preload. Changes in ventricular preload operate via Frank-Starling law of the heart. This law states that, 'with all factors equal, stroke volume increase as cardiac filling increases'. Several factors determine preload including intra-thoracic pressure, venous return, body position, skeletal muscle pump function, total blood volume, intra-pericardial pressures and atrial contractility. Contractility is the intrinsic ability and degree of contraction of the cardiac muscle. Ejection fraction is an approximate guide to the degree of contractility. Important factors determining cardiac contractility include sympathetic activity, circulating/exogenous inotropes, cardio-depressant drugs, hypoxia, acidosis, and ischaemia. Sympathetic stimulation increases muscle shortening, and therefore, increases stroke volume by decreasing end-systolic volume (ESV). Myocardial contractility is understood well by the LV pressure-volume curve (**Figure 7**). The curve shifts upwards when cardiac contractility

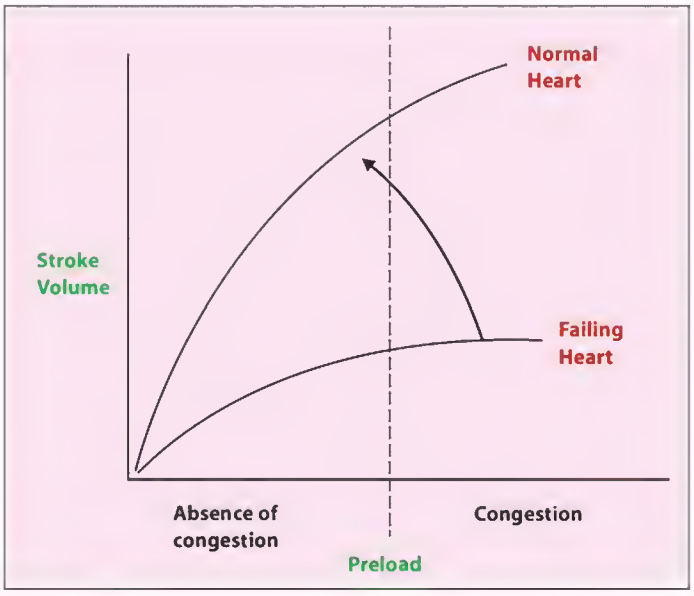

Figure 7: Pressure-volume curve of the normal and failing heart.

is enhanced. In heart failure, the curve is plateau. Afterload is the resistance against which the ventricle is contracting. It is also defined as the wall tension generated during cardiac contraction. The common measures of afterload are: aortic pressure, systemic arterial resistance, arterial impedance, myocardial peak wall stress and LV pressure. An abnormally high afterload decreases stroke volume by decreasing ESV.

Pressure-Volume Loops

These can be constructed in the catheterisation laboratory using high fidelity catheters. When the ventricular volumes during one cardiac cycle are plotted against simultaneous pressures within the ventricle, a pressure-volume loop is generated. End-diastolic pressure-volume relationships (EDPVR) and end-systolic pressure-volume relationship (ESPVR) are the key components of a pressure-volume loop. The cardiac muscle length tension behaviour is the underlying basis for ventricular function. The physiologic measurements obtainable from pressure-volume loop are: volumes (EDV and ESV), pressures (end-systolic and end-diastolic pressures), compliance, elastance, stroke work and contractility.

Compliance is the change in volumes for a given change in pressure (Reciprocal of EDPVR). Compliance is greater at lower volumes. Structural and pressure changes in heart, pericardium and thorax affect changes in compliance. Elastance is the linear relationship between the change in pressure for a given change in volume at end-systole. Stroke work is represented by the area of the pressure-volume loop and represents the work of the heart during each heart beat. Contractility is an intrinsic attribute independent of loading conditions.

Cardiac Energetics

The myocardial adenosine triphosphate (ATP) pool turns over every 10 seconds. In adults, 60% to 90% of ATP is derived from fatty acids, whereas in foetus and neonates, glucose and lactate are the main ATP sources. In advanced heart failure, the cardiac energetics shift back to the faetal form. Cardiac energy requirement is derived primarily from aerobic metabolic pathways such that cardiac work is tightly related to myocardial oxygen consumption. A simple index of the energy demands of the heart is obtained by the product of peak systolic arterial pressure and heart rate. Determinants of myocardial oxygen consumption include myocardial muscle mass, wall stress, contractility and heart rate.

Normal LV diastolic function implies LV filling to a normal EDV, on exercise, as well as rest, without elevating mean LA pressure above 13 mm Hg. Diastolic dysfunction may be seen in several conditions, including systemic hypertension, LV hypertrophy, restrictive cardiomyopathies and pericardial diseases (e.g. constrictive pericarditis). Diastolic dysfunction eventually leads to heart failure with preserved ejection fraction.

The vascular endothelium has been called the cardiovascular endocrine organ. It produces various compounds (e.g. nitrous oxide, endothelin, prostacyclin, endothelial-derived hyperpolarising factor, vascular endothelial growth factor and adhesion molecules). A number of enzymes are located on the surface that control the levels of circulating compounds such as angiotensin, bradykinin and serotonin. It also plays regulatory roles (control of vasomotion, thrombotic status, immune response modulation and vascular cell growth).

12.2 Cardiovascular Diseases—A Clinical Approach

GS Sainani

To evaluate a patient with cardiovascular disorder, one has to elicit a proper history, carry out clinical examination, and routine investigations such as roentgenogram of the chest, electrocardiogram, pertinent biochemical and haematological tests. However, a definitive diagnosis is not made on the basis of these; further investigations like echocardiography (M-mode, 2-dimensional, colour Doppler), treadmill exercise test, Holter ambulatory ECG monitoring, radionuclide tests (multigated blood pool studies, thallium exercise test), digital subtraction angiography, cardiac catheterisation and coronary angiography may also be needed.

HISTORY

A patient may be asymptomatic and unaware of his underlying cardiac disease. The common symptoms are:

Dyspnoea

This is a subjective feeling of difficulty in breathing and is due to passive congestion in pulmonary veins and pulmonary capillaries secondary to left-sided cardiac failure.

Dyspnoea has been graded by the New York Heart Association (NYHA) into 4 grades in the presence of cardiac disease.

Grade I : No dyspnoea on any work

Grade II : Dyspnoea on ordinary work

Grade III : Dyspnoea while doing less than accustomed work

Grade IV : Dyspnoea at rest

Dyspnoea may manifest as exertional dyspnoea, paroxysmal nocturnal dyspnoea, orthopnoea or acute pulmonary oedema. *Orthopnoea* is the stage when a patient feels breathless while he lies flat and is relieved by sitting up. In *paroxysmal nocturnal dyspnoea,* the patient gets sudden attacks of dyspnoea during sleep; these wake him up and force him to sit upright. The attack may pass off in a few minutes. In acute pulmonary oedema, which occurs as a result of acute left ventricular failure, the patient gets a sudden attack of dyspnoea and cough with white or pink frothy sputum, sweating, tachycardia and cyanosis.

Cough

Cough of pulmonary venous hypertension is irritating, non-productive and worse at night. In some cases, such dry cough occurring during exertion may first raise the suspicion of underlying cardiac disease.

In severe pulmonary venous hypertension and pulmonary infarction, blood-tinged sputum is seen while in pulmonary oedema, the sputum is pink and frothy.

Oedema

Oedema occurs over the dependent parts (feet in an ambulatory person). In advanced cases, there is generalised oedema with ascites. **Table 1** gives other causes of oedema.

Table 1: Important Causes of Oedema Feet

Congestive cardiac failure
Nephrotic syndrome
Liver cirrhosis
Hypoalbuminaemia (nutritional, protein-losing enteropathy)
Venous insufficiency (obesity, old age)
Chronic lymphatic obstruction
Drug induced (steroids, NSAIDs, nifedipine)
Idiopathic

Pain in Right Upper Abdomen

This is due to congestive hepatomegaly. Due to systemic venous congestion, the liver becomes enlarged and tender. The patient may present with pain in the upper abdomen.

Oliguria and Nocturia

Due to oedema, the patient complains of oliguria particularly during the day. At night, due to redistribution of fluid, the patient's renal perfusion improves and he gets nocturia, with the result that oedema becomes less in the morning.

Palpitation

Palpitation is consciousness of heart beating. This may be due to an enlarged, hyperdynamic left ventricle as seen in mitral and aortic incompetence, or may occur due to arrhythmias like extrasystole, sinus tachycardia and paroxysmal tachycardias.

Chest Pain

Angina pectoris is chest pain due to impaired coronary flow. The classical features are shown in **Figure 1**.

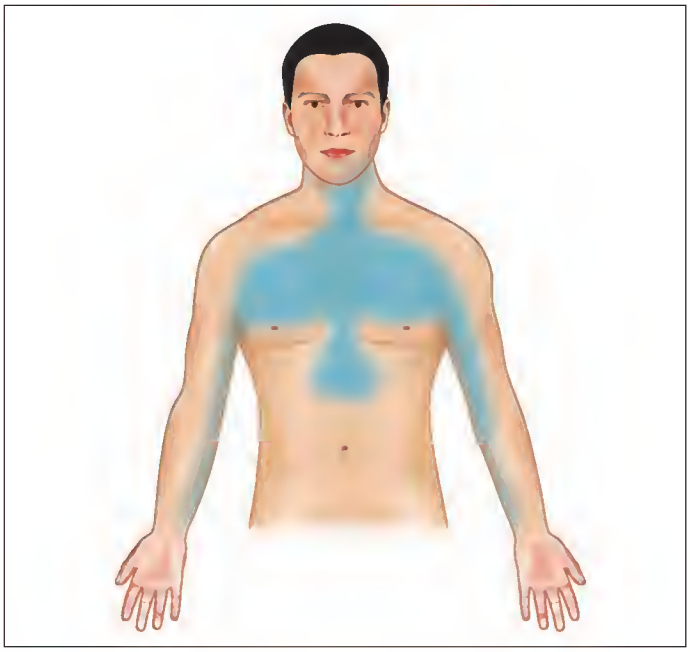

Figure 1: Location of pain in angina pectoris.

1. *Site of pain:* Retrosternal.
2. *Character:* Constricting/crushing.
3. *Radiation:* Across the chest, both arms and shoulders (more commonly left-sided), interscapular region, neck, jaw, fingers and epigastric region.
4. *Duration:* Exertional angina lasts 1 to 5 minutes, emotion-induced angina, 5 to 15 minutes; any pain which lasts for a few seconds is not ischaemic in origin.
5. *Precipitating factors:* Exertion, climbing stairs or uphill, anger, excitement, sudden exposure to cold.
6. *Relief:* Rest, sublingual nitroglycerine or isosorbide dinitrate relieves the pain. This is a stable angina.

Unstable angina occurs at any time, even at rest, without obvious precipitating factors. The pain lasts for several minutes.

In acute myocardial infarction, the characteristics of the pain are the same but it lasts longer, is more severe and is accompanied by sweating, breathlessness and even circulatory collapse. In pericarditis, pain is constant, not related to exertion, pricking in character and localised to the mid praecordium.

Syncope

Syncope is a transient loss of consciousness due to impairment of cerebral perfusion. In heart disease, due to low output, there is cerebral underperfusion.

Fatigue

This is caused by low cardiac output leading to poor blood supply to the muscles. Low cardiac output is due to defective pumping action of the heart which is secondary to myocardial muscle disease, valvular heart disease, coronary artery disease or even pericardial disease (constrictive pericarditis and pericarditis with effusion).

Cyanosis

Though patients may complain of cyanosis, usually this is observed by the physician. Cyanosis may be peripheral or central.

Peripheral cyanosis is restricted to the distal parts of the extremities, i.e. fingers, toes, nails and tip of the nose and ears. It occurs in low cardiac output states with peripheral vasoconstriction.

Central cyanosis occurs in the mucous membranes (tongue, lips) and nails where it is usually associated with clubbing. The hands are warm in contrast with peripheral cyanosis in which the hands are cold.

It is due to shunting of blood from the venous to the arterial side at the ventricular, atrial or aortopulmonary level. Another cause of central cyanosis is inadequate ventilation and impaired oxygenation as seen in interstitial pulmonary fibrosis and gross obesity (Pickwickian syndrome). It must be remembered that in patients with severe anaemia, with haemoglobin of 5 g/dL or less, cyanosis will not be perceptible because for central cyanosis to appear, capillary content of reduced haemoglobin should be more than 5 g%.

Differential cyanosis is a rare situation in which cyanosis is restricted to the lower extremities. This is seen in patients with patent ductus arteriosus and pulmonary hypertension with a right-to-left shunt.

Squatting

The squatting position is assumed by cyanotic children, particularly those with tetralogy of Fallot. By squatting, arterial resistance is increased, thus diverting greater volume of blood to the pulmonary circulation for better oxygenation. This relieves the anoxic spells.

GENERAL EXAMINATION

The child may be underdeveloped and short statured due to long-standing valvular heart disease or congenital heart (particularly cyanotic) disease. In adults, chronic congestive heart failure may lead to cachexia. Some congenital heart diseases are associated with systemic disorders related to the musculoskeletal system (**Table 2**), endocrine system (**Table 3**), metabolic and chromosomal disorders (**Table 4**), and connective tissue disorders (**Table 5**). One should therefore look for non-cardiac features.

Table 2: Syndromes Associated with Cardiac and Musculoskeletal Manifestations

Syndrome	Cardiac Abnormality	Non-cardiac Findings
Holt-Oram	Atrial septal defect	Hypoplastic thumb and radius
Ellis-van Creveld	Atrial septal defect	Dwarfism, polydactyly
Noonan's	Pulmonary valve dysplasia	Webbed neck, pectus excavatum
Kartagener's	Dextrocardia	Sinusitis, bronchiectasis
Laurence-Moon-Biedl-Bardet	Variable defects	Polydactyly, obesity

Table 3: Endocrine Disorders with Cardiac Manifestations

Disorder	Cardiac Findings	Non-cardiac Findings
Hypo-thyroidism	Pericardial effusion, congestive heart failure	Dry thick skin, dry hair, loss of lateral eyebrows, slow relaxation phase of tendon jerk
Hyper-thyroidism	Sinus tachycardia, atrial fibrillation	Asthenic build, tremors, exophthalmos, etc.
Cushing's	Hypertension	Moon face, obesity, striae, etc.
Addison's	Hypotension	Pigmentation of skin and oral mucosa, generalised wasting
Phaeochromo-cytoma	Labile hyper-tension	Neurofibromata
Acromegaly	Hypertension, cardiomyopathy	Tall stature, prognathism, visceromegaly

Pulse

Brachial arterial pulse is better felt, but conventionally the radial artery is examined. To assess the volume of the pulse, the palpating finger should compress the artery with pressure just sufficient to obliterate it during diastole. Thus, the artery can re-expand against the palpating finger during systole. Other arteries, e.g. the opposite radial, femorals, dorsalis pedis, posterior tibials, carotids, subclavians and temporals should be palpated and compared for any delay or difference in volume. In coarctation of the aorta, the volume of the femoral pulse is not only lower than the radial but the femoral pulse is also delayed.

Table 4: Metabolic and Chromosomal Disorders with Cardiac Manifestations

Disorder	Cardiac Findings	Non-Cardiac Findings
Mucopolysaccharidosis, e.g. Hurler's and Hunter's syndromes	Multivalvular disease	Growth and mental retardation, etc.
Chromosomal disorders		
Down's syndrome	Endocardial cushion defects	Mongoloid facies, mental retardation, etc.
Turner's syndrome	Coarctation of aorta	Short female, broad chest, webbed neck, etc.

Table 5: Connective Tissue Disorders with Cardiac Manifestations

Disorder	Cardiac Findings	Non-Cardiac Findings
Marfan's	Aortic dilatation, aortic and mitral regurgitation	Tall thin built, arachnodactyly, etc.
Ehlers-Danlos	Mitral regurgitation	Hyperelastic skin and joints
Pseudoxanthoma elasticum and elastic fibres	Arterial disease	Angioid streaks, degeneration of skin
Osteogenesis imperfecta	Aortic regurgitation	Fragile bones, blue sclera

The pulse is described under the following headings: rate, rhythm, volume, character, condition of arterial wall.

1. *Rate*

The normal rate in an adult varies from 60 to 90 per minute. A rate below 60 per minute is called bradycardia and above 90 per minute is tachycardia.

2. *Rhythm*

Normally the pulse is regular except for a slight increase in rate on inspiration and slowing on expiration (sinus arrhythmia). An irregular pulse may be regularly irregular (as in ectopic beats which are unifocal and come at fixed intervals) or irregularly irregular (e.g. multiple, multifocal ectopics or atrial fibrillation with varying ventricular response).

3. *Volume*

It is the amplitude of pulse wave as judged by the palpating finger. It depends on pulse pressure and is graded as high, normal, small and poor.

A. *High-volume pulse* (water hammer, collapsing or Corrigan's pulse) is caused by: (a) leakage of blood from the aorta (aortic regurgitation, patent ductus arteriosus) or from the left ventricle (mitral incompetence, ventricular septal defect); (b) high output states (anaemia, hyperthyroidism, beriberi, Paget's disease, arteriovenous fistula); and (c) increased stroke volume (complete heart block). Large volume causes high systolic pressure and escape of blood during diastole causes low diastolic pressure, resulting in large pulse pressure.

B. *Low-volume pulse*: Here the amplitude of pulse wave is small; this is due to low systolic pressure or raised diastolic pressure (secondary to peripheral vasoconstriction) or both.

It is caused by low stroke volume; all stenotic lesions (mitral, aortic, tricuspid, pulmonary), cardiogenic shock, tachycardias, dilated cardiomyopathy and heart failure have low stroke volume. The pulse in mitral stenosis is low volume but ill sustained (pulsus parvus), whereas in aortic stenosis it is low volume, well sustained and late peaking (pulsus parvus et tardus).

C. *Varying volume pulse:*

(a) Pulsus alternans is regular pulse (sinus rhythm) but alternating beats are strong and weak. It is difficult to appreciate pulsus alternans by palpating fingers. It is diagnosed while measuring blood pressure. When the mercury is being lowered, the stronger beats are heard first, and on further lowering, the weaker beats also become audible, thus suddenly doubling the number of audible beats. Pulsus alternans is seen in left ventricular failure.

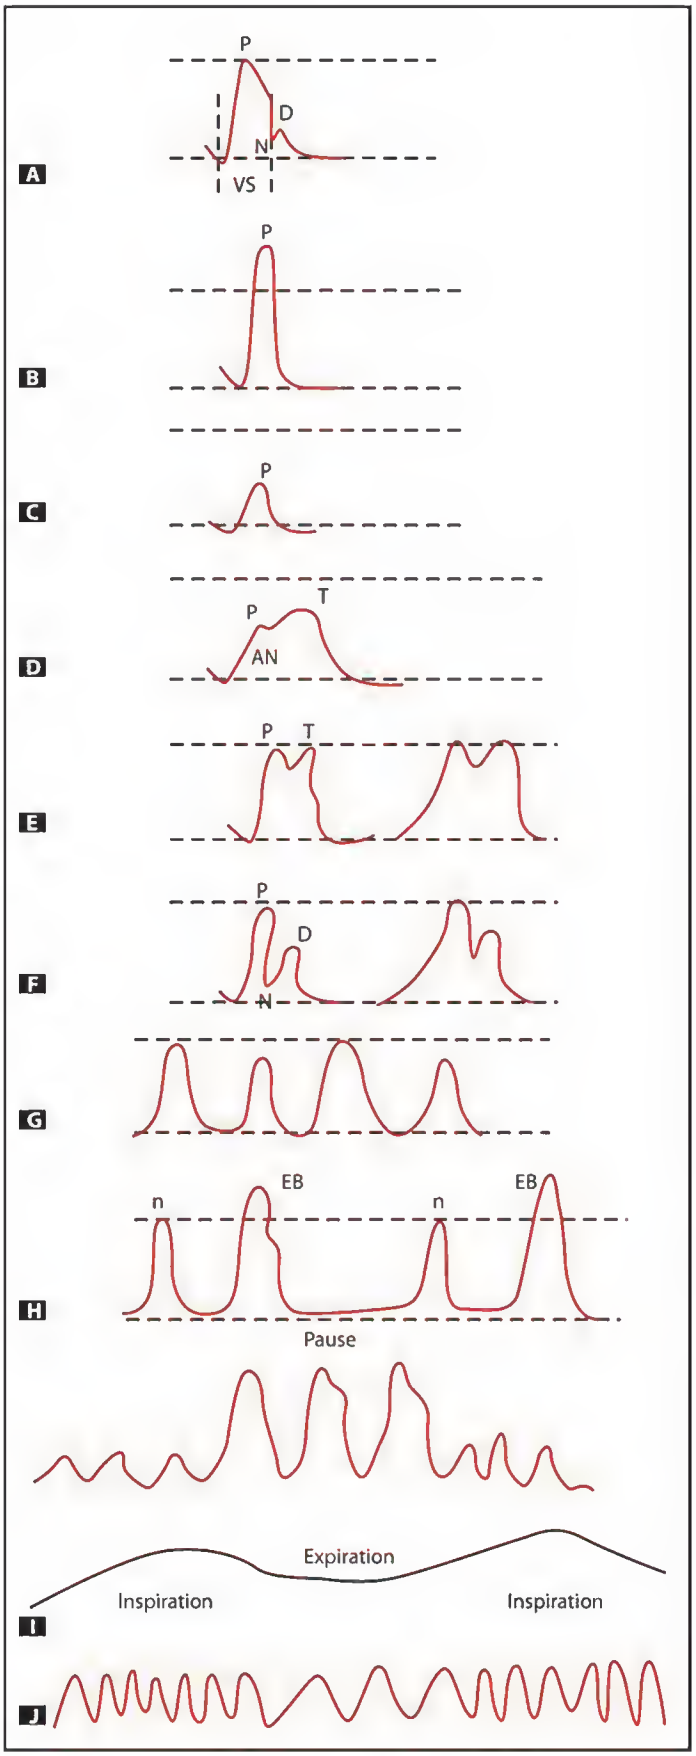
(b) Pulsus paradoxus is an exaggeration of the normal phenomenon of low-amplitude pulse during inspiration and better amplitude during expiration (normal fall by <10 mm Hg on inspiration). Thus, the name 'paradoxus' is a misnomer.

Pulsus paradoxus is caused by:

(i) Restriction in diastolic filling of ventricles (constrictive pericarditis, massive pericardial effusion). Limitation in the diastolic filling of the right atrium and right ventricle during inspiration results in lowering of left ventricular stroke volume.

(ii) Advanced right ventricular failure. Increase in lung volume during inspiration accommodates the reduced right ventricular stroke volume, which in turn results in low left ventricular stroke volume.

(iii) Increased respiratory effort (severe asthma). During inspiration, owing to enhanced intrathoracic negative pressure, there is pooling of blood in pulmonary veins resulting in lowered left ventricular stroke volume. Various types of pulses are shown in **Figures 2A to J**.



4. *Character*

Some classical characteristics of pulse can provide clues to certain cardiac conditions:

A. *Water hammer or collapsing pulse*: The water-hammer character is due to a steep rising, forceful, high-amplitude percussion wave which gives a sharp tap to the palpating hand similar to the feeling of a water hammer (a hermetically sealed toy glass tube half-filled with water). The collapsing character is attributed to a sudden disappearance of the pulse wave from the palpating hand and is due to the descending limb of the pulse wave. This is classically seen in aortic incompetence.

B. *Anacrotic pulse* is a slow rising, small-volume, well sustained pulse, seen classically in aortic stenosis. There is a distinct anacrotic notch between the slowly rising percussion and tidal waves.

C. *Pulsus bisferiens* is a double-peak pulse during systole. It is seen in combined aortic stenosis and aortic regurgitation.

Figures 2A to J: Type of pulses: (A) normal pulse wave; (B) collapsing (water hammer) pulse; (C) pulsus parvus (D) anacrotic pulse; (E) pulsus bisferiens; (F) dicrotic pulse; (G) pulsus alternans; (H) pulsus bigeminus; (I) pulsus paradoxus; (J) sinus arrhythmia.

P = Percussion wave; T = Tidal wave; D = Dicrotic wave; N = Dicrotic notch; VS = Ventricular systole; AN = Anacrotic notch); EB = Extra beat; N = Normal beat.

The first peak is due to a quick rising percussion wave and the second peak is due to a delayed tidal wave, with a notch in between. Thus, it is a double-peak pulse of the same amplitude during systole.

D. *Dicrotic pulse* is due to accentuation of the normal dicrotic wave, giving the feeling of two impulses with each beat. One impulse comes during systole and is due to the percussion wave, while a second, lower amplitude impulse comes during diastole and is due to accentuated dicrotic wave. It is seen in high-grade fever.

E. *Pulsus bigemini* or *trigemini* or *quadrigemini:* Here the pulse is regularly irregular and is due to fixed unifocal extrasystoles coming after every normal beat or after every two or three normal beats, with the usual pause after the extrasystole.

5. *Condition of arterial wall*

This is appreciated by rolling the radial artery with fingers against the underlying bone. In young persons, it feels soft and elastic; in the elderly, it may be hard and tortuous.

6. *Comparison of other arterial pulses*

Delayed and lower amplitude femoral artery pulse compared to the radials could be due to coarctation of aorta (post-subclavian), aorto-arteritis, or saddle embolus. Unequal radial pulses (right having better volume than left) are due to aortic coarctation (pre-subclavian). Unequal carotid pulses could be due to atheromatous plaque in one of the arteries.

Blood Pressure

This is the pressure at which blood is flowing in the arteries. It is due to pressure exerted by the intravascular blood column laterally on the vascular wall. Systolic blood pressure depends mainly on the cardiac output and diastolic blood pressure depends on peripheral resistance.

Clinically, blood pressure is measured by a mercury sphygmomanometer. The standard cuff (14 cm width) is for the average sized upper arm. For children a small sized (10 cm width) cuff, and for obese persons a large sized (16 cm width) cuff should be used to avoid wrong readings. In a patient with hypertension, blood pressure should ideally be taken in the supine, sitting and standing positions.

Jugular Venous Pressure (JVP)

Examination of jugular veins is of paramount importance to study right heart events. Since there are no valves between the right atrium and internal jugular veins, right atrial pressure is reflected in these veins. Carotid artery pulsations can sometimes be mistaken for the jugular venous pulsation (**Table 6**). The vertical distance from the top of the venous column to the sternal angle is a measure of the venous pressure. For measurement, 3 rulers are used; two are held horizontally, one at the upper level of the blood column in the right internal jugular vein and the other at the angle of Louis. The third ruler is used to measure the vertical distance between the first two, corresponding to the JVP (**Figure 3**). The normal mean pressure when the patient is supported on a backrest or pillow at 45° to the horizontal is 0 to 4 cm. In CCF, JVP is raised with pulsatile veins, whereas, in superior vena cava obstruction JVP is raised but non-pulsatile.

Table 6: Differences between Jugular Venous and Carotid Arterial Pulsations

Venous	Arterial
Visible but not palpable	Visible and palpable
Obliterated by pressure at root of neck	Not obliterated
Two peaks in each cycle	Single
Varies with breathing and position of patient	No change
Abdominal pressure causes rise in hepato-jugular reflux	No effect

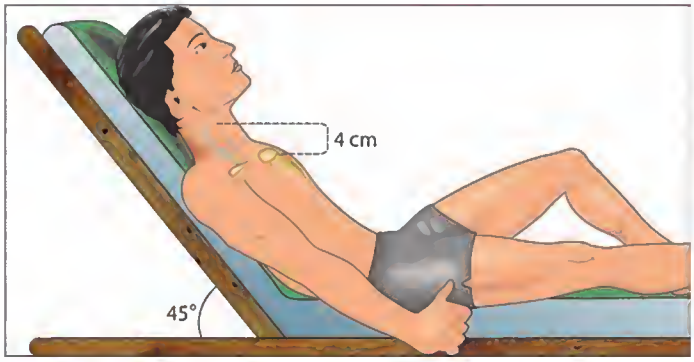


Figure 3: Measurement of jugular venous pressure. Patient's chest, neck and head are at an inclination of 45° to the horizontal. The patient lies with a backrest so that the neck muscles are relaxed.

Jugular veins usually depict 3 positive waves (a, c, v) (**Figure 4**). The *a* wave is due to atrial systole. The *c* wave is due to ballooning of the tricuspid valve into the right atrium during systole. It is also due to transmitted carotid pulse. At the bedside, it is very difficult to identify the *a* and c waves separately. The *a* and c waves are usually fused as an *ac* complex. The *a* wave disappears in atrial fibrillation; it is prominent (giant) in pulmonary stenosis or hypertension, tricuspid stenosis, tricuspid atresia, and Ebstein's anomaly. Cannon waves which are giant '*a*' waves occur when atrial contraction occurs against a closed tricuspid valve. These are seen intermittently in complete heart block and ventricular tachycardia when atrial and ventricular

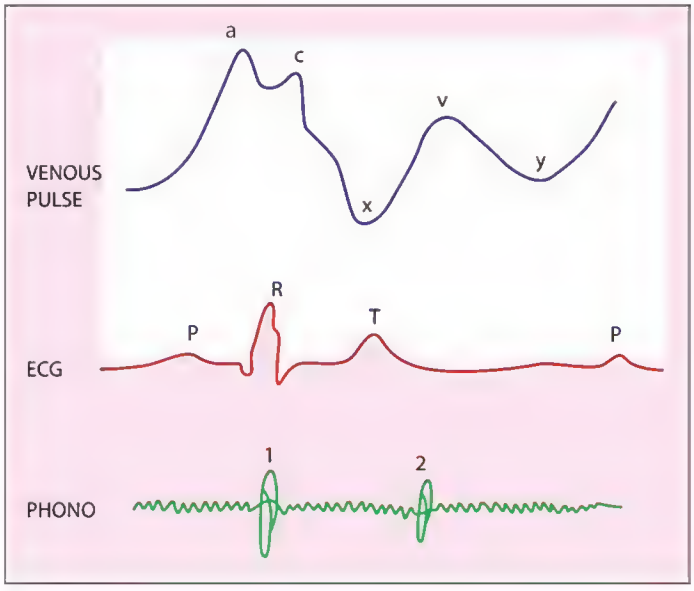

Figure 4: Venous pulse wave.

systole coincide. The x trough is due to atrial relaxation. The x descent is absent in atrial fibrillation and tricuspid insufficiency. The *v* wave that follows the x descent is the wave of venous filling of the right atrium during ventricular systole. It is exaggerated in tricuspid incompetence, heart failure and constrictive pericarditis. The trough that follows is the y descent which is due to emptying of the right atrium. The y descent is accentuated in heart failure, constrictive pericarditis and tricuspid insufficiency.

Oedema

It may be localised or generalised. Localised oedema is due to lymphatic or venous obstruction. The causes of generalised pitting oedema include cardiac, hepatic and renal disorders, beriberi, and severe anaemia with hypoproteinaemia. Myxoedema causes generalised non-pitting oedema, while filariasis causes localised non-pitting oedema.

Cardiac oedema is seen mostly on dependent parts, i.e. over the legs in ambulatory patients and the sacral area and posterior aspects of the thighs in recumbent patients; the oedema in kidney disorders occurs first over the eyelids and is more when the patient wakes up. In cirrhosis of the liver, ascites is the first presentation of fluid collection.

Clubbing

This is usually classified into 4 grades:

1. *Mild (early):* Obliteration of the normal angle between the nail and the dorsum of the finger.
2. *Moderate:* In addition to obliteration of the angle, longitudinal curving of the nails.
3. *Severe:* Drumstick appearance of the terminal phalanges due to swelling of soft tissues (**Figure 5**).
4. *Gross:* In addition to severe clubbing of the finger and toe nails, there is thickening and enlargement around the wrists and ankles due to thickening of the distal ends of bones.

Icterus

This is seen in patients with chronic hepatic congestion, as in chronic heart failure and constrictive pericarditis. In pulmonary infarction, icterus may occur due to lysis of RBCs with release of bilirubin.

Rheumatic Nodules

A patient with active rheumatic carditis may have subcutaneous, painless, mobile rheumatic nodules on the dorsal aspect of fingers, wrists and elbows.

Osler's Nodes

These are small, red, painful cutaneous nodules usually seen over the pulp of fingers in cases with infective endocarditis.

EXAMINATION OF PRAECORDIUM

The term praecordium refers to the aspect of the chest which overlies the heart. The angle of Louis corresponds to the second costochondral junction. Traditionally, praecordial examination is carried out under the following heads:

Inspection

1. Look for praecordial bulging which is seen in long-standing cases of cardiomegaly or pericardial effusion.

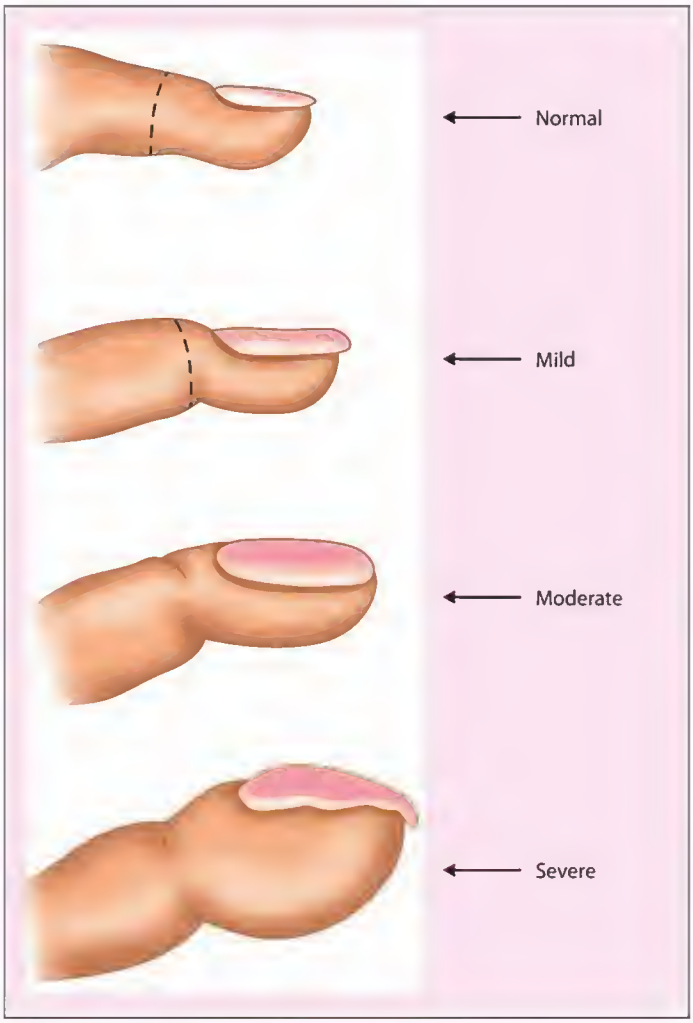

Figure 5: Various grades of clubbing.

2. The apex beat is the lowermost and outermost point of cardiac impulse and is formed normally by the left ventricle.
3. Look for right ventricular pulsations in the left 3rd and 4th intercostal spaces in the parasternal area and in the epigastric region.
4. Pulsations of a prominent pulmonary artery are visible in the left second space parasternally and those of the aorta in the suprasternal notch or sometimes in the right second space parasternally.

Palpation

1. First palpate and define the apex beat. This is best done by the flat of the palm and accurately localised with the tip of the middle finger. This outermost and lowermost point of cardiac impulse gives maximum uplift to a palpating finger kept perpendicular to the chest wall. The apex beat is normally localised in the left 5th intercostal space 1 cm inside the left midclavicular line. Ascertain the character of the apex beat and feel for a thrill. Thrills are palpable vibrations (purring sensation) corresponding to loud murmurs. One may occasionally feel a loud opening snap or third heart sound.

   A tapping or slapping apex beat which is characteristic of mitral stenosis is an ill-sustained, low-amplitude apex beat. It represents a palpable loud first heart sound. An abrupt, forceful or hyperkinetic apex beat is indicative of a diastolic-overload type of left ventricular hypertrophy as seen in aortic incompetence, mitral incompetence, ventricular septal defect and patent ductus arteriosus. A sustained heaving apex is suggestive of a systolic-overload type of left ventricular hypertrophy as seen in aortic stenosis, hypertension and coarctation of aorta. The apex may not be palpable if it is lying under a rib and in emphysema or obese persons.

2. Feel for mid praecordial right ventricular pulsations or heave in the left 4th space in the parasternal plane. A sustained powerful heave indicates systolic-overload type of right ventricular hypertrophy as in pulmonary stenosis and pulmonary hypertension. An abrupt, forceful and hyperkinetic pulsation indicates diastolic-overload type of right ventricular hypertrophy, e.g. tricuspid incompetence.
3. Feel for pulsations in the left second space; these are indicative of enlarged pulmonary artery. Aortic pulsations due to aneurysmal dilatation or unfolding of the aorta are appreciated in the suprasternal notch and right second space. In pulmonary hypertension, a loud pulmonary second sound is palpable as a diastolic shock in the pulmonary area.

Percussion

First percuss the left border of the heart, starting from the left anterior axillary line and proceeding medially with the plexiimeter finger kept parallel to the left border. Defining the right border formed by the right atrium is difficult unless there is gross enlargement of this atrium. One should first find out the upper border of liver dullness and start percussion one space above it from the right mid clavicular plane towards the right sternal plane. Percuss over the left second space and right second space parasternally for dull note in case of pulmonary artery and aortic dilatation.

Auscultation

This is done over the mitral, tricuspid, pulmonary and aortic areas. The mitral area overlies the apex beat; the tricuspid area is over the 5th intercostal space just left of the sternum. The pulmonary area is over the left 2nd space along the lateral sternal border; the aortic I area is over the right second space along the lateral sternal border and the aortic II area (Erb's area) is over the left 3rd space parasternally (**Figure 6**).

Heart Sounds

The first and second heart sounds should be identified, and their intensity and splitting determined. The *first heart sound* is mainly due to closure of the mitral and tricuspid valves. This sound coincides with the R wave on the ECG and the beginning of left ventricular pressure rise.

The *second heart sound* is produced by closure of the aortic and pulmonary valves. The aortic closure sound (A2) corresponds to the incisura of the aortic pressure pulse, and the pulmonary closure sound (P2) corresponds to the incisura of the pulmonary pressure pulse. Both A2 and P2 occur at the end of the T wave on ECG.

The *third heart sound* is due to stretching of the papillary muscle and chordae tendineae during the maximum filling phase of

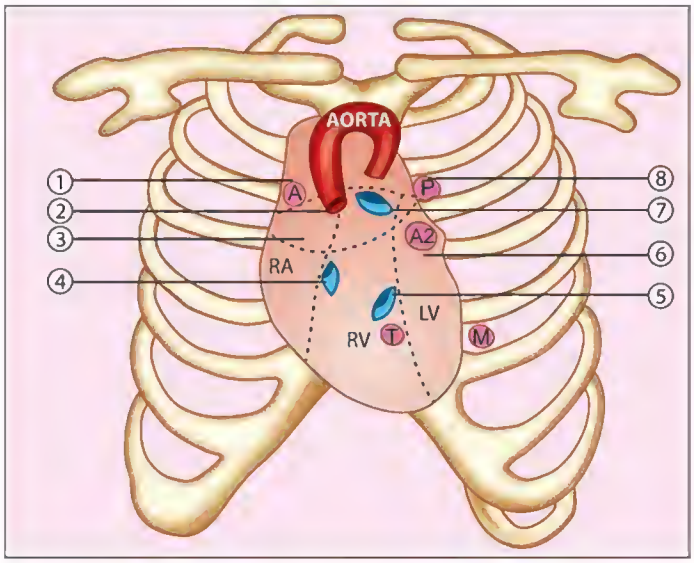

Figure 6: Position of cardiac valves and chambers.

1 = Superior vena cava; 2 = Aortic valve; 3 = Base of the heart; 4 = Tricuspid valve; 5 = Mitral valve; 6 = Left atrial appendage; 7 = Pulmonary valve; 8 = Pulmonary artery, Auscultatory areas; M = Mitral area; T = Tricuspid area; A = Aortic area; A2 = Erb's area; P = Pulmonary area.

diastole. It may be heard normally as a soft sound in children 0.16 s after the aortic component of the second sound. The fourth heart sound is produced during atrial systole by tensing of the mitral or tricuspid cusps; it is not heard normally.

The *opening snap* of the mitral valve is a sharp snappy sound due to abrupt opening of this valve under pressure in mitral stenosis. It occurs 0.06 to 0.12 s after the aortic component of the second sound. *Ejection click* is a sharp sound due to a sudden opening of the semilunar valves under pressure, as in aortic or pulmonary stenosis. It is heard 0.06 s after the first heart sound. In mitral valve prolapse, a mid-systolic click is heard; this is due to tense bulging of floppy mitral cusps into the left atrium.

Murmurs

Murmurs are produced by turbulence of blood flow. It depends on the anatomical abnormality, the pressure gradient along the passage, the volume of blood flow and the viscosity of blood. The anatomical abnormality can be obstruction to forward flow of blood, as in stenosed valves; regurgitation of blood through incompetent valves; and abnormal passage of blood, as in shunts.

The following points should be ascertained about murmurs:

1. Timing in the cardiac cycle
2. Location
3. Conduction
4. Intensity and any special character
5. Influence of posture and breathing

1. *Timing*

Murmurs may be systolic, diastolic, to-and-fro or continuous (**Figure 7**).

A. *Systolic murmurs* may be pansystolic, long systolic, mid-systolic or late systolic.

Pansystolic murmur starts with the first sound and merges with the second sound. Usually, it is of uniform intensity and is classically seen in organic mitral or tricuspid regurgitation and ventricular septal defect. Long systolic murmur starts with the first heart sound but falls short of

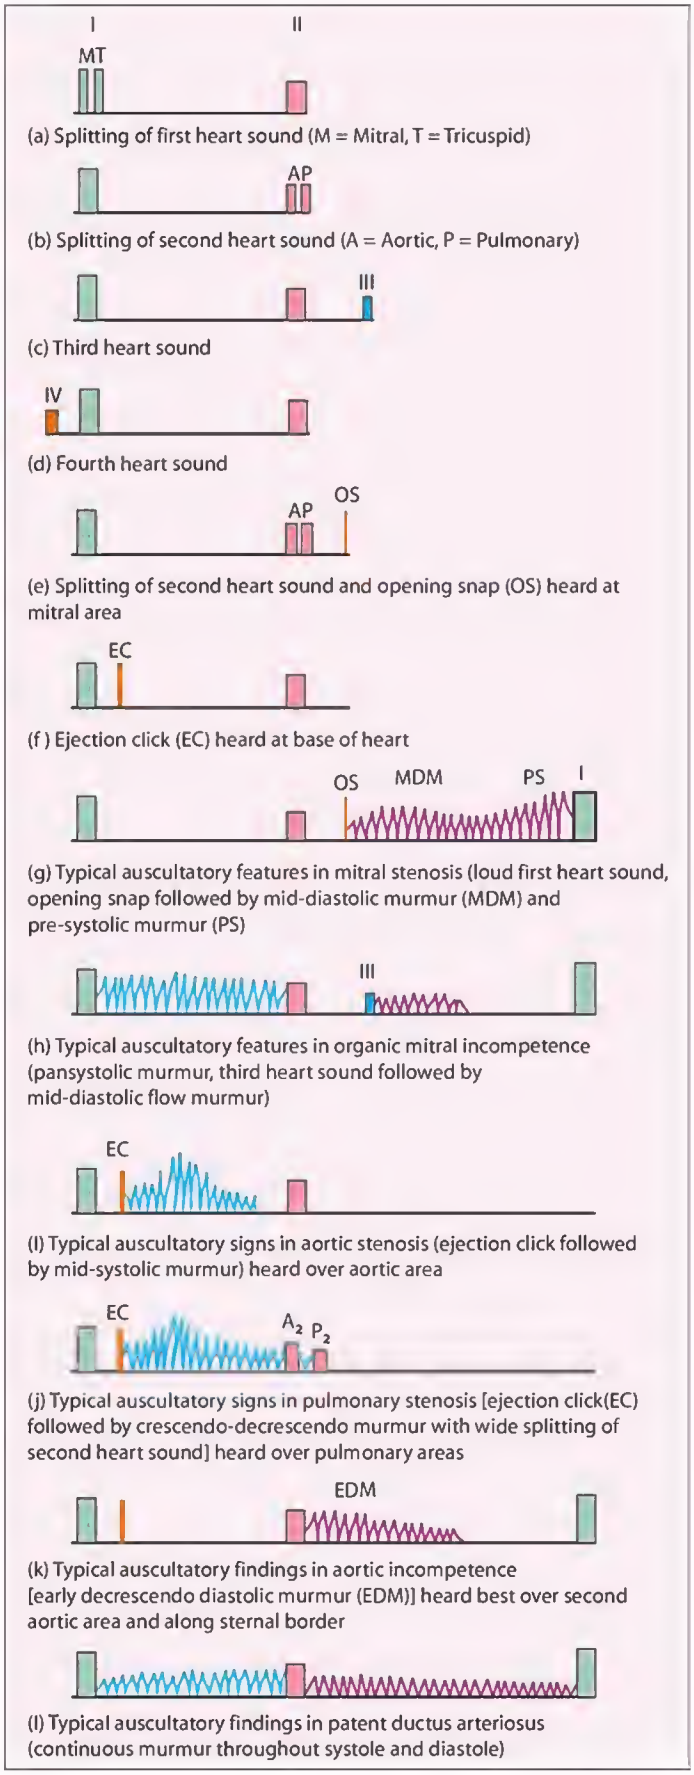

Figure 7: Heart sounds and common murmurs.

the second sound and is usually heard in functional mild mitral or tricuspid regurgitation. Mid-systolic (ejection) murmur starts after the ejection click and ends before the second heart sound. It is crescendo-decrescendo in character with maximum intensity during mid-systole. It is heard in aortic and pulmonary stenosis, systemic hypertension, atherosclerotic aortic disease and in atrial septal defect due to increased flow across the pulmonary valve. Late systolic murmur begins in mid-systole, usually preceded by a mid-systolic sound. It is usually heard in floppy mitral valve syndrome and papillary muscle dysfunction.

B. *Diastolic murmurs* may be early diastolic, mid diastolic or pre-systolic. Early diastolic murmur starts immediately after the second sound, is decrescendo in character, and is best heard at the base of the heart. It is classically seen in aortic and pulmonary regurgitation. In aortic regurgitation, it is best heard over aortic II (Erb's) area with the patient sitting and leaning forward in expiratory apnoea; it is associated with peripheral signs of large-volume pulse. In pulmonary regurgitation, the murmur is best heard over the pulmonary area during inspiration and the pulse is of small volume.

Mid diastolic murmur, seen typically in mitral and tricuspid stenosis, is a rumbling harsh murmur usually preceded by an opening snap. Mitral stenosis murmur is localised over the apex.

Carey-Coomb murmur is a short mid diastolic murmur heard in acute rheumatic fever, due to acute mitral valvulitis. The pre-systolic murmur is a crescendo murmur which ends in a loud, sharp first sound; it is caused by powerful atrial contraction forcing blood through a stenosed mitral or tricuspid valve. This murmur disappears in atrial fibrillation.

C. *To-and-fro (biphasic) murmurs* are encountered when there is a combined stenosis and regurgitation of a valve (e.g. aortic stenosis with regurgitation). To-and-fro murmurs do not cover the second heart sound.

D. *Continuous murmurs* are audible uninterrupted throughout the cardiac cycle. In continuous murmur, the blood flow is in the same direction all throughout, whereas in to-and-fro murmurs the direction reverses in diastole. Continuous murmurs are caused by flow of blood from high to low pressure areas, e.g. in patent ductus arteriosus, aortopulmonary window, rupture of aneurysm of sinus of Valsalva into the right ventricle or right atrium, arteriovenous shunts, and aorto-pulmonary collaterals (bronchial collaterals) as seen in severe tetralogy of Fallot or pulmonary atresia.

Venous hum is a soft, continuous humming sound mimicking a continuous murmur; it is caused by blood flowing through large veins.

2. *Location*

The location where the murmur is heard with maximum intensity is described. For example, murmurs of mitral stenosis and mitral incompetence are best heard over the mitral area, murmur of aortic stenosis is best heard over aortic I area, and that of aortic incompetence is best located at aortic II area.

3. *Conduction*

While a murmur of mitral stenosis is localised over the apex, the murmur of mitral incompetence is conducted towards the posterior axillary or scapular line because the direction of blood flow is from left ventricle to left atrium. The murmur of aortic stenosis is conducted to the neck vessels, and the murmur of aortic incompetence is conducted along the left sternal border towards the apex.

4. *Intensity and pitch*

Levine graded the intensity of murmurs from grades 1-6. Grade 1: very faint, just heard in quiet surroundings; 2: easily audible; 3: moderately loud but without thrill; 4: loud, with thrill, audible with full chest piece of the stethoscope; 5: very loud, with thrill, heard even with the edge of the chest piece; 6: loudest possible, with thrill, audible even with the chest piece just above the chest wall. This grading is for systolic murmurs. Diastolic murmurs are usually classified into 4 grades (from 2-5).

The pitch of a murmur reflects the pressure at which turbulence occurs. If turbulence occurs at high pressure the murmur is called high pitched, and if turbulence occurs at low pressure it is called low pitched. Small leaks produce high pitched murmurs and larger leaks produce low pitched murmurs.

5. *Influence of breathing and posture*

Mitral murmurs are best heard with the patient in the left lateral position, and aortic murmurs, with the patient sitting and leaning forward. Murmurs from the right side of the heart (pulmonary and tricuspid valve lesions) are accentuated during inspiration whereas murmurs from the left-side (aortic and mitral valve lesions) are better appreciated during expiration. With standing, most murmurs diminish except murmurs of hypertrophic obstructive cardiomyopathy (HOCM) and mitral valve prolapse (MVP) which gets louder. With squatting, most murmurs become louder but those of HOCM and MVP usually diminish.

6. *Influence of exercise*

Stenotic murmurs of mitral stenosis (MS), aortic stenosis (AS) and pulmonary stenosis (PS) become louder with both isotonic and submaximal isometric (handgrip) exercise. Murmurs of mitral regurgitation (MR), aortic regurgitation (AR) and ventricular septal defect (VSD) also increase with handgrip, but murmur of HOCM often decrease with hand grip.

7. *Influence of drugs*

Amyl nitrite inhalation decreases murmurs of MR, AR and VSD and increases murmur of AS. During the later tachycardia phase, murmurs of MS and right-sided lesions increase. Vasoconstriction by phenylephrine tends to produce opposite effects.

Functional murmurs

Organic murmurs are produced due to pathologic changes in the heart; murmurs which have no underlying anatomical abnormality are called functional or haemic murmurs.

These are mostly systolic murmurs, invariably without thrill, mainly audible at the base of the heart and are mostly found in young persons.

Prosthetic Valves Sounds

The sounds produced by prosthetic valves vary. Mechanical valves produce opening and closing clicks. Absence or diminution of click sounds raises the suspicion of malfunction of the prosthetic valve. The sounds produced by tissue prosthetic valves are more like normal heart sounds and there are no clicks.

Auscultation of Blood Vessels

A rough continuous murmur with systolic accentuation is heard over an arterio-venous fistula. In aortic insufficiency, a loud first sound or pistol-shot sound is heard over the femoral arteries. Duroziez' murmur is both systolic and diastolic and is brought about by appropriate pressure of the chest piece over the femoral artery.

Continuous arterial murmurs can be heard over the skull or eyeball in arterio-venous fistula and vascular brain tumours, over bones in Paget's disease, over the thyroid in hyperthyroidism, and over a pregnant uterus (uterine souffle). Bruits over blood vessels are due to atheromatous plaques and one should auscultate over the anterior triangle of the neck for the carotid artery, posterior triangle for the vertebral artery, infraclavicular area for the subclavian artery, and flanks or abdomen for renal artery occlusions.

Veins

A continuous humming murmur is heard over the jugular veins in hyperdynamic circulation, e.g. anaemia, hyperthyroidism. In liver cirrhosis with portal hypertension, a venous hum (Cruveilhier-Baumgarten murmur) may be heard over dilated veins connecting the caval and portal venous systems.

Friction Sounds

Friction sounds (rub) synchronous with the heart beat are diagnostic of fibrinous pericarditis. Pericardial rub is unaffected by respiration whereas pleural or pleuro-pericardial friction rubs alter with breathing.

12.3 Electrocardiology

MJ Gandhi

INTRODUCTION

Before the heart contracts, an electric impulse originating in sinus node activates the heart. Electrocardiogram (ECG) is a graph obtained when the electrical potentials of an electrical field originating in the heart are recorded at the body surface. It has many limitations: it records only projections of voltage on a particular lead; it is very approximate; lead positions are not true representations of axis; it has many technical errors. Despite limitations, it has tremendous clinical utility. ECG provides information that is essential for diagnosis and therapy of many cardiac conditions. It reflects anatomic, haemodynamic, molecular, ionic and drug-induced abnormalities of the heart. It may serve as an independent marker of myocardial disease.

ACTIVATION OF HEART

The electrical impulse originates in the sinus node and activates the atria longitudinally and by contiguity. The impulse then reaches the atrioventricular (AV) node, His bundle, left and right bundle and activates the ventricles transversely from endocardial to epicardial surface. Earliest activation is septal depolarisation from left to right. This gives rise to septal Q in I, aVL, V_5 and V_6. This is followed by apical depolarisation of both RV and LV. This causes R in I, II, III. Then occurs depolarisation of entire RV and lateral wall of LV. Finally, the base of LV is activated. In entire depolarisation of ventricles LV potentials predominate over RV. The activation process will change with bundle branch blocks, and ventricular hypertrophies, presence of accessory pathway and in ventricular premature beats.

TECHNICAL ASPECTS

Electrocardiogram Paper

The ECG paper is a strip of graph paper which has vertical and horizontal lines 1 mm apart. The horizontal axis represents time, while the vertical axis denotes amplitude. There is a heavy line every 5 mm in both the planes. Thus, there are small squares, 1 mm × 1 mm and big squares, 5 mm × 5 mm.

Paper Speed

Conventional ECG is taken at a paper speed of 25 mm per second. One small square (1 mm) corresponds to 0.04 s, while a big square (5 mm) is equivalent to 0.20 s. When the ECG paper runs through 5 big squares, 1 sec recording has been taken.

Sensitivity

Voltage is measured along the vertical axis. Usually a 10 mm deflection is equivalent to 1 millivolt (mV). There is a provision to change the sensitivity in special circumstances, e.g. when ECG complexes are too small, the sensitivity can be doubled so that a 1 mV deflection is equivalent to 20 mm. When ECG complexes are too large, sensitivity may be halved so that 1 mV is equivalent to 5 mm.

Lead Systems

The following leads are taken in a conventional 12-lead ECG- (**Figure 1, Table 1**).

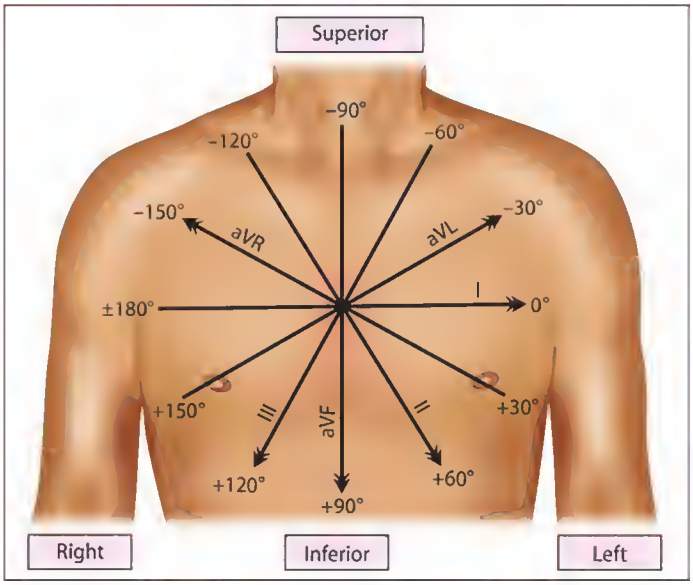

Figure 1: Leads in 12-lead ECG.

Table 1: ECG Leads

Lead	+ve input	–ve input
Bipolar limb lead		
I	LA	RA
II	LL	RA
III	LL	LA
Augmented unipolar limb leads		
aVR	RA	LA + LL
aVL	LA	RA + LL
aVF	LL	LA + RA
Praecordial leads		
V_1	Right sternal margin 4th space	Wilson central terminal (LA + RA + LL)
V_2	Left sternal margin 4th space	Do
V_3	Midway between V_2 and V_4	Do
V_4	Left midclavicular line 4th space	Do
V_5	Left ant. axillary line in same plane as V_4	Do
V_6	Left mid axillary line in same plane as V_4	Do

LA = Left arm; RA = Right arm; LL = Left leg.

Technically Good Electrocardiogram

Correct interpretation of ECG requires attention to several technical points:

With good standardisation, the corners of the signal form a right angle. When the pressure of the stylus over the ECG paper is excessive, there is over-damping which results in rounding-off of these corners. In under-damping, the calibration signal

overshoots the horizontal line. ECG complexes may become spuriously small in an over-damped tracing and small complexes like q and s waves may disappear altogether and ST depression may appear. In under-damping the complexes may become larger and small complexes like q may look significant because of artefactual increase in amplitude.

ECG should have a stable baseline. It should contain at least 3 ECG complexes in each lead. A long strip of II and V_1 should be taken if arrhythmia is suspected or present. There should be absence of alternating current interference and muscle potentials. ECG complexes should be at the centre of the ECG paper, not overshooting the margins.

DEFINITIONS

Waves (Figure 2)

The P wave is the deflection produced by atrial depolarisation. QRS complex is the deflection produced by ventricular depolarisation. Q wave is the initial negative deflection in a QRS complex. When small, it is designated 'q' but when large or pathological, it is depicted as 'Q'. R wave is the first positive deflection in the QRS complex. It is also depicted as r or R depending on its size. It may or may not be preceded by a Q wave. S wave is the first negative deflection after a positive (R) deflection. R' wave is the second positive deflection after an S wave. S' wave is the second negative deflection after an R' wave. QS complex is the term used when the entire QRS complex is negative, without any positive deflection either preceding or following it. ST and T waves are produced by ventricular repolarisation. Atrial repolarisation is represented by a wave which is not visible in the ECG as it is buried within the QRS complex. U wave is the deflection between the T wave and the ensuing P wave. Its origin is uncertain.

Intervals and Segments (Figure 2)

The RR interval is measured between two successive R waves. Either the peak of the R wave or the beginning of the QRS complex can be taken for the measurement of this interval. Ventricular rate can be calculated from the RR interval. The PP interval is the interval measured between either the peak or the beginning of two successive P waves. The PP interval is measured for calculation of the atrial rate. PR interval is measured from the beginning of the P wave to the beginning of the QRS complex. It represents the (AV) conduction time. QRS interval is the total duration of the QRS complex and is measured from the onset of Q or R wave to the J point of the complex. QT interval is measured from the beginning of the QRS complex to the end of the T wave. QT interval corresponds to the duration of electrical systole. PR segment lies between the end of the P wave and the beginning of the QRS complex. ST segment lies between the end of the QRS complex and the beginning of the T wave. The point where the QRS complex ends and ST segment begins is called the J point.

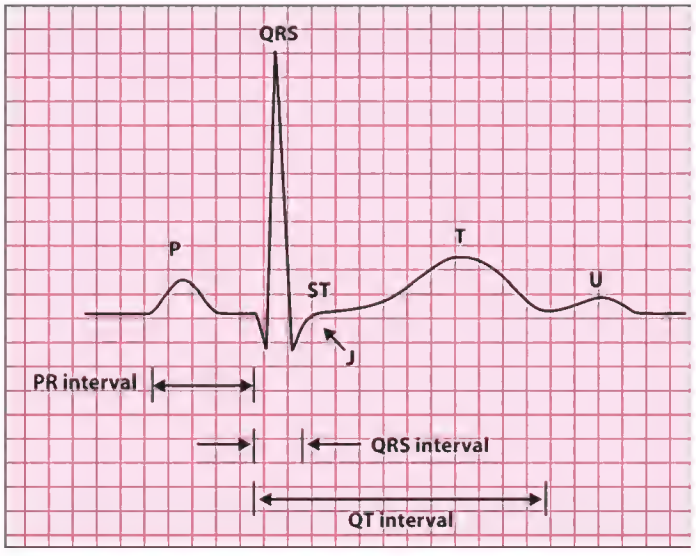

Figure 2: Waves and intervals.

NORMAL ECG

Rhythm

Normally, heart beats are regular; thus the PP and RR intervals are constant. There may be a minor variation of these intervals in normal subjects; a variation of up to 10% in adjacent cycle lengths is considered to be normal.

Rate

Comment should be made on both the atrial and ventricular rates. The atrial rate is derived from the PP interval, while the ventricular rate is derived from the RR interval. At a paper speed of 25 mm/sec the formulae are:

$$\text{Atrial rate/min} = \frac{1500}{\text{PP interval in mm}}$$

$$\text{Ventricular rate/min} = \frac{1500}{\text{RR interval in mm}}$$

Normal atrial and ventricular rates range from 60 to 100/min.

For calculation of the ventricular rate when the RR interval is irregular, as in atrial fibrillation, the number of QRS complexes are counted over 5 s in the rhythm strip and this number is multiplied by 12 to provide the number of QRS complexes in 60 s (1 min). This method enables measurement of the average ventricular rate.

Mean QRS Axis in Frontal Plane

The mean QRS vector is the approximation of all main QRS vectors due to activation of the heart in the frontal plane. It can be measured from all frontal plane leads viz. I, II, III, aVR, aVL, aVF. Attempts are also made to measure the axis in horizontal plane from praecordial leads. However, as these are unipolar leads they do not truly represent horizontal plane (HP) and hence axis in HP, thus measured, is not very reliable.

Methods

Perpendicular method

The mean QRS axis is perpendicular to lead with equiphasic or small QRS complex. For example, if the QRS is equiphasic in lead II, the QRS axis must be perpendicular to the axis of lead II.

Leads with Equiphasic QRS	QRS Axis in Frontal Plane
I (0°)	+90° or –90°
II (+60°)	–30° or +150°
III (+120°)	+30° or –150°
aVR (–150°)	+120° or –60°
aVL (–30°)	+60° or –120°
aVF (+90°)	0° or +180°

Quadrant method

QRS complexes are viewed in I and aVF. When the QRS complexes are predominantly upright (i.e. there is a dominant R in both leads), the axis is normal. If the QRS complex in I is predominantly negative (i.e. dominant S in I) while it is predominantly positive in aVF (i.e. dominant R in aVF), there is right axis deviation. If the QRS complex is predominantly positive in I but negative in aVF, left axis deviation is present. When the QRS complexes in both I and aVF are predominantly negative, the axis is indeterminate. Normal mean QRS axis in the frontal plane varies from –30° to +110°. When the axis is more than +110°, there is right axis deviation, while an axis of less than –30° represents left axis deviation.

Visual method (Table 2)

The same principles can apply to P, T and even ST segment. It makes it easy to predict ECG from QRS axis. In fact, Grant popularised ECG diagnosis by such vectorial analysis. In vectorcardiography one can measure each 0.01 s vector as there is lot of information hidden in each such vector.

Table 2: QRS in Frontal Plane (Visual Method) Predominant QRS Defection (R or S)

I	II	III	AXIS	aVL	aVR	aVF	AXIS
R	R	R	+ 30° to +90°	R			+30° to +60°
				S			+60° to 90°
S	R	R	+90° to +150°		S		+90° to +120°
					R		+120° to +150°
S	S	R	+150° to –150°			R	+150° to ±180°
						S	±180° to –150°
R	R	S	+30° to –30°			R	+30° to 0°
						S	0° to –30°
R	S	S	–30° to –90°		R		–30° to –60°
					S		–60° to –90°
S	S	S	–90° to –150°	S			–150° to –120°
				R			–90° to –120°

P Wave

Normal P wave duration does not exceed 0.10 s. Normal P waves are not more than 2.5 mm tall. P waves are normally upright in I, II, aVF and V_3 to V_6, inverted in aVR and upright, inverted or biphasic in III, aVL and V_1, V_2. P wave morphology is best studied in II and V_1.

PR Interval

Normal PR interval varies from 0.12 s to 0.20 s, i.e. 3 to 5 small squares. Normally, the PR interval should be constant though minor variations may be present.

QRS Complex

Amplitude of QRS in each limb lead (i.e. I, II, III, aVR, aVL and aVF), should be 5 mm or more. In each praecordial lead (i.e. V_1 to V_6), the QRS amplitude should be 10 mm or more. ECG is termed low voltage below these values. Normal QRS complex duration does not exceed 0.11 s (i.e. 2.75 mm) in adults. R wave is dominant in I, II, V_4 to V_6, S wave is dominant in aVR and V_1, V_2. Either R or S wave may be dominant in III, aVL, aVF and V_3 depending on QRS axis.

Q Wave

Small q waves are normally present in I, aVL, V_5, V_6. When the mean QRS axis in the frontal plane approaches +90°, small q waves may be present in II, III, aVF and V_3, V_4 also. A QS complex is commonly found in aVR. There may be deep Q waves in III alone in normal individuals; this may become less prominent on deep inspiration. Occasionally, a deep Q or QS complex is found in V_1 and even V_2. Barring III, aVR, aVL and V_1, V_2 the depth of a normal q wave is less than 25% of the height of the ensuing R wave. In aVL, the depth of a normal q wave may be up to 50% of the height of the ensuing R wave. Any Q wave with amplitude more than this is considered to be pathological. Normal q waves generally do not exceed 0.04 s (i.e. 1 mm) in duration.

ST Segment

The normal ST segment is isoelectric but ST depression < 0.5 mm in any lead is not considered to be abnormal. ST segment elevation up to 1 mm in limb leads and V_5, V_6 and 2 mm in V_1 to V_4 may be normal. The reference line for ST segment elevation is the TP segment while that for depression is the PR segment.

T Wave

Normal T waves are upright in I, II, V_4 to V_6, inverted in aVR and upright, inverted or biphasic in III, aVL, aVF and V_1 to V_3.

QT Interval

The upper limit of normal QT interval is 0.42 s in males and 0.43 s in females. QT interval should be measured in the lead where the end of the T wave is best discernible. QT interval varies with heart rate and, therefore, a correction for heart rate is done by Bazett's formula:

$$QT_C = \frac{QT\ (s)}{\sqrt{RR\ (s)}}$$

ABNORMAL ECG

Abnormal Axis Deviation

Right axis deviation may be due to right ventricular hypertrophy, left posterior hemiblock, Wolff-Parkinson-White (WPW) syndrome, technical dextrocardia and mirror image dextrocardia. Left axis deviation is commonly due to left anterior hemiblock, WPW syndrome, inferior myocardial infarction, chronic obstructive airway disease and left ventricular hypertrophy.

P Wave Abnormalities (Table 3, Figure 3)

These may be due to atrial enlargement and intra-atrial conduction abnormality. Common causes of left atrial enlargement are mitral and aortic valve disease, coronary artery disease and cardiomyopathies. Common causes of right atrial enlargement include mitral valve disease with pulmonary hypertension, cor pulmonale and acute pulmonary embolism.

Table 3: Diagnostic Criteria for LA and RA Abnormalities

LA Abnormalities	RA Abnormalities
P mitrale	P pulmonale
P Duration >120 ms in II	P amplitude >0.25 mV in II
P notching in II PR segment >1.6 mm in II	P axis >175
P terminal force in V_1 > –0.04 mm-s	Area in positive part of P in V_1 >0.06 mm-s
	qR in V_1 V_2 without infarction
	Low QRS in V_1 with three-fold or more increase in V_2

Biatrial enlargement is suggested by combined criteria.

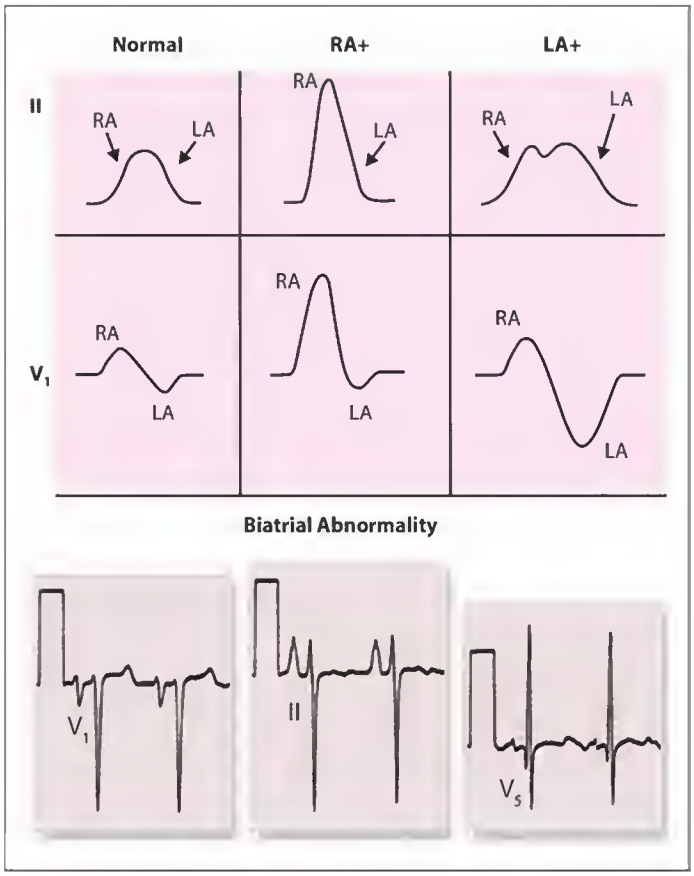

Figure 3: P wave in atrial hypertrophy.

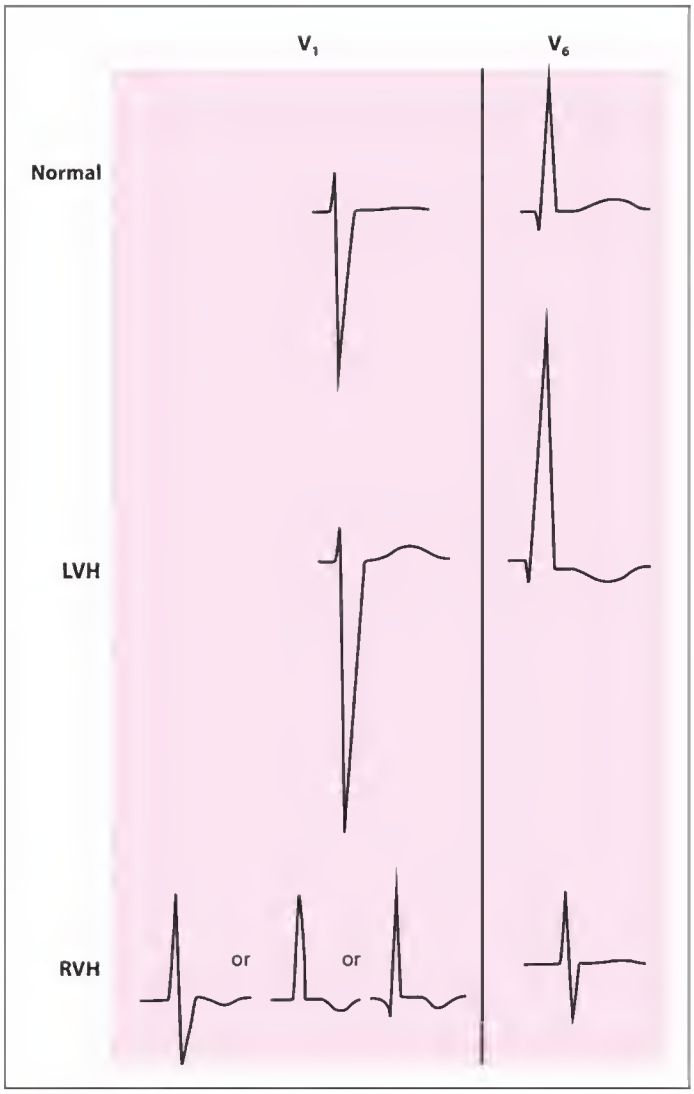

Figure 4: QRS in ventricular hypertrophy.

Abnormal PR Interval

Short PR interval is found in WPW syndrome, Lown-Ganong-Levine syndrome, nodal rhythm and atrial premature beats. Long PR interval (first degree AV block) is commonly observed in rheumatic carditis, digitalis effect and coronary artery disease.

Abnormalities of QRS Complex

Low voltage ECG, i.e. QRS amplitude of less than 5 mm in all limb leads and less than 10 mm in all chest leads, may be due to marked emphysema, myxoedema, pericardial effusion and cardiomyopathy. High amplitude is most commonly due to ventricular hypertrophy. Electrocardiographic criteria of RVH are (**Figures 4 and 5**) qR or qRS pattern in V_1, and tall R wave in V_1 R/S ratio >1, (R/S >1 is also found in true posterior myocardial infarction, WPW syndrome type A and right bundle branch block), deep S waves in V_5, V_6, rS pattern in all praecordial leads. QRS width is within normal limits. ST segment may be depressed and T wave inverted in V_1, V_2 (right ventricular strain). Right axis deviation may be present. P pulmonale is an indirect ECG sign of RVH. RVH is commonly due to mitral valve disease with pulmonary hypertension, cor pulmonale, pulmonary stenosis, tetralogy of Fallot and tricuspid regurgitation.

Left Ventricular Hypertrophy (LVH)

There are several scoring systems which have been suggested for diagnosing LVH, of which the Romhilt-Estes points scoring system is most useful (**Table 4, Figure 4**). ECG criteria for systolic (pressure) or diastolic (volume) overload are different (**Table 5**). Common causes of LVH are mitral regurgitation, aortic valve disease, systemic hypertension, coarctation of aorta and tricuspid atresia.

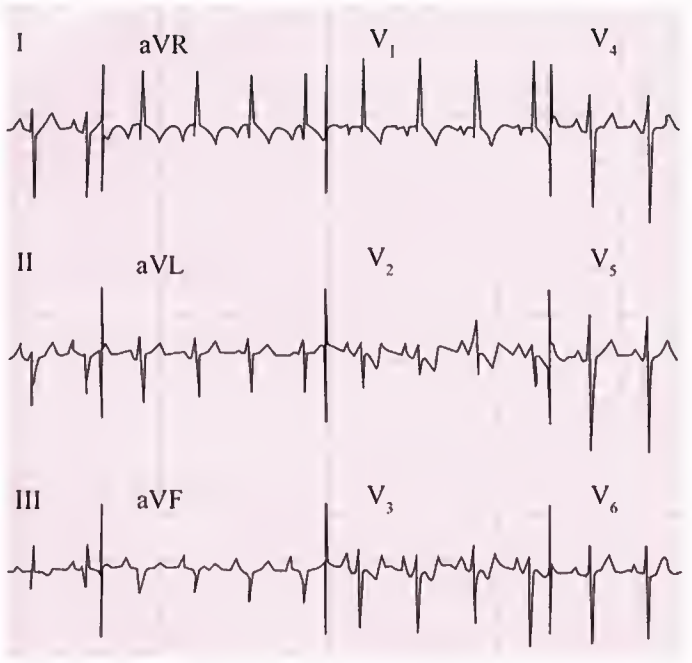

Figure 5: Right ventricular hypertrophy.

Table 4: Criteria for Left Ventricular Hypertrophy

Sokolow-Lyon Index

SV_1 + (RV_5 or RV_6) >35 mm
RaVL >11 mm

Romhilt-Estes point score system (≥5 points)	**Points**
(i) Any limb lead R or S ≥20 mm	3
SV_1 + SV_2 ≥30 mm or RV_5 + RV_6 ≥30 mm	3
(ii) ST-T changes	3
with digitalis	1
without digitalis	3
(iii) LA +	3
(iv) Left axis (≤30)	2
(v) QRS ≥90 ms	1
(vi) Intrinsicoid deflection in V_5/V_6 ≥50 ms	1

Cornell voltage criteria

SV_3 + SaVL ≥28 mm (men)
≥20 mm (women)

Table 5: ECG Criteria in LVH

	Systolic Overload	**Diastolic Overload**
Examples	Aortic stenosis, hypertension	Aortic incompetence, VSD, PDA
Septal q in V_5 to V_6	Attenuated	Prominent
Intrinsicoid deflection in V_5 to V_6	↑	Normal
ST changes in V_5, V_6, I, aVL	↓	Normal or ↑
T inversion in V_5, V_6, I, aVL	↓	Upright
QRS voltage	↑	↑

Biventricular Hypertrophy

ECG criteria of biventricular hypertrophy are definite features of LVH with right axis deviation or deep S waves in V_5, V_6 and definite features of RVH plus tall R waves in V_5, V_6 or deep Q waves in I, aVL, V_5, V_6 or large equiphasic QRS complexes in V_3, V_4 (Katz-Wachtel phenomenon).

Abnormal QRS Configuration

During sinus rhythm, the causes of abnormal QRS configuration include bundle branch block, hemiblocks, non-specific intraventricular conduction defects and pre-excitation.

Right Bundle Branch Block (Figure 6)

Causes of right bundle branch block (RBBB) include acute myocardial infarction, acute pulmonary embolism, chronic cor pulmonale and atrial septal defect. RBBB is sometimes found in healthy persons. The ECG criteria are shown in **Table 6**.

Table 6: Criteria for Right Bundle Branch Block (RBBB)

QRS > 120 ms
Broad notched R (rsr', rSR' or rSR') in V_1, V_2
Wide, deep S in V_5, V_6, and I

Left Bundle Branch Block (Table 7, Figure 6)

The common causes of left bundle branch block (LBBB) are hypertensive heart disease, dilated cardiomyopathy and acute myocardial infarction. It is most often associated with organic disease.

Pathological Q Waves

The criteria for pathological Q waves; usually present in a set of several leads, e.g. in V_1 to V_4 in anteroseptal myocardial infarction; in II, III, and aVF in inferior wall myocardial infarction (**Table 8**). Depth more than 25% of the height of the ensuing R wave in aVL, Q wave is considered to be abnormal if its amplitude is more than or equal to 50% of the height of the R wave. Deep Q waves in III may be entirely normal. In abnormal Q, the duration is more than 0.04 s. Pathological Q waves are mostly due to acute or old myocardial infarction. Rarely, pathological Q waves may be due to other causes, they are then known as 'pseudo-infarction' patterns. Deep Q waves may also be found in severe left ventricular hypertrophy but such Q waves are narrow and are not considered to be abnormal.

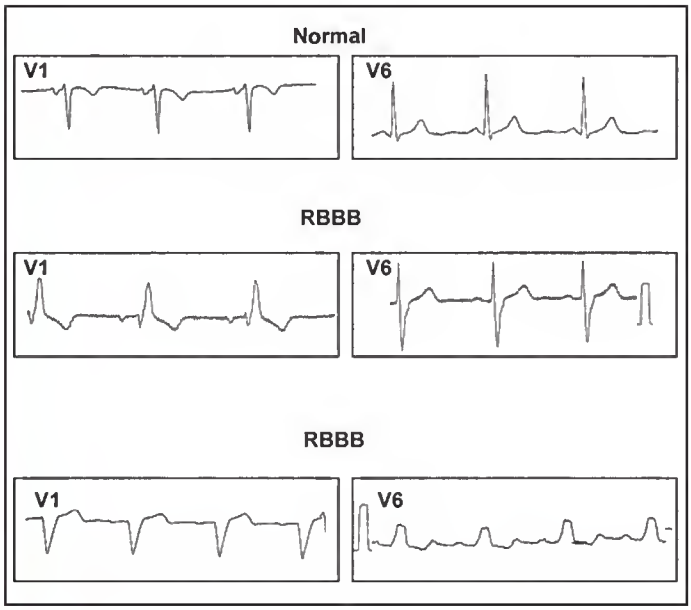

Figure 6: Lead V_1 and V_6 in Bundle Branch Blocks.

Table 7: Criteria for Left Bundle Branch Block (LBBB)

QRS ≥ 120 ms
Broad notched R in V_5 V_6 and usually in I, aVL
Small or absent initial r in V_1 V_2 with deep S
Absent septal q in left-sided leads
Intrinsicoid deflection >60 ms in V_5 V_6

Table 8: Q in Myocardial Infarction

Infarction Site	**Leads**	**Differential Diagnosis**
Inferior (diaphragmatic)	II, III, aVF	WPW (PSAP), HCM
Inferolateral	II, III, aVF, V_4 to V_6	—
Inferoposterior	II, III, aVF, V_1 (Tall R)	WPW (LT. PSAP), HCM
True posterior	V_1 (Tall R)	RVH, Atypical IRBBB, Left AP
Inferior with RV	II, III, aVF + V_{4R} to V_{6R} or V_1 to V_3	ASMI
Anteroseptal	V_1 V_2 V_3	LVH, COPD, LBBB. Chest electrode misplacement
Anterolateral	I, II, aVL, V_{4-6}	HCM, VSD
Extensive anterior	I, aVL, V_1 to V_6	—
High lateral	I, aVL	—
Anterior (apical)	V_3 to V_4	—
Posterolateral	V_{4-6}, V_1 (Tall R)	WPW (left AP)
Right ventricle	V_4R to V_6R or V_1 to V_3	ASMI

PSAP = Posteroseptal accessory pathway; AP = Accessory pathway; HCM = Hypertrophic cardiomyopathy; VSD = Ventricular septal defect; ASMI = Anteroseptal myocardial infarction.

Abnormalities of ST Segment

ST segment elevation

It is seen in acute myocardial infarction. ST segment is convex upwards. It is present over the site of infarction. It can also occur when there is transmural ischaemia, e.g. in coronary artery spasm (Prinzmetal angina) or occasionally during stress test. Occasionally, it may persist in post-myocardial infarction phase (ventricular aneurysm pattern). In acute pericarditis ST elevation is seen in all leads except aVR. ST segment is concave upwards. The above two are the commonest. But, there are other causes, viz. early repolarisation, in V_1-V_2 or V_3 in LVH/LBBB, or type IC anti-arrhythmic drugs, hyperkalaemia, hypercalcaemia, after DC-cardioversion, intracranial haemorrhage, myocarditis, trauma, tumour in LV or Brugada syndrome (RBBB with ST elevation in right praecordial leads).

ST segment depression

It is an electrocardiographic sign of myocardial ischaemia when the entire ST segment is depressed rather than the J point (QRS-ST segment junction) alone. The depression is horizontal or down-sloping. The depression exceeds 0.5 mm at a point 80 ms (2 mm) from the J point. Greater the degree of ST segment depression, more are the chances of this representing myocardial ischaemia. ST depression is however seen in many abnormalities, viz. hypertrophies, bundle branch blocks, myocarditis, cardiomyopathies, drugs, etc. They are non-specific if such changes can be mimicked by hyperventilation or standing and are also called labile ST changes.

Abnormalities of T Wave

T waves are termed tall when their height exceeds 1 mV (10 mm). Causes of tall T waves include hyperacute myocardial infarction (tall and wide T) and hyperkalaemia (tall but narrow-tented T waves).

T wave inversion is most often non-specific and transient. Causes of T wave inversion are given in **Table 9**. The most important issue in the differential diagnosis of inverted T waves is whether T wave inversion is due to myocardial ischaemia or not. The differences which may serve to separate ischaemic from non-ischaemic T waves are given in **Table 10**.

Table 9: Causes of T Wave Inversion

Physiological	Pathological
Young children (V_1 to V_4)	Ventricular hypertrophy (strain)
Young females (V_1 to V_4)	Pre-excitation syndrome
Change of posture	Bundle branch block
Deep respiration	Digitalis effect
After heavy meals	Myocardial ischaemia

Abnormal QT Interval

Prolonged QTc may be due to hereditary causes with or without deafness as a part of specific syndromes, anti-arrhythmic drugs, e.g. quinidine, procainamide, disopyramide and amiodarone, electrolyte disturbances like hypokalaemia, hypocalcaemia, liquid protein diet; during acute myocardial infarction and idiopathic. QTc prolongation may be associated with a form of polymorphous ventricular tachycardia known as 'torsades de pointes'. QTc shortening may signify hypercalcaemia.

Table 10: Ischaemic versus Non-Ischaemic T Waves

Ischaemic T Waves	Non-ischaemic T Waves
Deep	Shallow
Symmetrical	Asymmetrical
Relatively sharp and well-defined (arrow head)	Rounded and vague

Myocardial Infarction (Figure 7)

Electrocardiographic hallmarks of acute myocardial infarction are shown in **Figure 7**. The electrocardiogram also provides information about the site of infarction, its extent and stage and complications like arrhythmias and pericarditis. Depending on the location of the infarct, ECG changes of acute myocardial infarction occur in different sets of leads (**Table 8**). Persistent ST segment depression with T wave inversion signifies subendocardial or nontransmural infarction while the infarction is called transmural when new pathological Q waves appear. In resolving (recent) myocardial infarction the ST segment begins to settle down progressively till it is isoelectric. Persistent raised ST segment after 6 weeks may represent ventricular aneurysm. T wave inversion persists for a longer time but ultimately becomes upright except uncommonly when it may persist indefinitely. Reciprocal changes disappear concomitantly with ST-T changes or even earlier. Old myocardial infarction is characterised by persistent Q waves. In most instances pathological Q waves constitute the only electrocardiographic evidence of old myocardial infarction. Though pathological Q waves persist indefinitely in most cases, the size may reduce in about 20% of patients. Very rarely, Q waves may disappear altogether, especially following inferior infarction.

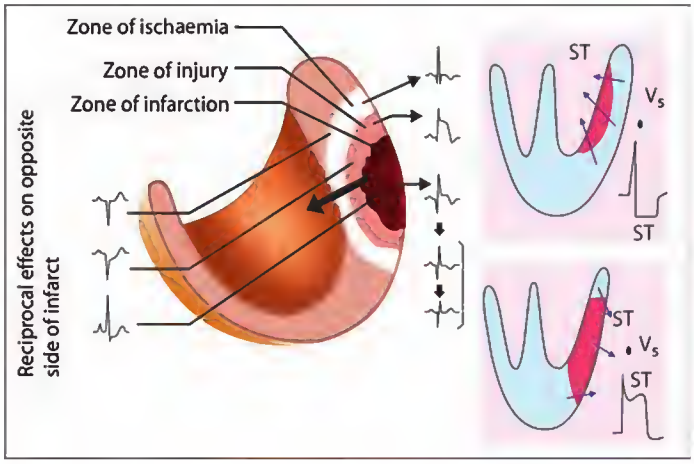

Figure 7: ECG changes in myocardial infarction.

Abnormalities of Heart Rate

Bradycardia (Figure 8)

Bradycardia is a heart rate below 60/min. This may be due to sinus bradycardia, junctional rhythm and atrio-ventricular blocks. Sinus bradycardia is recognised when a P wave precedes each QRS complex with a fixed PR interval. The ventricular rate in sinus bradycardia usually does not fall below 45/min. Causes of sinus bradycardia include athletic training, sick sinus syndrome, drugs (e.g. beta-blockers), myxoedema, uraemia, obstructive jaundice and raised intracranial pressure. In nodal rhythm, no P waves precede the QRS complexes, and the ventricular rate is generally from 45/min to 60/min (**Figure 8**).

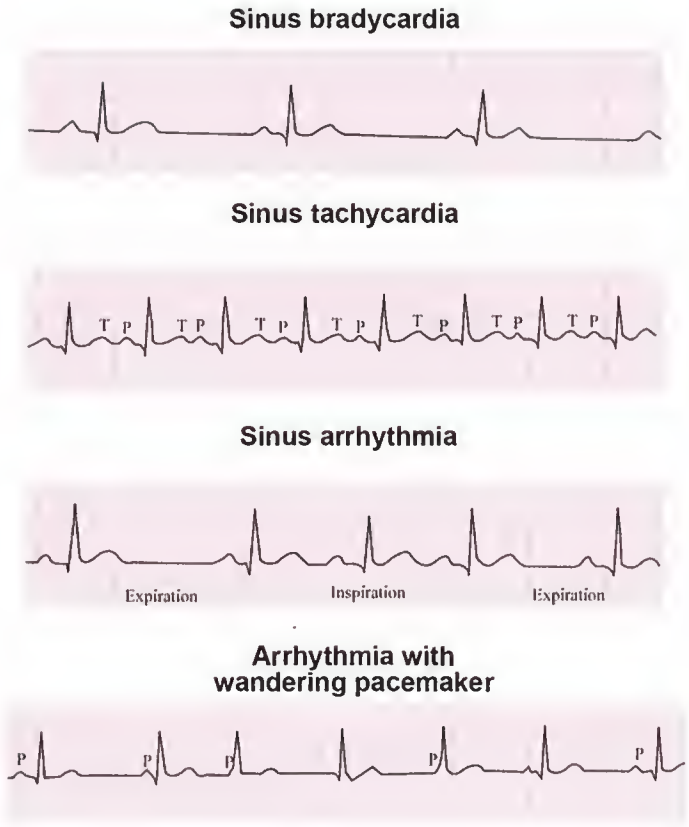

Figure 8: Abnormalities of heart rate.

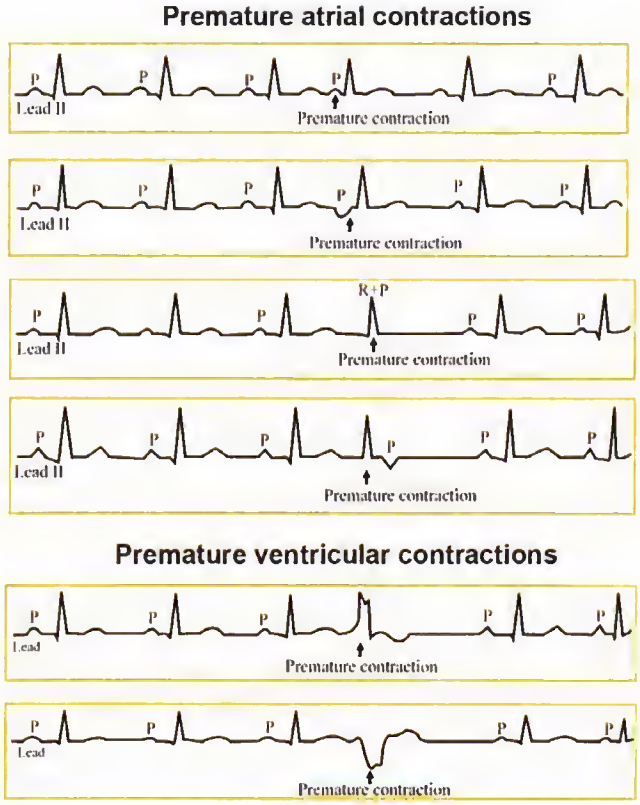

Figure 9: Ectopic beats.

Sinus tachycardia

Tachycardia is heart rate above 100/min. It is recognised by a normal P wave preceding each QRS complex. Heart rate usually does not exceed 150/min, but occasionally may be higher especially in children. Causes of sinus tachycardia include anxiety, fever, hypoxaemia, drugs, e.g. vasodilators and atropine, thyrotoxicosis, cardiac failure and acute carditis.

Ectopic beats, ectopic or re-entrant tachycardias

Atrial premature beats (Figure 9)

Atrial ectopic beats occur due to premature discharge from an ectopic atrial focus. The P wave of an atrial ectopic beat occurs before the next sinus P wave is anticipated. The configuration of the ectopic P wave is abnormal because it arises from a focus different from the sinus node. The premature, abnormal P wave of the atrial ectopic is designated P'. The compensatory pause is incomplete, i.e. the PP interval between the sinus beats which precede and follow the atrial ectopic beat is less than twice the PP interval between the two consecutive sinus beats. Atrial ectopic beats may or may not be associated with heart disease; more often they are not. Sometimes, these precede development of atrial tachycardia or atrial fibrillation. Causes of atrial ectopics are physiological like anxiety, excess tea, coffee or cola drinks and pathological as in viral infections, rheumatic heart disease, coronary artery disease, digitalis toxicity and cardiomyopathies.

Paroxysmal supraventricular tachycardia (Figure 10)

The most common form of paroxysmal supraventricular tachycardia (PSVT) is due to AV nodal re-entry with dual AV nodal pathways. Identification of P waves is difficult or impossible because atrial and ventricular depolarisations occur simultaneously. Occasionally, abnormal P waves may follow QRS complexes. The ventricular rate varies from 170 to 250/min. The rhythm is absolutely regular, i.e. the RR interval is constant. QRS morphology is usually normal. The ST segment may be depressed, and T wave may be inverted. PSVT most commonly occurs in individuals with structurally normal hearts. It is precipitated by an atrial premature beat. Occasionally PSVT occurs in association with Wolff-Parkinson-White or Lown-Ganong-Levine syndrome.

Atrial fibrillation (Figure 10)

In atrial fibrillation, the electrical activation and recovery of the atria are chaotic. Waves of depolarisation bombard the AV node at frequent (350 to 500/min) and irregular intervals with only some of them being able to pass through to the ventricles. The baseline is irregular and wavy (fibrillatory waves usually best seen in V_1). In rheumatic heart disease, the amplitude of the fibrillatory waves exceeds 0.1 mV (coarse fibrillation), while in coronary artery disease, fibrillatory waves are smaller (fine fibrillation). Occasionally the deflections are so fine that the baseline appears smooth in which case the irregular QRS complexes help to diagnose atrial fibrillation. Ventricular rate is usually 120 to 180/min in atrial fibrillation of recent onset unless the patient is already digitalised or is receiving beta-blockers or drugs like verapamil or amiodarone. The RR interval is irregularly irregular. The causes of atrial fibrillation include rheumatic heart disease, especially mitral stenosis, coronary artery disease, cardiomyopathies, thyrotoxicosis, and rarely constrictive pericarditis. Sometimes atrial fibrillation is idiopathic (lone atrial fibrillation) or occurs in chronic obstructive airway disease especially during acute respiratory infection. Transient or paroxysmal atrial fibrillation may occur following any surgery. Other causes of paroxysmal atrial

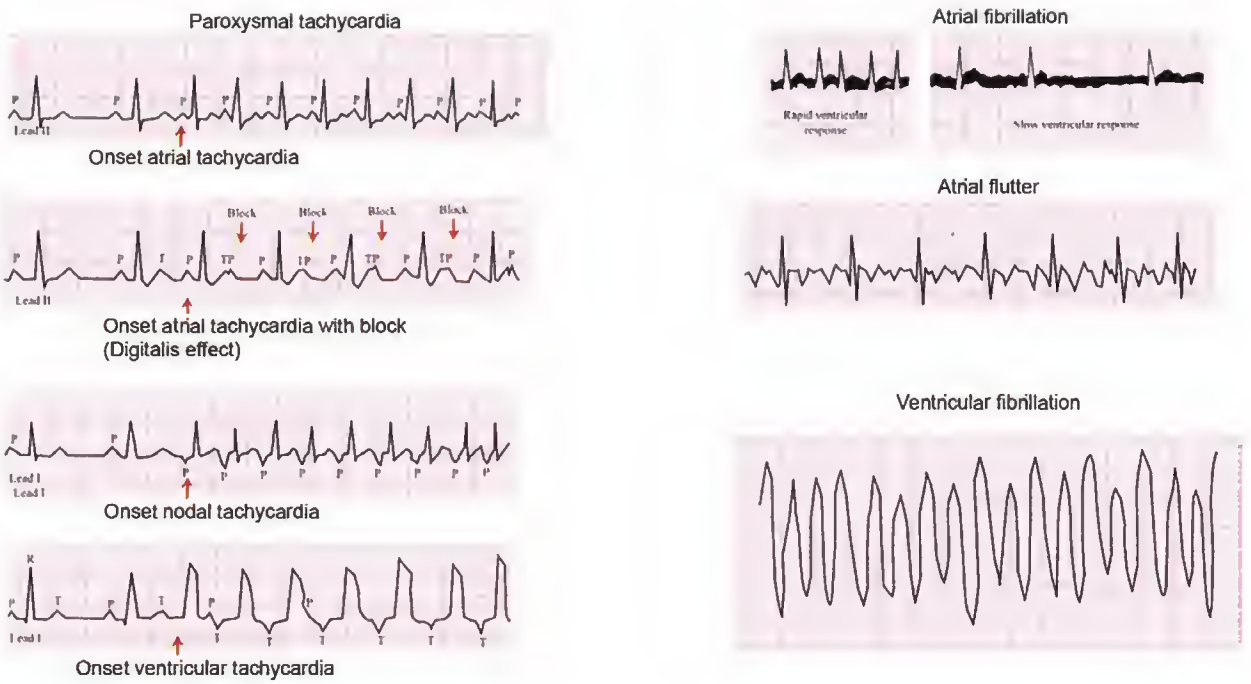

Figure 10: Atrial and ventricular tachyarrhythmias.

fibrillation include WPW syndrome, thyrotoxicosis and elderly age group.

Atrial flutter (Figure 10)

Atrial flutter (AF) is due to intra-atrial re-entry. Electrocardiographically, it is characterised by a regular, undulating baseline (flutter or F waves) resulting in a saw-tooth or corrugated appearance. There is no isoelectric line in between two P waves unlike in ectopic atrial tachycardia. Flutter waves are usually best seen in II, III, aVF and V_1. Flutter waves appear at a regular rate of 250 to 350/min. When flutter waves show some irregularity, the rhythm is designated 'flutter-fibrillation'. QRS complexes are normal and the RR interval is regular. Usually two flutter waves follow one QRS complex (2:1 AV block); however, 1:1 AV conduction may also occur. Other patterns of AV conduction like 4:1 may also occur but odd conduction ratios (e.g. 3:1) are rare. Occasionally, the AV conduction pattern is variable, giving rise to an irregular RR interval. Causes of atrial flutter are the same as for atrial fibrillation, i.e. chronic mitral valve disease, coronary artery disease and thyrotoxicosis.

Ventricular premature beats (VPBs) (Figure 9)

Ventricular premature beats (VPBs) occur due to premature discharge of a ventricular ectopic focus. There is usually no P wave preceding the QRS complex, unless the VPB is relatively late (late diastolic ventricular ectopic). The QRS complex appears earlier than anticipated, i.e. the RR interval shortens abruptly. The QRS complex is wide, bizarre and slurred or notched. When there are frequent VPBs, all may be similar in morphology (unifocal VPB) or they may show varying morphology (multifocal or multiform VPB). The ST segment is depressed and T wave inverted when the R wave is dominant in the QRS complex of the VPB. A dominant S wave is associated with the opposite pattern. A retrograde P wave may follow the QRS complex due to retrograde activation of atria across the AV node. The compensatory pause is complete, i.e. the RR interval between two sinus beats immediately preceding and following the VPB is twice the RR interval between two consecutive sinus beats. The coupling interval, i.e. the interval between the VPB and the preceding sinus beat is constant in unifocal VPBs. The coupling interval remains constant when the VPBs are multiform but is variable when these are multifocal. This is because multiform

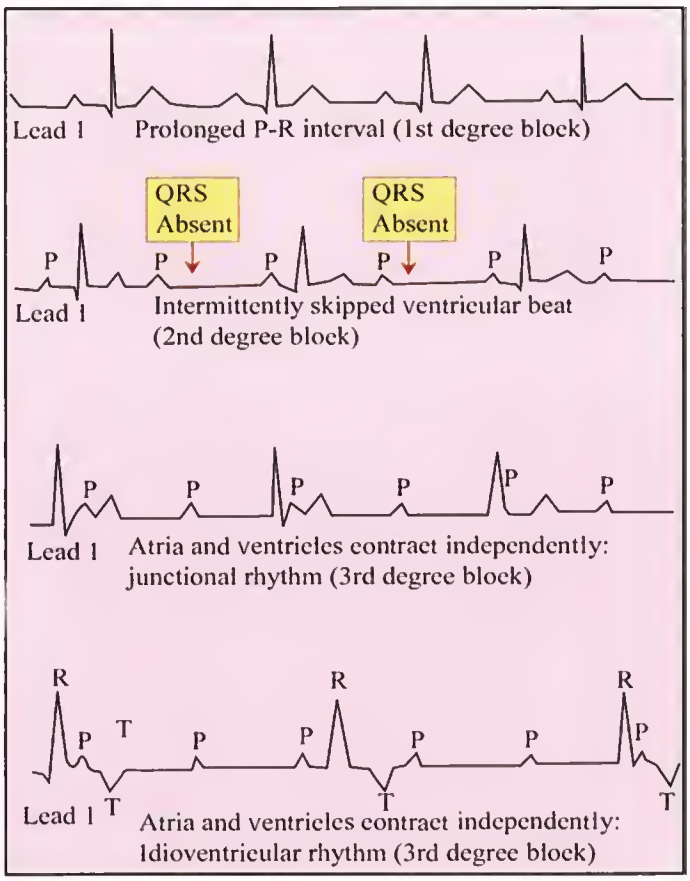

Figure 11: Atrioventricular block.

VPBs arise from the same focus though their morphology is variable while multifocal VPBs arise from different foci. The term 'ventricular bigeminy' is used when every alternate beat is a ventricular ectopic beat. It often occurs as a part of digitalis toxicity and in acute myocardial infarction. Isolated VPBs may be present in healthy individuals, especially in the elderly. Other common causes are digitalis toxicity, acute myocardial infarction, cardiomyopathies and electrolyte imbalance.

Ventricular tachycardia (Figure 10)

The diagnostic criterion of ventricular tachycardia (VT) is the occurrence of three or more successive ventricular premature contractions at a rate exceeding 100/min. Ventricular tachycardia may be non-sustained or sustained. Non-sustained tachycardia terminates spontaneously within 30 seconds while sustained ventricular tachycardia lasts for >30 seconds. Unless treated, ventricular tachycardia may degenerate into ventricular fibrillation and death. Causes of ventricular tachycardia are the same as those of VPBs. Coronary artery disease, especially acute myocardial infarction and the post-infarction period, account for a large number of cases of ventricular tachycardia. It may also occur in absence of structural heart disease when it is labelled as idiopathic ventricular tachycardia.

Ventricular fibrillation

Ventricular fibrillation (VF) is characterised by completely chaotic and irregular deflections of various height and width without any recognisable wave pattern. VF is the most common terminal event before death. Other terminal events are complete asystole, agonal rhythm (irregular ventricular complexes without any meaningful rhythm) and electromechanical dissociation (lack of mechanical contraction of myocardium despite organised electrical activity).

Atrioventricular block (Figure 11)

First degree atrioventricular block (AV block, heart block) when PR interval is >0.2 seconds. Second degree AV block is present when a QRS complex is missing following a P wave after a fixed or variable number of cardiac cycles. Second degree AV block is of two types—Mobitz type I block or Wenckebach type is characterised by a progressive prolongation of PR interval, shortening of RR intervals and dropping of a QRS complex following a number of conducted sinus beats. Mobitz type II block is characterised by a fixed PR interval without serial

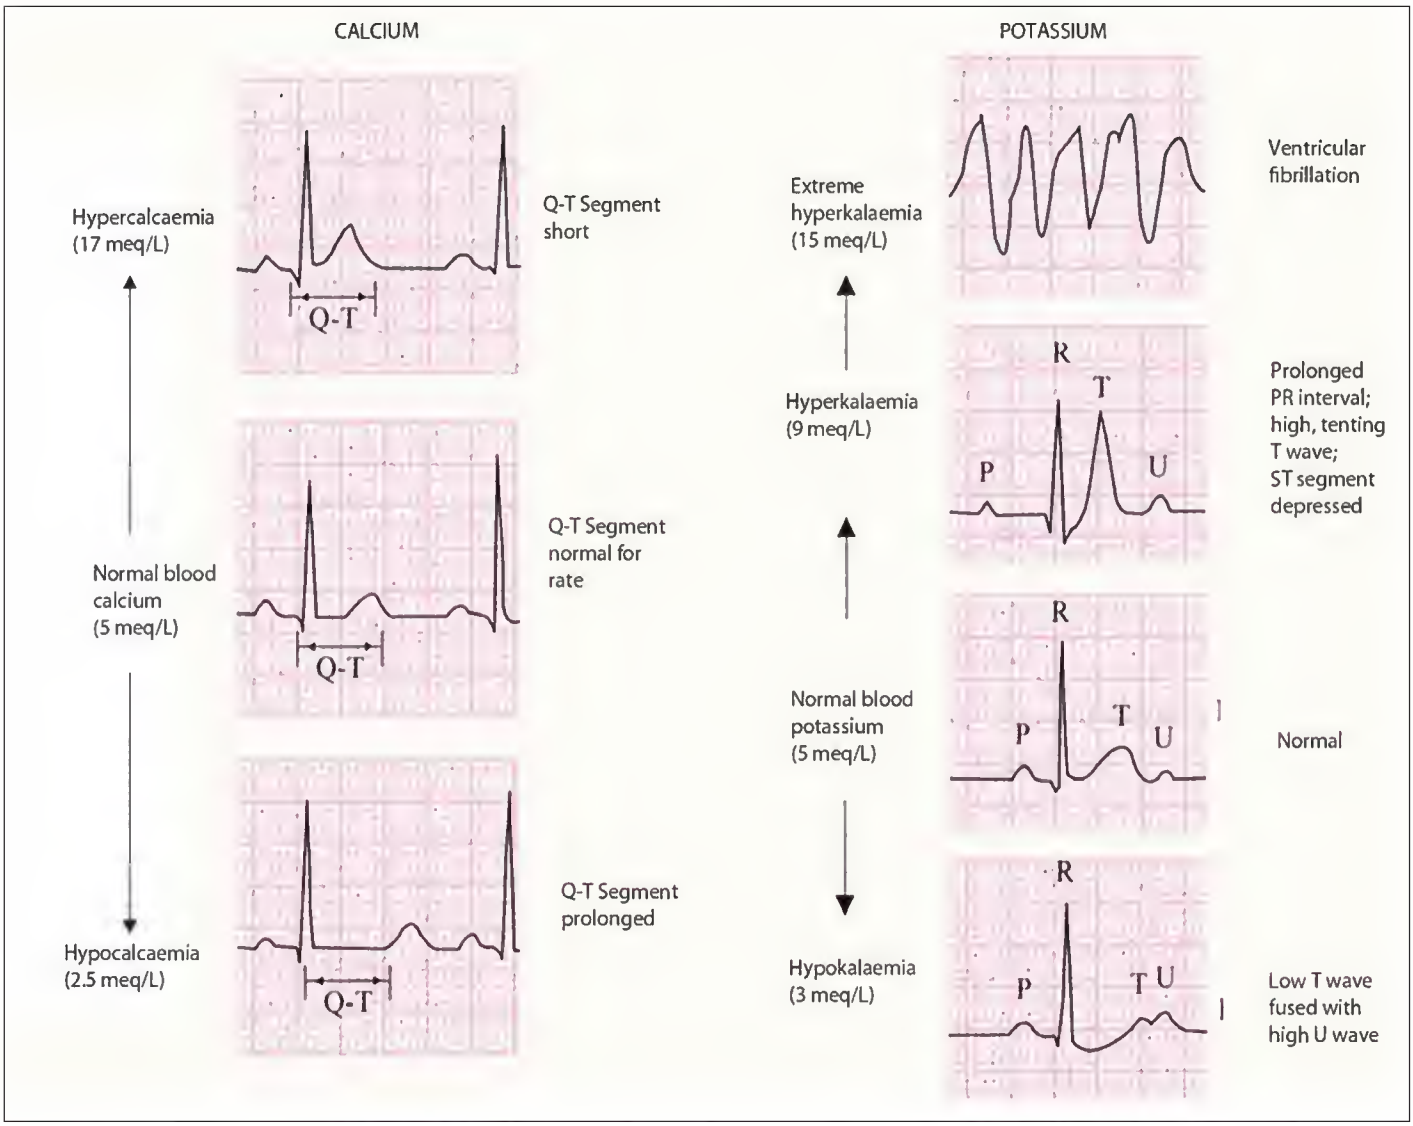

Figure 12: Effects of electrolytes on electrocardiogram.

prolongation, and intermittent, abrupt dropping of a QRS complex following a number of conducted sinus beats. The QRS complex is often wide and may exhibit either RBBB or LBBB pattern.

Mobitz type I (Wenckebach) block is generally due to failure of AV conduction at the level of the AV node. Prognostically, it is not so serious as it is unlikely to be progressive. Complete heart block either does not occur or occurs transiently following type I block. Type II block is most often due to failure of conduction below the AV nodal level, in the bundle of His or below it. It is more serious since it may progress on to an irreversible complete heart block. Common causes of second degree AV block are:- type I-acute inferior myocardial infarction, digitalis intoxication and acute carditis; type II-acute anterior myocardial infarction and degenerative disease of the conduction system. Complete heart (atrioventricular) block (CHB) is characterised by regular appearance of P waves which do not bear any relationship to the QRS complexes, i.e. the QRS complexes are dissociated from P waves. The former appear regularly at a rate of 20 to 40/min and represent discharge from the escape focus. The QRS may be normal or wide depending on the site of origin of the ventricular impulse. Failure of the escape ventricular focus to develop immediately or to remain stable after the onset of CHB, or a very slow rate, results in syncopal (Stokes–Adams) attacks due to interruption of blood supply to the brain. Recovery of the escape focus leads to consciousness within a few seconds in most cases. However, failure of recovery of the escape mechanism may result in death. Common causes of complete AV block include acute myocardial infarction (inferior and anterior), sclero-degenerative disease of the conduction system, and digitalis intoxication. Uncommonly, CHB is congenital in origin.

Electrolyte Disturbances (Figure 12)

Hypokalaemia is characterised by a prominent U wave which is generally the earliest change. Other electrocardiographic features are flattening and inversion of the T wave, ST segment depression, prolongation of PR interval and predisposition to ventricular arrhythmias. In hyperkalaemia the earliest change associated is occurrence of tall, peaked and narrow T waves. Progressive hyperkalaemia leads to a prolonged PR interval, atrial asystole, QRS widening, merging of QRS with T wave leading to sine wave configuration, and ultimately ventricular fibrillation followed by ventricular asystole.

Hypocalcaemia causes prolonged QT interval. Hypercalcaemia causes shortening of QT interval, with decreased T wave amplitude, sometimes with notching or inversion of the T wave.

12.4 Exercise Testing

Yash Pal Munjal

INTRODUCTION

Exercise testing is a non-invasive test used to evaluate the cardiovascular system's response to graded exercise under controlled conditions. Over the past eight decades it has provided useful diagnostic and prognostic information in patients of cardiopulmonary disease. With the advent of computer technology and digital imaging the various tests to assess the cardiovascular system have shown a remarkable progress and increase in their accuracy. Exercise testing has also improved in its technology, interpretation and accuracy of results. This has established 'the exercise test' as an important and useful test. This test in combination with other imaging modalities like echocardiography or radionucleotide imaging provides much more sensitivity and specificity to this test resulting in better diagnosis, better prognostication, assessment of cardiac perfusion and localisation of lesion. On the flip side the addition of these modalities significantly adds to the cost. This test has also been used to assess the athletic performance and for cardiovascular research. In association with pulmonary gas exchange measurements during exercise it provides unique and clinically relevant information about the cardiopulmonary health.

EXERCISE PHYSIOLOGY

The body adapts itself to the increasing intensity of exercise by increasing the metabolic rate. The body can increase the metabolic rate by up to 20 times the basal metabolic rate. During this adaptation the cardiac output (CO) also increases from 5 litres per minute to 25 litres to 30 litres per minute. The various adaptations mentioned above are achieved by the following haemodynamic changes:

1. Increase in heart rate
2. Increase in CO (achieved by increase in stroke volume and heart rate)
3. Increase in systolic blood pressure while the diastolic blood pressure is maintained at basal level or may show a downward trend
4. There is a fall in the total peripheral vascular resistance

To achieve the increase in the metabolic rate there is a progressive increase in the consumption of oxygen (mL/min) by various tissues. This is achieved by extracting more oxygen from the increased volume of circulating blood. Despite exercise the arteriovenous oxygen-difference is maintained within the narrow range of 15 mL/dL to 17 mL/dL. These changes in various parameters are dependent on age, gender, body mass index, type of exercise, body fitness, training and finally presence or absence of cardiovascular disease. It is evident from the above description that to meet the requirement of increased work load during exercise the total body oxygen consumption (VO_2 Max) and the oxygen consumption by the myocardium (MVO_2) increase considerably. These two parameters are distinct and their pathophysiology is at variance with one another.

The Total Body Oxygen Consumption

This is the total amount of oxygen extracted from the inspired air by the body to perform increased load of work. The CO and peripheral arteriovenous oxygen difference are the major determinants of VO_2 Max. Since the body mechanisms restrict the maximal arteriovenous oxygen (AVO) difference to a maximum of 15 mL/dL to 17 mL/dL. Thus the CO indirectly is a measure of maximal oxygen uptake (MVO_2 Max). During treadmill exercise the VO_2 Max may also be presented as the units of work load achieved. This is expressed as metabolic equivalent (MET), and it represents the oxygen consumption in litres/min. One MET is equated with the resting metabolic rate (approximately 3.5 mL of O_2/kg/min). The MET value achieved during an exercise test is presented as a multiple of the resting metabolic rate which can be measured directly by the oxygen uptake or estimated from the maximal workload achieved using equations. **Table 1** shows the level of work load achieved with various levels of exercise and its clinical significance.

Table 1: Clinically Significant Metabolic Equivalents for Maximum Exercise

1 MET	Resting
2 METs	Level walking at 3.2 kmph
4 METs	Level walking at 6.4 kmph
<5 METs	Poor prognosis, peak cost of basic activities of daily living
10 METs	Prognosis with medical therapy as good as coronary artery bypass surgery
13 METs	Excellent prognosis regardless of other exercise responses
18 METs	Athletes with high level of endurance
20 METs	Athletes at world class athletic performance

MET = Metabolic equivalent or a unit of sitting, resting oxygen uptake; 1 MET = 3.5 mL/kg/min oxygen uptake; kmph = kilometres per hour.

The Myocardial Oxygen Consumption

The myocardial oxygen consumption is the amount of oxygen utilised by the heart muscle during exercise. This is determined by various factors like left ventricular pressure and end-diastolic volume, contractile force of the heart and the heart rate. Myocardial oxygen uptake is estimated as the product of heart rate and systolic blood pressure (double product). It provides clinically useful information as angina on effort often occurs at the same myocardial oxygen demand (double product). The greater is the double product the better is the myocardial perfusion and prognosis. The double product may be low due to other limiting factors like a heavy meal, abnormal ambient temperature, organic coronary occlusion or coronary artery spasm.

The clinical and electrocardiographic (ECG) manifestations of exercise test are due to abnormalities in myocardial perfusion and function. The ECG response and angina are closely related to the increasing level of myocardial ischaemia. The other manifestations are limitation of the exercise capability, sudden spurt in systolic blood pressure or a fall in the systolic blood pressure and aberrant heart rate response to exercise. The ischaemia can also trigger cardiac rhythm disturbances and serious forms of cardiac arrhythmias may occur during exercise. These provide useful parameters to assess the myocardial ischaemia and long-term prognosis.

METHODOLOGY OF EXERCISE TESTING

There are three types of exercise modalities: (i) isotonic exercise or dynamic exercise, (ii) isometric or static exercise, and (iii) combination of the two forms of exercise.

Commonly, it is the isotonic or dynamic exercise which is used for conducting the exercise test. This can be performed on a treadmill or a bicycle ergometer. Treadmill test involves greater muscle mass and hence achieves a higher level of oxygen uptake. Based on this various dynamic protocols for conducting stress test have been enunciated. Some of them are Bruce, Naughton and Ellstead which are commonly used and, out of these, Bruce protocol is the one which is put to the maximum use. The protocol chosen for a particular patient should be such that it lasts for about 8 minutes to 12 minutes for continuous progressive exercise so that relevant information can be elucidated.

The test involves testing the heart under the stress of exercise and therefore the following prerequisites are essential:

1. The equipment must be properly calibrated and standardised.
2. A detailed history, physical examination and a pretest electrocardiogram must be done to evaluate the condition of the cardiovascular system of the patient.
3. Emergency resuscitative measures should be available at hand.
4. All due precautions must be taken before the test is performed, during the test (i.e. during the period of exercise) and after the termination of exercise.
5. All through the test the following parameters must be monitored at all times. These are electrocardiogram, blood pressure and clinical features like chest pain, dizziness, syncopal feeling or development of a third heart sound gallop or basal crepitations.
6. After the exercise has been terminated it is important to put the patient back in supine position and the monitoring should continue till all the parameters of electrocardiogram, blood pressure and heart rate have settled. But in normal individuals it must be done for at least 5 minutes post exercise.

Indications and Contraindications of Exercise Test

The indications and contraindications for stress testing are enunciated in **Tables 2 and 3** respectively.

In exercise testing, it is important to know when to stop the exercise so that no harm occurs (**Table 4**).

Table 2: Indications for Stress Testing

Evaluation of the status of coronary artery disease in patients of angina pectoris
Diagnosis of coronary artery diseases in patients with atypical chest pain or variant angina
Screening of high risk individuals, patients of diabetes or patients with two or more other coronary risk factors
Assessment of prognosis, functional capacity and evaluation of therapy
Assessment of functional capacity in patients of congestive heart failure, congenital or valvular heart disease
To evaluate patients with exercise related arrhythmias
To test the endurance capacity of athletes and those individuals who are in high risk vocations like pilots, drivers, etc.

Table 3: Contraindications to Exercise Testing

Absolute Contraindications
Unstable angina/acute myocardial infarction
Symptomatic cardiac arrhythmias with haemodynamic instability
Severe aortic disease like aortic valve stenosis and aortic dissection
Severe congestive heart failure
Recent pulmonary embolism
Test can be done with caution
Use of drugs, e.g. digitalis, β-blockers, etc.
Electrolyte imbalance
Arterial hypertension
Non-critical cardiac arrhythmias
Obstructive hypertrophic cardiomyopathy
Physical disability or unsound mind.

Table 4: Termination of Exercise Testing

Moderate to severe angina
Ataxia, dizziness
Fall in systolic blood pressure
Development of cardiac arrhythmias especially ventricular tachycardia
Significant ST segment depression (>2 mm of horizontal or down-sloping ST segment
Development of left bundle branch block or high degree of AV block
Increase in blood pressure more than 200 mm Hg
Refusal of the patient to continue exercise

Safety of Exercise Test

Exercise test is relatively a safe procedure with a high yield of diagnosis and prognosis in patients of cardiovascular disease. From a large number of series and experience of over 20 years it is estimated that there is one event per 10,000 patients. Despite the safety record of the test, it is essential to reiterate that the test must be done in the presence of a trained professional and with all resuscitative measures at hand.

INTERPRETATION OF EXERCISE TEST

It is important to interpret the exercise test in a comprehensive manner. This means that non-ECG and ECG parameters have to be taken together for interpretation. Various equations and scores have been devised based on these parameters. It is

estimated that the accuracy of stress test per se can go up to 80% with the use of these scores.

ELECTROCARDIOGRAPHIC CHANGES

Normal Electrocardiographic Changes During Exercise

The following changes in the electrocardiogram are observed while exercise in a normal adult:

(i) Increase in P wave amplitude

(ii) Shortening of PR, QRS and QT intervals with increasing heart rate

(iii) PR segment progressively becomes down-sloping in leads II, III, aVF and associated with this is the J point depression

Abnormal Response

It is predominantly the ST segment changes which are used to interpret the exercise test. The changes in ST segment can be:

(i) No change in the ST segment

(ii) Upsloping depression of ST segment

(iii) Horizontal ST segment depression

(iv) Down-sloping ST segment depression with T inversion

(v) ST segment elevation

These changes are diagrammatically presented in **Figure 1**.

ST segment depression indicates global ischaemia. The ST segment depression in inferior leads (II, III, aVF) does not predict ischaemia correctly. The ST segment depression cannot localise the site of ischaemia and the coronary artery involved. The horizontal or down-sloping ST segment depression of equal to or more than 1 mm is definite indicator of ischaemia. ST segment depression in anterior pericardium leads, i.e. V_4, V_5 and V_6, is quite important. Of all these leads, the changes in lead 5 as a single lead has maximum validity. An upsloping ST segment depression has doubtful accuracy in diagnosing ischaemia. ST segment depression 0.80 second beyond the J point of more than 1.5 mm is suggestive of ischaemia. ST segment depression seen in leads with Q wave does not carry the same importance. ST segment depression seen during the recovery phase may also indicate coronary artery diseases. ST segment elevations seen in leads without Q wave is highly suggestive of coronary artery disease and if it is associated with ST segment depression in the reciprocal leads, it indicates critical coronary lesion or a severe spasm of the coronary arteries.

ST segment depression in patients with left bundle branch block, Wolff–Parkinson–White syndrome, intraventricular conduction defects, implanted with pace makers or on drugs does not have the usual diagnostic power of ST segment depression. Some of the representative exercise tests are shown in **Figures 2 to 4**.

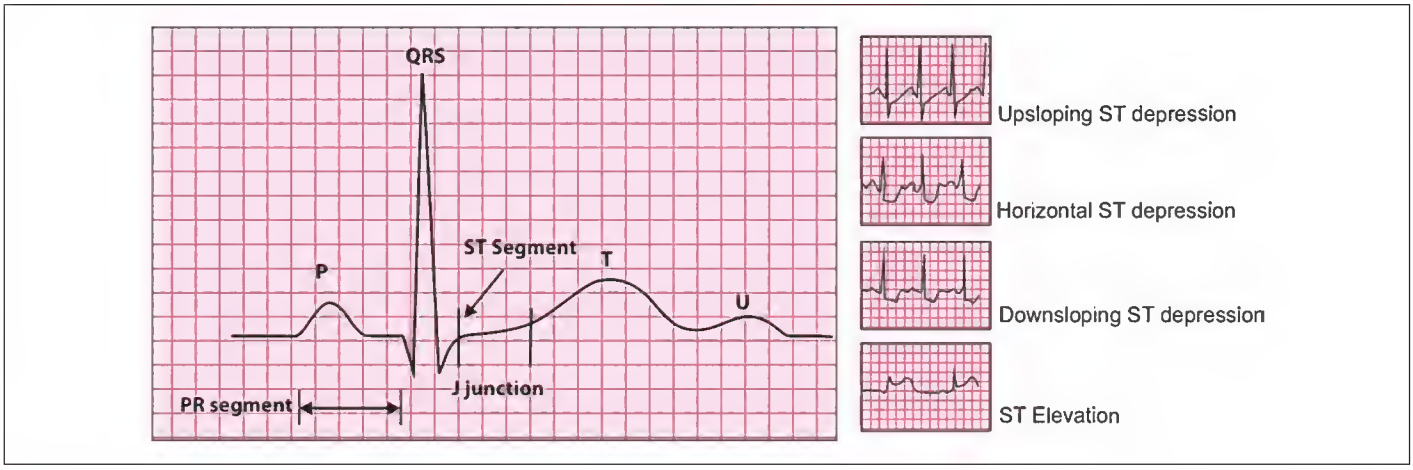

Figure 1: Electrocardiograph nomenclature.

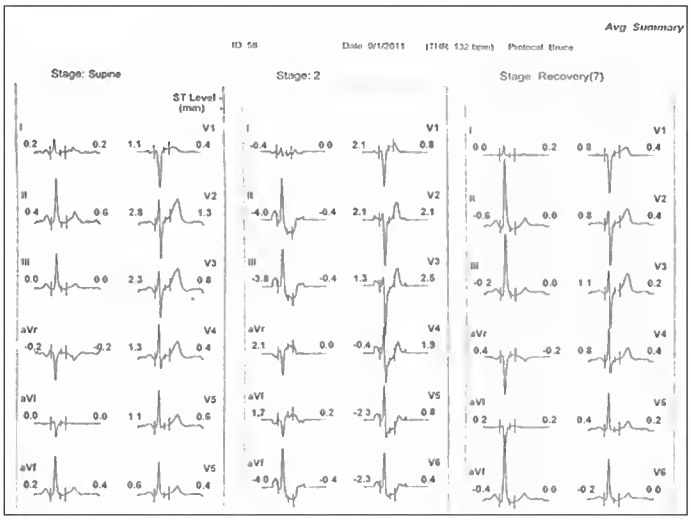

Figure 2: Exercise test showing significant horizontal ST depression.

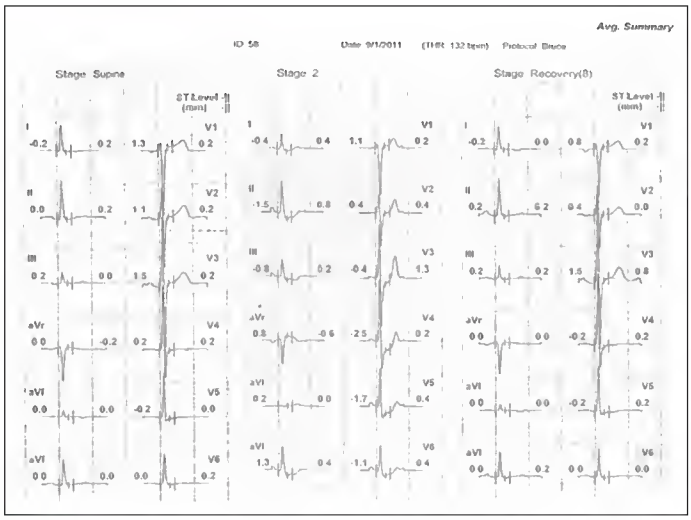

Figure 3: Exercise test showing upsloping ST depression.

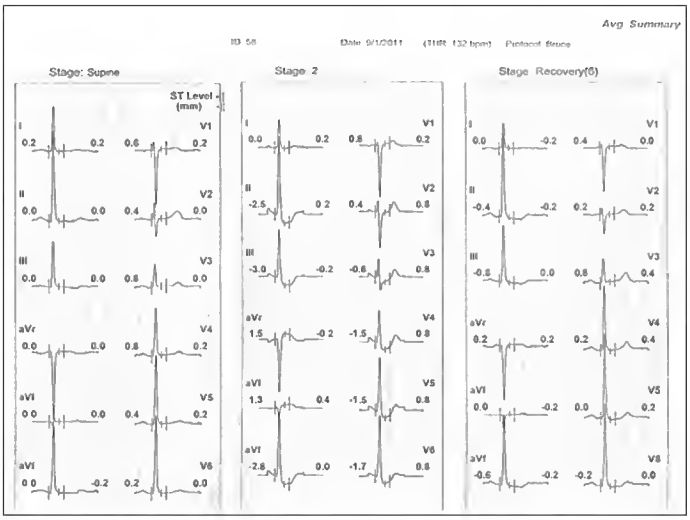

Figure 4: Exercise test showing ST-T changes and persisting in recovery.

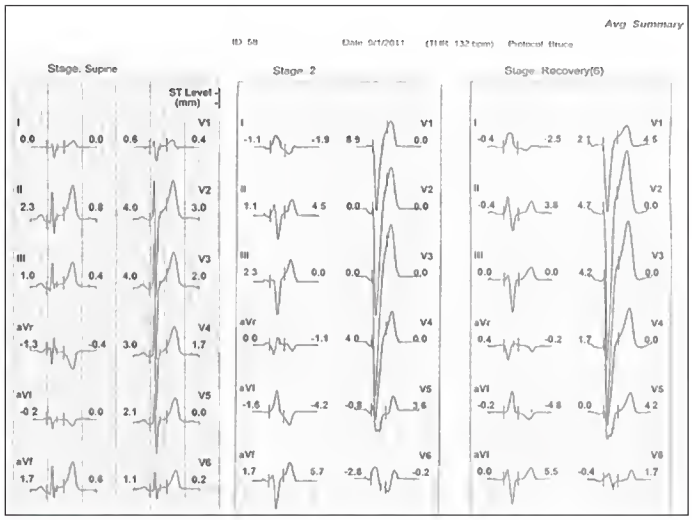

Figure 5: Exercise-induced LBBB.

Disturbances in Cardiac Rhythm

Ventricular arrhythmias in patients with known coronary artery disease or asymptomatic coronary artery disease have an increased risk of death and disability. In patients with congestive heart failure, presence of murmurs in the heart and existing ECG abnormalities at baseline, the exercise induced ventricular arrhythmias carry a grave prognosis. A sustained ventricular tachycardia with a normal baseline electrocardiogram also is associated with poor outcomes. Supraventricular tachycardias are an uncommon occurrence and do not seem important as ventricular arrhythmias. Similarly, bradyarrhythmias like development of high degree AV block are suggestive of poor myocardial function and critical coronary artery disease.

Bundle Branch Block

The development of right or left bundle branch block (LBBB) in isolation during the exercise does not indicate a bad prognosis (**Figure 5**). In case there is associated angina pectoris with development of bundle branch block then it is of grave importance.

NON-ECG PARAMETERS

Heart Rate

The heart rate increases with exercise, and inappropriate increase in the heart rate at the beginning of exercise can occur in patients predisposed to atrial fibrillation, poor effort tolerance, hypovolaemia, anaemia and in patients of left ventricular systolic dysfunction. The increase in the heart rate in response to the exercise may be blunted in patients where the sympathetic tone does not increase with the level of exercise or in sinus node dysfunction, myocardial ischaemia and patients on beta-blockers. The delay in heart rate recovery is indicative of abnormalities of vagal tone and is associated with high mortality.

Blood Pressure

As described earlier, the increasing work load of treadmill is associated with progressive increase in the systolic blood pressure while no significant change takes place in diastolic blood pressure or there may be slight fall. In patients with increased sympathetic tone, there may a sudden increase in blood pressure and an increase in blood pressure to more than 200 mm Hg systolic is an indication to stop exercise. There may be exertional hypotension (i.e. fall in blood pressure of >10 mm Hg) or the failure of the systolic blood pressure to increase beyond 120 mm Hg indicates triple vessel disease. The possibility in such patients of cardiomyopathy, hypovolaemia and left ventricular outflow obstruction has to be kept in mind and excluded.

Other Parameters

The myocardial oxygen consumption and the perfusion of the heart are measured by the double product (i.e. heart rate x blood pressure). This is also a useful predictor and a double product of more than 25,000 is desirable. It has been seen that the onset of angina most of the time takes place at the same level of double product and therefore can help in planning of exercise for patients of coronary artery disease.

The following factors, viz. duration of exercise, maximum heart rate achieved, associated ST segment changes can provide useful information about the diagnosis and prognosis.

Other Physical Parameters

The cardiac examination also has to be carried out before and during the exercise test. The development of cardiac murmurs, 3rd heart sound or evidence of left ventricular failure (development of basal crepitations) point strongly to the triple vessel disease and poor outcomes.

BENEFITS OF EXERCISE TESTING

Diagnostic Utility

An isolated stress test has a sensitivity and specificity of 68% to 77%. This is significantly lower in patients of single vessel coronary artery disease but in patients of triple vessel disease or left main disease, it may reach 80%. Use of various scores, especially like Duke Treadmill, increases the sensitivity to over 80%. The test may be false positive in women, patients on digitalis therapy, valvular heart disease, hypokalaemia and anaemia. The diagnostic utility of stress test has been established in patients with non-specific chest pain or screening of high risk cardiovascular patients. It may be used as a research tool to evaluate the effects of various forms of therapy and similarly to test patients in risky vocations like pilots, drivers, etc. The utility of stress test in assessment of

the functional status in patients of coronary artery disease, congestive heart failure, valvular heart disease is now well established and an objective assessment of improvement can be done pre- and post-therapy.

Prognosis

Stress test has been found to be quite useful to provide information on prognosis in the following clinical situations:

(i) Patients with coronary artery disease who have suffered a cardiac event or have undergone a cardiac intervention

(ii) Patients with valvular heart disease

(iii) Patients with congestive heart failure

The prognosis cannot be given in isolation but is based on the evaluation of ECG changes, changes in the heart rate, blood pressure and work load achieved. Patients who achieve a work load of less than 5 MET are associated with poor prognosis. **Table 1** gives the work load achieved, its clinical implications and prognosis. ST segment depression which is either down-sloping or horizontal and seen in more than 5 leads or ST segment depression at the beginning of exercise with a heart rate of less than 100 all carry a sinister prognosis.

CONCLUSION

Exercise stress test is the second most commonly performed test after electrocardiogram. It is a useful complimentary test to medical history and physical examination. The evidence has clearly shown that interpretation of stress test using various treadmill scores (e.g. Duke Treadmill score) improves the diagnostic and prognostic capability of the test without escalating the cost. A well-calibrated instrument and the performance of the test in an accurate manner is critical for obtaining good results. The test should only be done with clearly defined indications, and it should be avoided strictly in presence of contraindications. In this particular test, it is of vital importance that the operator should be well versed when to terminate the exercise test. The knowledge and the limitations in interpreting the test have to be understood and the result should be interpreted in a comprehensive manner using both the ECG and non-ECG criteria. The knowledge of the limitations in case of abnormal electrocardiogram at the beginning of the test has to be properly understood and rightly excluded. The use of diagnostic and prognostic scores, such as Duke Treadmill score, has increased the value of stress test very significantly.

12.5 Echocardiography

Satish Kumar Parashar

INTRODUCTION

Echocardiography is the heart of clinical cardiology. In today's rapidly evolving fields of interventional cardiology, cardiac surgery, electrophysiology and clinical cardiology, echocardiography plays a major role like never before. Echo-Doppler imaging is a key component in not only establishing diagnosis, but also critical to medical and therapeutic decision-making and monitoring response to therapy. In a statement by American College of Cardiology 'Echo has been a fastest growing technique, the wealth of information which provides is unmatched, and is likely to be the stethoscope of the future'. This is because, not only it provides full anatomical and functional information, but also complete haemodynamic information. Because of its portability and providing immediate diagnosis, its role has extended to critical care areas, cardiac catheterisation and electrophysiology laboratories, operating rooms, etc. The strength of information it provides has mitigated the need of invasive studies in large number of cardiac disorders, especially valvular and congenital lesions. One of the many dramatic advances in the instrumentation is the miniaturisation of the equipment, and now palm-sized equipment is available which can be carried in the pocket during clinical rounds (**Figure 1**). Some of the other technological advancements have been transoesophageal echocardiography (TEE), 3D echocardiography, myocardial contrast echocardiography (MCE), quantitative tissue Doppler imaging (TDI), etc.

As echocardiography and Doppler is a very vast subject with its application in practically every cardiac disorder, hence due to constraint of space, some basic aspects will be discussed.

Figure 1: A small-sized hand held ultrasonic device weighing only 390 grams (*Reproduced with permission from the Editor, Indian Heart Journal*).

BASIC MODALITIES OF ECHOCARDIOGRAPHY

The basic imaging techniques, for the beginners, include conventional 2D and M-mode imaging, Doppler modalities including colour flow imaging. All these modalities rely on the presence of a special type of crystals, called piezoelectric elements, located in the transducer which is a very essential component of the equipment. These crystals vibrate by the passage of electrical current and generate ultrasound waves which are transmitted in the body. Part of the ultrasound waves are reflected back and are electronically processed in the equipment producing characteristic images. Different types of electronic transducers are available which are used for different imaging A high frequency transducer (4 to 7.5 mHz) is used for infants because they have less penetration and better resolution, because in infants and small children, the cardiac structures are closer to the chest wall. In contrast, a low frequency transducer is used in adults, because they need a deeper penetration but with lesser resolution. The current digital machines have increasingly fast processors allowing the handling of immense quantity of data.

M-Mode Echocardiography

This was the earliest form of echocardiographic examination. It provides limited information because it is virtually a single point study and does not provide information in the lateral dimension. There has been a controversy whether this modality needs to be abolished. However, it will continue to stay because in a large number of centres, it is still being used for various chamber dimensions and thickness. As will be discussed later, it still gives useful information.

2D Echocardiography

This is the starting point in any echo examination and gives a wider view of the heart. As such multiple structures can be seen in one imaging plane. Its main applicability is that it provides complete anatomical and functional information, including ejection fraction. However, it does not provide any haemodynamic information.

Standard Imaging Planes

There are a large number of imaging planes, the description of which is beyond the scope of this paper. Every plane depicts different structures and myocardial segments in a different format. However four scan planes must be used in every patient. These are: (a) Parasternal long axis view commonly referred as PLAX view (**Figure 2**); (b) Short axis view – SAX view, which is at various levels like aortic valve and great vessels mitral valve, papillary muscle, apex; (c) Various apical views like four chamber view (**Figure 3**), three chamber or long axis view, two chamber view; and (d) Subcostal view which is the best view for initiating a paediatric examination. Suprasternal, right parasternal and right supraclavicular views are taken in special situations. In any particular patient attempt should be made to obtain all views as twhese are complementary to each other. Every transducer has an index mark which is utilised for imaging the structures in a particular format, e.g. in apical four chamber view, if the index mark is pointing towards the right shoulder then the LV will be on the left-side of the screen and if it is at about 3o'clock position then it will be on right-side of the screen.

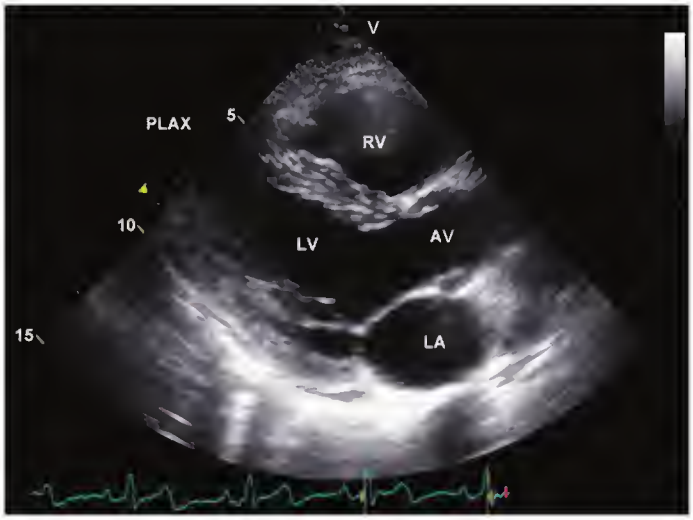

Figure 2: Systolic frame of parasternal long axis view showing opened aortic valve (AV) within the aortic root, left atrium (LA), right and left ventricles (RV, LV), closed mitral valve is between LA and LV. Interventricular septum is between RV and LV.

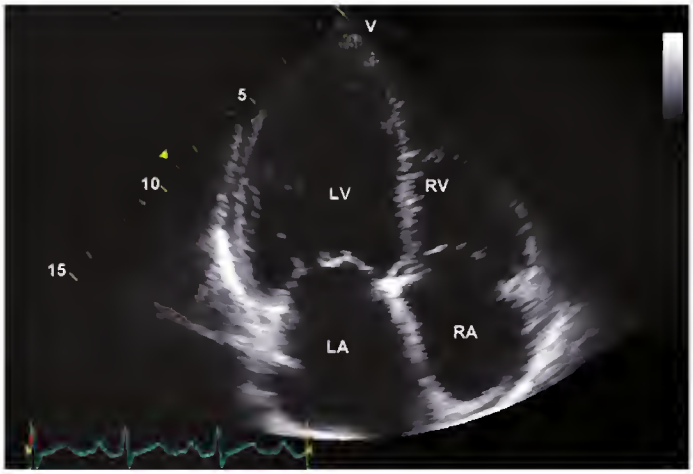

Figure 3: Apical four chamber view showing both ventricles (LV and RV) and both atria, LA (left atrium), RA (right atrium). The interatrial and interventricular septum are well seen. The mitral and tricuspid valves are between their respective atrio-ventricular chambers. The index mark is towards the right shoulder.

Doppler Echocardiography

Currently it is an integral part of any echocardiographic examination as it provides a comprehensive haemodynamic information. This is the main technique to provide accurate assessment of severity of any cardiac lesion. In Doppler, the moving red blood cells are the target from where ultrasound waves are reflected. The Doppler principle and computerised analysis of returning Doppler signals allow velocity and direction of flow to be determined. The blood flowing towards the transducer is depicted as a positive wave above the baseline and *vice versa* (**Figure 4**). Irrespective of any 2D imaging view, the transducer is always pointing downwards from the top (apex). This helps in determining whether the Doppler spectrum will be above or below the baseline. Doppler records velocity of blood flow at a particular area. This allows determination of gradients (difference of pressure between two chambers) by the well validated modified Bernoulli equation, i.e. $4 \times (\text{velocity})^2$. If the peak velocity across any valve is 4 m/s, then the peak gradient is $4 \times 4^2 = 64$ mm Hg. The mean gradient, which is an average of multiple instantaneous gradients over a cardiac cycle, is more diagnostic of severity of a lesion rather than peak gradient which is dependent on the blood flow across a structure. It is obtained by tracing the Doppler envelope (**Figure 4**). The two main Doppler modalities are: (a) pulsed Doppler which calculates low velocity flow at specific points along the jet of blood flow; and (b) continuous wave Doppler which records high velocity flows, hence is used for all diseased states like valvular lesions, shunt flows, estimation of pulmonary artery pressure, etc. One of the most important requirements of Doppler study is that best quantitative results are obtained by putting Doppler beam as parallel to the flow as possible. All quantitative parameters are under-evaluated if one is off angle to the flow. This is unlike 2D examination where best imaging is obtained if the ultrasound wave is perpendicular to the structures. This is why PLAX and SAX views are best imaged. The Doppler velocities are depicted in the vertical axis while timing is along the horizontal axis.

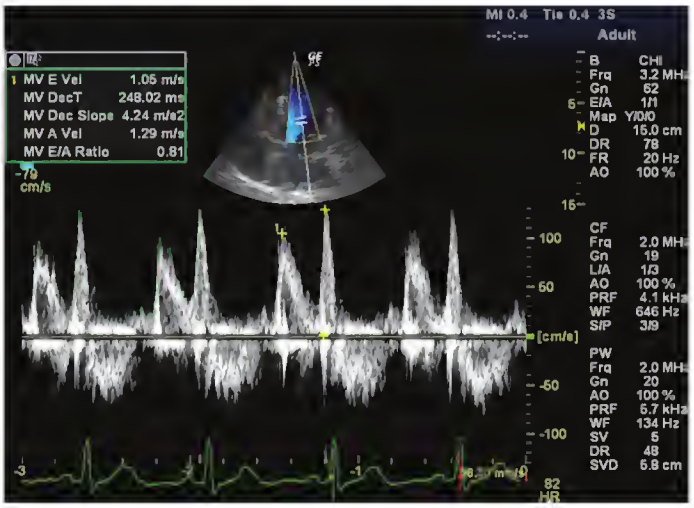

Figure 4: Doppler spectrum of mitral valve showing a positive shift above the baseline. By tracing the Doppler envelope (second from right), peak and mean gradients are obtained.

Colour Flow Mapping (CFM)

CFM is effectively an automated 2D version of Pulsed Doppler technology, in which one can visualise the actual colour coded blood flow. By convention, flow towards transducer is depicted as a red colour and flow away in blue. Normally the flow colours are smooth while in diseased flow states additional colours are added to the conventional colours known as turbulent 'mosaic pattern'. In day-to-day practice, the two main advantages of CFM are: (a) by seeing the direction of the Doppler beam can be placed parallel to the blood flow to get best quantitative results; and (b) by seeing a turbulent flow, it is immediately evident that a diseased area is being studied.

Requisites for a good echocardiographic examination:

1. A good clinical evaluation is mandatory to form a clinical impression.
2. ECG tracing must be available to know the timing sequence.
3. Patient should be as comfortable as possible.
4. The sequence of study should be 2D, CFM followed by Doppler.
5. All scan planes should be thoroughly studied.
6. All haemodynamic information should be obtained.

7. Multiple lesions can be present, so never be satisfied with detection of one lesion.
8. Determine aetiology of a particular abnormal finding, e.g. if LVH is present, explain whether it is due to aortic valve disease/cardiomyopathy/hypertension/any other lesion.

HAEMODYNAMIC INFORMATION OBTAINED FROM ECHOCARDIOGRAPHY

One of the major advantages of echocardiography is providing a haemodynamic information non-invasively. As mentioned earlier, 2D echocardiography provides a structural and functional information while Doppler gives a haemodynamic information, i.e. velocities, gradients, etc. As haemodynamics is an extensive subject hence evaluation of only right atrial (RA), and right ventricular/pulmonary artery (RV/PA) pressure will be briefly discussed.

The importance of determining RA pressure (RAP) is mainly two-fold: (a) it gives an idea of intravascular volume status and helps in management strategy; and (b) RAP is added to various right heart haemodynamic values to get a correct number. The RA pressure is mainly evaluated by inferior vena cava (IVC) diameter and its collapsibility during spontaneous respiration. In a normal individual the IVC diameter is 1.7 to 2.0 cm and there is a normal inspiratory collapse of >50%. This indicates a mean RA pressure of about 10 mm Hg. The IVC is scanned from subcostal view and measurements are made about 1 to 2 cm from IVC-RA junction with patient in supine position. The IVC collapsibility index is calculated as: IVC maximum diameter –IVC minimum diameter/IVC max × 100. A greater than 50% collapsibility indicates RAP of greater than 10 mm Hg (**Figure 5**). A dilated IVC with less than 50% collapse indicates an RAP of 15 mm Hg, while a dilated IVC and hepatic vein with no significant collapse of IVC indicates an RAP of about 20 mmHg necessitating fluid restriction and need for diuretics. On the other hand, a small IVC (<1.2 cm) with spontaneous collapse may indicate hypovolaemia requiring fluid replacement.

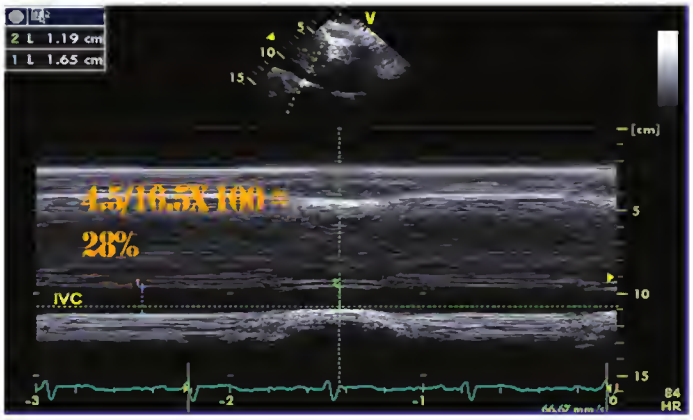

Figure 5: Decreased inspiratory collapse of inferior vena cava (IVC).

The RV and PA systolic pressures are identical in absence of any RV outflow obstruction. The quantitation is done by interrogating the jet of tricuspid regurgitation (TR). The TR occurs as a result of tricuspid annular dilatation, due to persistently increased pressure, and its peak velocity reflects pressure gradient between RV and RA. So RV/PA pressure is $4 \times V^2 + RAP$. Echocardiography underestimates PA pressure by ± 10 mm Hg because of two operator related factors: (a) underestimation of RAP; and (b) underestimation of TR jet velocity by not studying all scan planes and Doppler not being parallel to the TR jet.

COMMON CLINICAL INDICATIONS

Though the list is very exhaustive, but few clinical scenarios will be discussed as seen in day-to-day practice.

Evaluation of Cardiac Functions

Currently, the cardiac functions are classified into systolic and diastolic.

Systolic

Evaluation of systolic LV function is the most frequently asked investigation and is a very important component of cardiology practice. It forms the basis of diagnosis, prognosis and treatment of practically every cardiac disorder. Though there are a number of techniques to assess LV function like ventriculography, nuclear cardiology, cardiac MRI, cardiac CT, but echocardiography is the most practical in day-to-day practice and has a wonderful track record in assessment. The most common denominator of LV function continues to be the ejection fraction (EF) which is the stroke volume divided by end diastolic volume. The most common method for determining EF is Modified Simpsons method. It may be mentioned here that M-mode echocardiography has no role in assessing LV volumes and function. Certain factors affect the precise validity of EF like preload, afterload, contractility, heart rate, arrhythmias, poor endocardial delineation, grossly distorted left ventricle (LV), abnormal septal motion and is very operator-dependent. However, it continues to be the 'magic word' for clinicians. Though the value above 50% is considered normal but according to recommendations of American Society of Echocardiography (ASE), a value above 55% is normal, 45% to 54% is mildly abnormal, 30% to 44% moderately abnormal and below 30% severely abnormal.

To reduce the intra and inter-observer variability, other techniques are available like MCE, live 3D echocardiography, myocardial performance index, strain imaging, etc.

Diastolic dysfunction

Advanced diastolic dysfunction can lead to isolated diastolic heart failure, now referred to as heart failure with normal ejection fraction (HFNEF). In Western population it is seen in about 40% to 50% of cases. Conditions predisposing to HFNEF are hypertension with or without diabetes mellitus, coronary artery disease, cardiomyopathy, obesity, sleep apnoea syndrome, etc. Diagnosis of HFNEF is based on following criteria:

1. Presence of clinical syndrome of heart failure,
2. Presence of normal ejection fraction (>50%),
3. Presence of diastolic dysfunction,
4. E/E' (ratio of mitral Doppler E wave velocity to tissue Doppler early diastolic velocity, i.e. E' greater than 15:1 indicative of increased LV filling pressure, and
5. Usually non-dilated heart.

Echocardiography can confidently assess diastolic functions by evaluating mitral inflow Doppler, tissue Doppler, pulmonary vein, LA volume index, etc.

VALVULAR HEART DISEASE (VHD)

In view of a high incidence of rheumatic heart disease in our country, echocardiography has made a tremendous impact

in VHD. This is because of its high diagnostic capability and excellent correlation with cardiac catheterisation. As such haemodynamic studies are not required unless coronary arteries need to be evaluated. Moreover, echocardiography is very cost effective. The role of echocardiography in VHD is as follows:

1. Diagnosis
2. Assessment of severity
3. Presence of other valvular lesions, if any
4. Assessment of left ventricular functions
5. Assessment of indirect haemodynamic effects like PAH
6. Diagnosis of complications like vegetations, LA or appendage thrombus, etc.
7. Stress echocardiography in subset of patients
8. Guide to timing and type of intervention
9. Serial follow-up

To slightly elaborate few points mentioned above, echocardiography is ideal for the correct diagnosis of valvular lesions and the precise severity is assessed by Doppler, though indirect evidence is obtained by 2D echocardiography. The LV function (ejection fraction) is one of the important parameter in deciding intervention in VHD. An EF which could be normal for a normal person may be considered less for a patient with mitral regurgitation (MR), aortic stenosis (AS) or regurgitation (AR). A stress echocardiography is performed in a subset of patients, especially mitral stenosis (MS), when there is discordance between clinical symptoms and echocardiography findings, i.e. patient is dyspnoeic on mild exertion but echocardiography does not show a severe lesion. One is not clear whether dyspnoea is due to MS or other conditions like COPD, obesity, poor exercise conditioning, etc. A pre- and post-exercise study showing effect on gradients and rise of PA pressure gives a clue to diagnosis. The type of intervention depends upon various factors like the degree of calcification, status of subvalvular apparatus, leaflet mobility, thickening, degree of valvular regurgitation, etc. As such in MS, severe subvalvular thickening, calcification, large left atrial/appendage clot (**Figure 6**) or moderate mitral regurgitation favour surgical intervention.

Stenotic Lesions

All stenotic lesions, irrespective of the valve involved, are characterised by: (a) thickening/fibrosis/calcification depending upon the stage of disease; (b) doming of the cusps, when the valve is fully open, is a characteristic sign. Doming is in the direction of blood flow, i.e. convexity towards the distal chamber (**Figures 7 and 8**); (c) reduced valve mobility due to thickening or fibrosis of the cusps; (d) decreased valve orifice area; and (e) increased transvalvular gradients across the stenotic valve, depending on the degree of stenosis, as determined by Doppler.

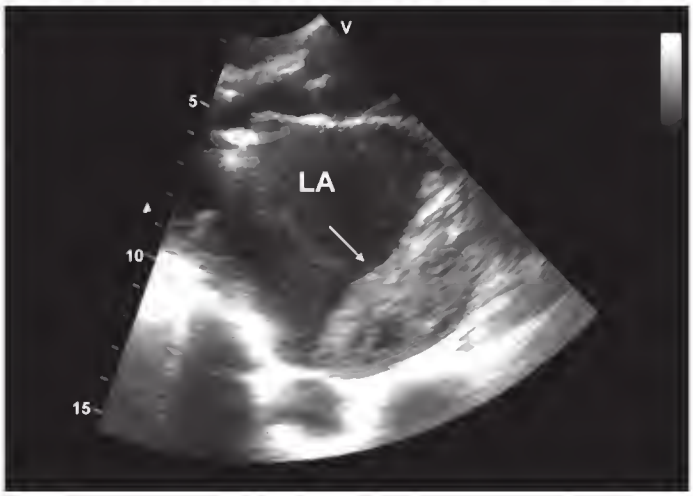

Figure 6: PLAX view showing a large thrombus (arrow) in left atrium (LA).

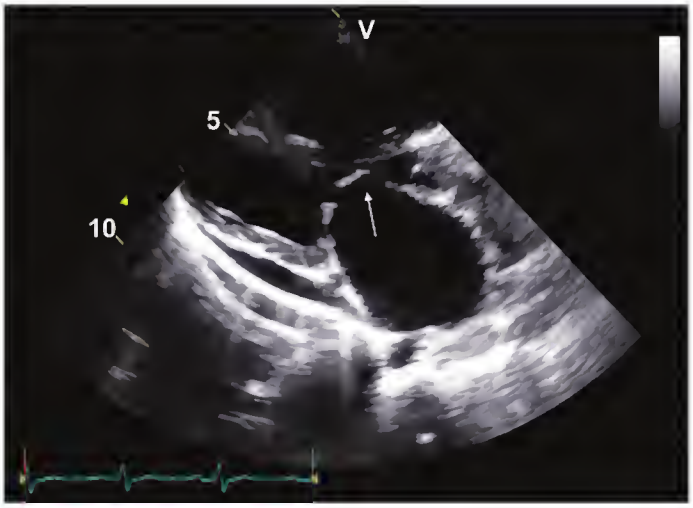

Figure 7: PLAX view in diastole showing doming of anterior mitral leaflet (arrow) with convexity towards left ventricle.

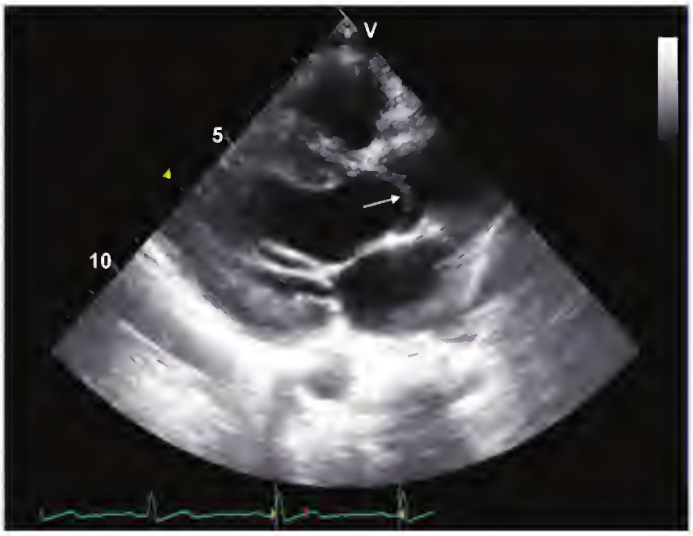

Figure 8: PLAX view in systole showing doming of aortic cusps (arrow) with convexity towards aorta.

The severity of the stenotic lesion is mainly determined by valve area and the pressure gradients, especially mean gradient across it. In MS a valve area of less than 1.0 cm^2 is indicative of severe stenosis, an area between 1.1 cm^2 and 1.5 cm^2 indicates moderate stenosis and 1.6 to 2.5 cm^2 suggests mild stenosis. The area is determined from SAX view. In case of aortic stenosis, an orifice area of less than 1.0 cm^2, in presence of normal cardiac functions, indicates severe stenosis. A mean aortic gradient of greater than 40 mm Hg, as per ASE or greater than 50 mm Hg as per European Society criteria, indicates severe stenosis.

It is imperative to scan all the valves meticulously. Concomitant tricuspid stenosis (TS) with MS is being often missed. The main cause of TS is rheumatic heart disease, but other aetiologies like tumour, vegetation, valvular damage

from catheters or pacemaker leads, etc. should not be overlooked. The normal TV velocity is 0.5 to 1.0 metres/second, and mean gradient is usually less than 2 mm Hg. TS is considered severe if mean gradient is more than 7 mm Hg, and valve area less than 1.1 cm^2.

Regurgitant Lesions

Echocardiography plays a key role in evaluation of valvular regurgitation.

The diagnosis is mainly aided by CFM which can directly visualise the jet in the receiving chamber. As regurgitant lesions produce volume overloading of the relevant chamber (LA, LV in MR and LV in AR), hence a semiquantitative idea of severity is assessed by degree of enlargement and thickening of chambers which are compensatory mechanisms. A reasonable idea of severity is assessed by Doppler and CFM. In MR an idea of severity is based on the traced area of jet, e.g. mild, moderate and severe MR are characterised by jet areas of 4.0 cm^2, up to 8 cm^2 and >8.0 cm^2 (**Figure 9**). However, there are various caveats and limitations in assessment. Vena contracta, the narrowest portion of the jet just beyond the regurgitant orifice, is a good method for assessment of severity of MR. A value more than 7 mm indicates severe MR. Similarly, in severe AR, the LV diastolic dimension is usually more than 7.5 cm, the area of LVOT occupied by AR jet is >60%, there is holodiastolic flow reversal from descending aorta as seen by pulsed Doppler and vena contracta diameter is >6.0 mm.

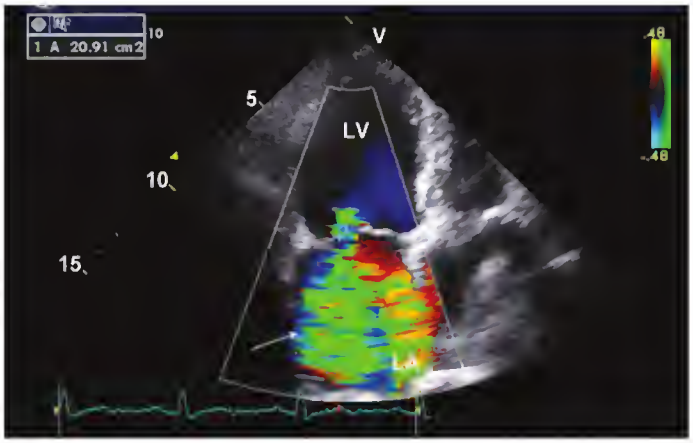

Figure 9: Apical four chamber view showing severe MR with an area of 20.9 cm^2.

LV = Left ventricle; LA = Left atrium.

Key Practical Points in Evaluation of VHD

1. A full clinical evaluation is mandatory
2. Always record heart rate, BP and cardiac rhythm as they have a bearing on severity
3. Proceed step wise from 2D echocardiography – colour flow – Doppler
4. Evaluate all scan planes to assess full anatomy and function
5. Scan all valves
6. Note any intercurrent illness which will affect the evaluation of severity by altering peak velocity
7. Match echocardiography findings with clinical findings and symptoms
8. Provide full anatomical and quantitative information including limitations of study, if any.

Prosthetic Valves

Echocardiography with Doppler is currently the modality of choice for evaluation of prosthetic valve function. The prosthetic valves are basically tissue (biological) or mechanical valves. The initial evaluation starts with clinical data followed by 2D echo for evaluation of size of cardiac chambers, LV thickness and systolic and diastolic functions. The opening and closing motion of moving parts of prostheses are visualised. The presence of abnormal echocardiography density attached to various components are seen, if present. It is advisable that magnified live images are obtained for better visualisation of leaflets and occluder mechanism. Doppler is vital for assessing valve function. It should be kept in mind that all prosthetic valves are inherent stenotic and have trivial or mild transprosthetic regurgitation. The gradients and effective orifice area across the valve are obtained. The normal and abnormal gradients depend upon the type and size of the valve.

A significantly increased gradients in a symptomatic patient points to a thrombus or pannus formation. TEE is an ideal method to look for certain complications like endocarditis, thrombosis or pannus formation. Differentiation between thrombus and pannus is important as thrombolytic therapy may be life saving in thrombus formation. Compared to pannus formation, obstruction due to thrombus is associated with a short duration of symptoms and a history of inadequate anticoagulation (INR <2.0). Thrombi are larger and have a soft ultrasound density, while pannus is a small dense mass more common in aortic position.

CONGENITAL HEART DISEASE

Over the past few decades echocardiography has become the most important technique for the diagnosis of both acyanotic and cyanotic congenital heart disease (CHD). In most of the cases a systemic and meticulously performed echocardiography gives a complete diagnosis to plan the appropriate management. Some important points in imaging an infant or neonate are as follows:

Sedation

The child should be quiet during the study. Many a times neonates and infants can be quietened by giving feed, using pacifier or keeping warm. If various methods fail, it is imperative to sedate the child as an echocardiography cannot be done in a struggling child. Sedation can be performed by oral chloral hydrate in dose of 50 to 100 mg/kg body weight with a maximum dose not exceeding 1.5 g. Alternatively, trichloryl in same dose or intranasal midazolam 0.2 to 0.5 mg/kg can be given usually up to the age of three years. It should be ensured that infant's upper clothing is removed before giving sedation.

Imaging

The aim is to image all the structures of the heart and blood vessels in a sequential and systemic, fashion by utilising all scan planes. The 2D study is followed by CFM and carefully interrogated Doppler of all valves and various other structures.

Transducer

As mentioned earlier, a high frequency transducer is preferred for infants and neonates. Sometimes, a high frequency

transducer and tachycardia gives a false impression of turbulent flow on CFM giving an appearance of 'obstruction'. Such flows should be interrogated by CW Doppler to confirm or rule out obstruction.

Cyanotic Lesions

In cyanotic lesions a right to left or bidirectional flow must be demonstrated by CFM or peripheral venous contrast echocardiography.

Peripheral Venous Contrast Echocardiography

This is a very simple but quite informative technique which can help in demonstrating a right to left intracardiac shunt in case of a cyanotic infant if CFM is inconclusive due to any technical problem. In this technique a small amount of agitated saline (3 to 5 ml of saline + about 0.5 mL of air are rapidly agitated with two syringes connected with a 3-way stop cock) is injected rapidly intravenously. As this agitated saline traverses RA and RV, these chambers get opacified. Once these microbubbles of air and saline reach the pulmonary circulation, they are destroyed as they are of a larger size than the red blood cells. Hence, in a normal situation, only right-sided chambers are opacified as these microbubbles are not able to reach the left-sided chambers (**Figure 10**).

As such an opacification of left-sided chambers implies that the contrast agent has bypassed the pulmonary circulation and opacified the left-sided chambers at any level of right to left intracardiac shunt (**Figure 11**).

As mentioned earlier, a meticulous examination obviates the need for invasive haemodynamic studies. However, it is important for the operator to have a good knowledge of basic anatomy and haemodynamics of various congenital lesions. Besides providing diagnosis, echocardiography plays a significant role in various catheter intervention procedures. **Table 1** summarises the role of echocardiography in some commonly encountered congenital cardiac defects (**Figures 11 to 17**).

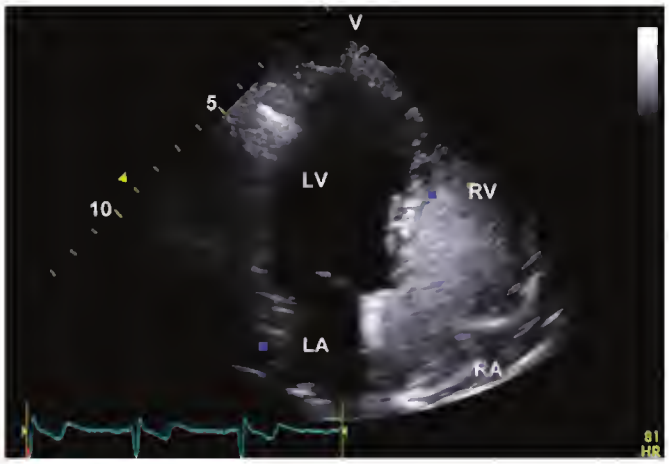

Figure 10: Normal contrast echocardiography showing opacification of only right atrium (RA) and right ventricle (RV) while LV (left ventricle) and LA (left atrium) are contrast free.

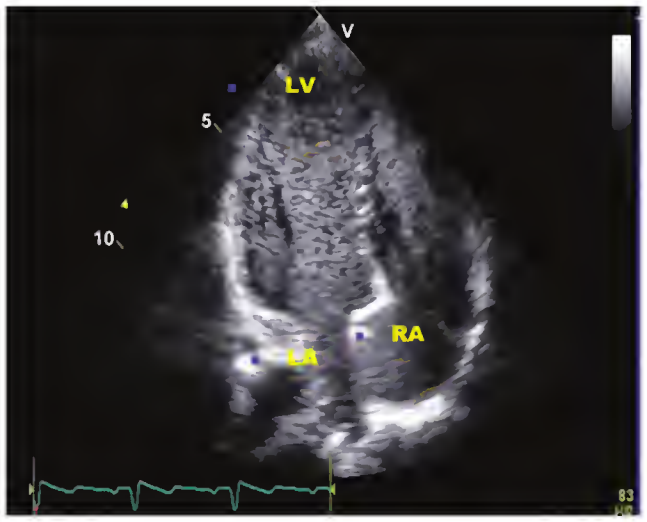

Figure 11: Contrast echocardiography in a case of secundum atrial septal defect (ASD) with saline contrast opacifying the left atrium (LA) indicating a right to left shunt at atrial level.

RA = right atrium; LV = left ventricle.

Table 1: Brief Role of Echocardiography in Some Common Congenital Cardiac Lesions

Lesion	Important Echocardiographic Features
Atrial septal defect (ASD)	Type, number and size of defects, degree of RV, RA enlargement, evaluation of PA pressure, adequacy of tissue rims around the defect, in cases of secundum ASD, for percutaneous device closure. Associated anomalies like cleft mitral valve in ostium primum defect. Sinus venosus defects can be diagnosed by transthoracic echocardiogram (TTE), though TEE is confirmatory
Ventricular septal defect (VSD)	Type, number and approximate sizing of defects, associated lesions like pulmonary stenosis, coarctation, etc. PA pressure, is it an isolated lesion or part of a complex lesion, complications like aortic regurgitation or vegetations, serial follow-up of small VSD's to see for spontaneous closure, assessment for suitability of percutaneous device closure, shunt direction of flow
Patent ductus arteriosus (PDA)	Size of the defect, direction of shunt, extent of LA and LV volume overload, pulmonary hypertension if any, suitability for percutaneous device closure, associated defects
Coarctation of aorta	Presence and site of coarctation, diameter and length of coarctation segment, gradient across the coarctation, LV functions, is there arch hypoplasia, associated anomalies like bicuspid aortic valve, left-sided obstructive lesions
Pulmonary stenosis	Site of stenosis, e.g. infundibular, valvular or supravalvular gradients across the site of stenosis, RV dysfunction if any, associated anomalies like VSD
Tetralogy of Fallot (TOF)	VSD, biventricular origin of aorta (aortic override), site and severity of RVOT obstruction which defines clinical picture and degree of cyanosis, RV hypertrophy, associated anomalies like right-sided aortic arch, concomitant ASD (pentalogy of Fallot), measurement of pulmonary annulus, pulmonary trunk
Transposition of great arteries (TGA)	Demonstrates atrio-ventricular concordance and ventriculo-arterial discordance. Origin of PA from LV and aorta from RV can be demonstrated. Associated VSD, ASD or PFO, LVOT obstruction and coronary abnormalities can be identified. Guiding catheter placement and movements during balloon atrial septostomy.

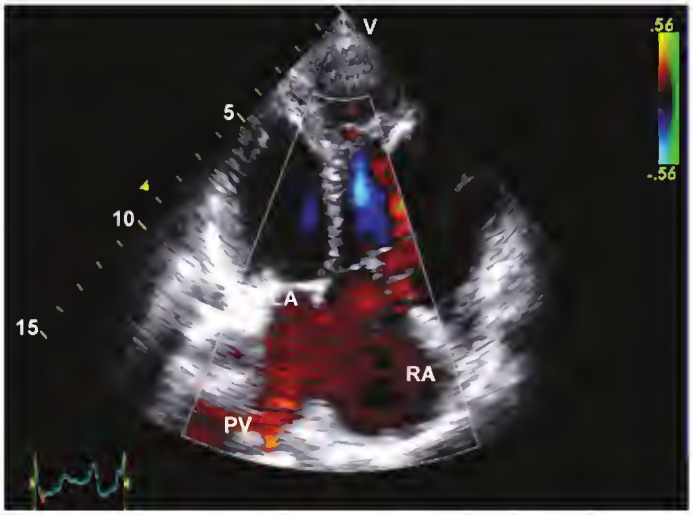

Figure 12: CFM in a case of secundum atrial septal defect with left to right shunt.

PV = Pulmonary vein; LA = Left atrium; RA = Right atrium.

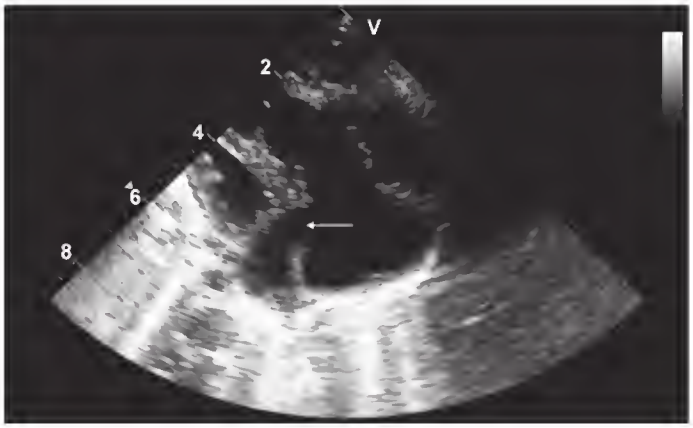

Figure 13: Apical four chamber view showing ostium primum ASD (arrow).

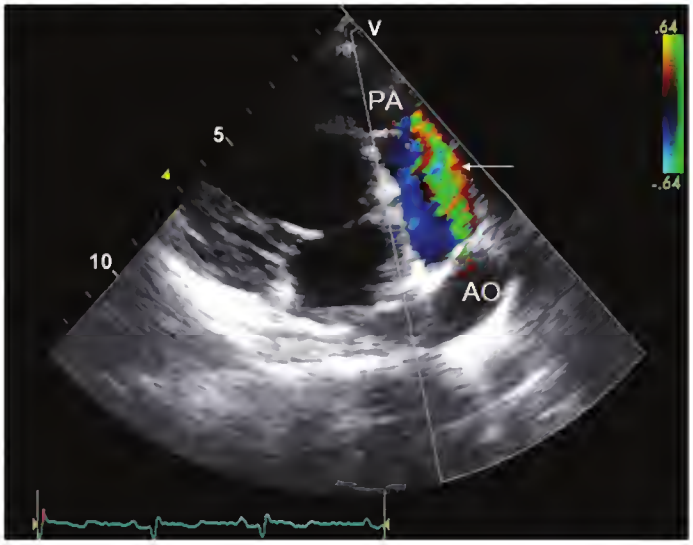

Figure 14: Short axis view showing patent ductus arteriosus (arrow) with flow from aorta (AO) to pulmonary artery (PA).

ISCHAEMIC HEART DISEASE (IHD)

In the current era of intense pharmacotherapy, thrombolytics and percutaneous coronary interventions an early diagnosis of IHD is mandatory to get maximum benefit of various interventions. Traditionally, the diagnosis of IHD is based on clinical presentation, ECG and cardiac enzymes. However, all the three have limitations

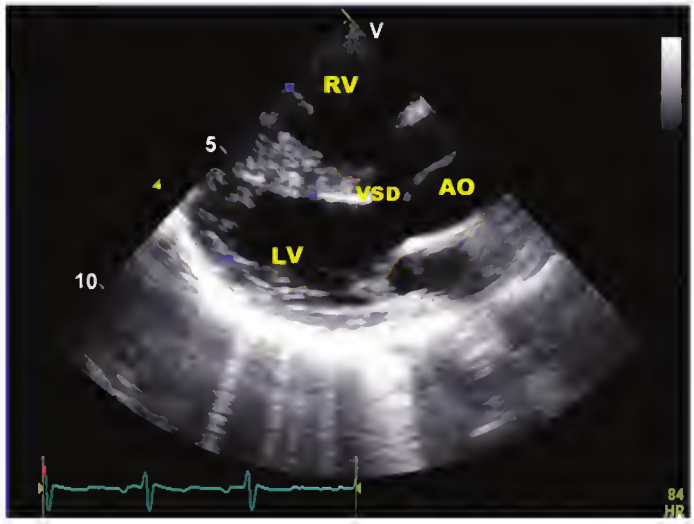

Figure 15: PLAX view in a case of teralogy of Fallot showing aortic override (AO), a large ventricular septal defect (VSD).

RV = Right ventricle; LV = Left ventricle.

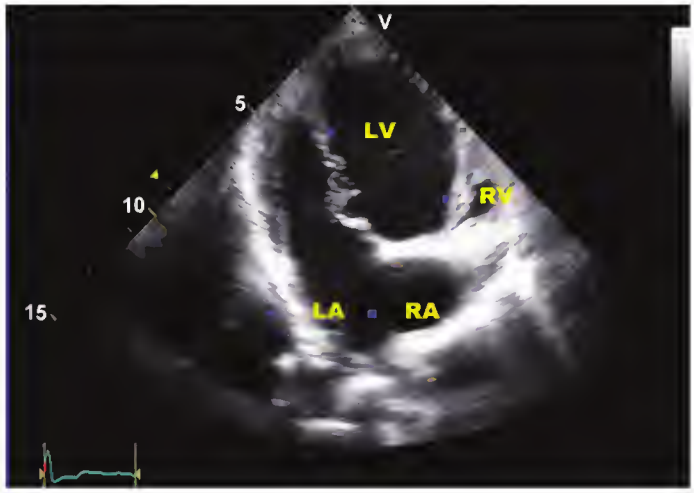

Figure16: A case of tricuspid atresia. There is atresia of tricuspid valve with a very hypoplastic right ventricle (RV), the main chamber is LV and a large ASD is present.

thereby delaying diagnosis and aggressive management. In acute myocardial infarction (AMI) echocardiography provides a correct diagnosis in about 95% of cases and hence is a life saving modality. This is because in the ischaemic cascade, in which the earliest abnormality is a perfusion defect followed by diastolic and systolic contraction abnormalities, which is then followed by chest pain, ECG changes and subsequently rise in cardiac enzymes. The earliest change of perfusion defects is diagnosed by myocardial contrast echocardiography, a technology which is still limited to few centres in India. However, the diastolic and systolic abnormalities are readily picked-up by conventional echocardiography thereby giving an immediate diagnosis. However, few practical points need to be kept in mind. What echocardiography picks-up in IHD is an ischaemia or injury at the time of study. As such echocardiography can be normal in cases of stable angina, despite having significant coronary artery disease. However, if the same patient develops spontaneous or induced angina during the study, then echocardiography will reveal regional contraction abnormalities of LV. Hence a practical dictum is that a normal echocardiography during chest pain virtually excludes IHD. Secondly, the clinician should not have a false perception that a normal resting echocardiography excludes coronary artery disease especially in both stable and unstable angina. The two most

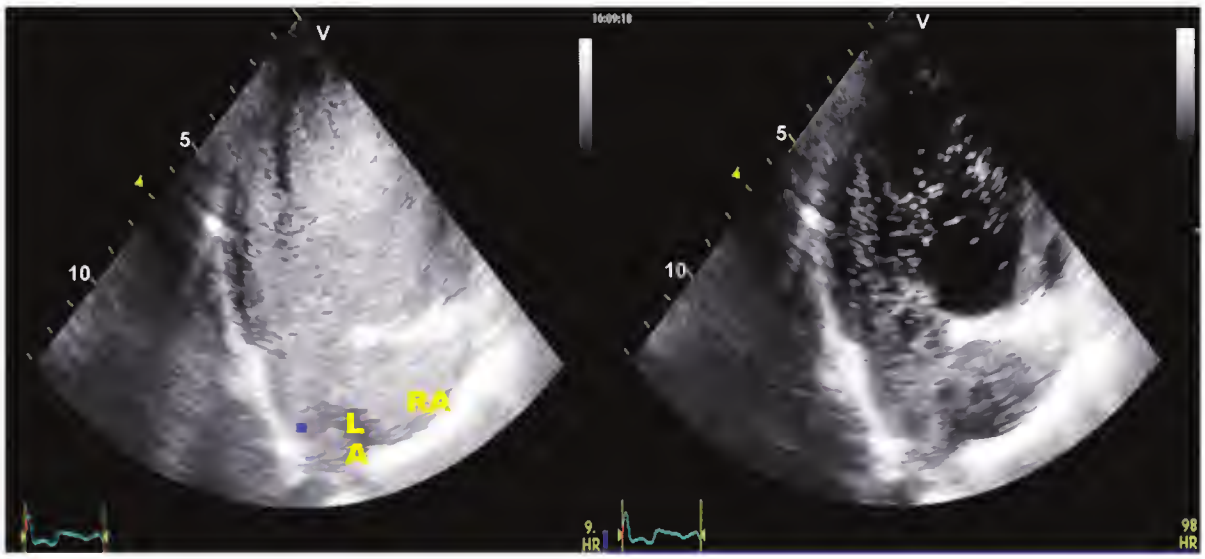

Figure 17: The patient in Figure 16 showing a large ASD, almost a common atrium, as seen on contrast echocardiography.

RA = Right atrium; LA = Left atrium.

specific diagnostic findings in AMI are: decreased systolic thickening of affected myocardial segment (a normal myocardium thickens by almost 50% during systole, while an ischaemic segment shows decreased or absent systolic thickening); and secondly, varying degrees of regional wall motion abnormalities (RWMA). The area affected is localised to the portion of myocardium perfused by the involved coronary artery. The extent of RWMA affects LV dysfunction and is one of the factors determining prognosis. The RWMA is always assessed by scanning various imaging planes. On the basis of this the myocardium is conceptually divided in 17 segments, the 17th segment being the apical cap. The role of echocardiography in IHD is summarised in **Table 2**.

Table 2: Role of Echocardiography in Ischaemic Heart Disease

Diagnosis
Diagnosis of associated cardiac defects, if any
Triage in chest pain units
Assessment of complications such as LV thrombus, acute MR, VSD, LV aneurysm, myocardial rupture, RV infarction which has a bearing on therapy
Assessment of coronary territory involved
Post-MI risk stratification/prognosis
Assessment of myocardial viability
Assessment of therapy effectiveness/change of therapy
Contribution of new technologies like MCE, tissue Doppler imaging, strain imaging, etc.

There are few situations where early echocardiography can be very informative as shown in **Table 3**.

Table 3: Early Echocardiography in Whom?

Doubt in diagnosis/early detection
Hypotension
Heart failure
Unexplained dyspnoea
Chest pain with left bundle branch block
Suspect other complications

The role of echocardiography in IHD is so important that it is recommended that every emergency room/critical care unit resident should be trained to at least recognise a RWMA.

Stress Echocardiography

This modality is being increasingly utilised in diagnosis and prognosis of IHD. This is based on the principle that in a resting state, despite significant coronary artery disease (CAD), there is no imbalance between oxygen supply and demand of the myocardium. However, if the same individual undergoes any form of exercise, the oxygen demand of myocardium is enhanced due to increased heart rate, contractility and rise in blood pressure. However, in the presence of CAD, this increased demand of oxygen cannot be met and it leads to systolic contraction abnormalities and LV dysfunction which are rapidly picked-up by echocardiography. In brief, a resting echocardiography is first performed, then the patient exercises on a treadmill till a standard end-point is reached and again an immediate post-exercise echocardiography is repeated. Instead of dynamic exercise, a pharmacological stress echocardiography with dobutamine can be performed. A normal response to exercise is hyperkinetic contractility with increasing LV ejection fraction. An abnormal response is indicated by decreased systolic thickening of affected segment, varying degrees of RWMA, paradoxical increase in LV chamber size, a decrease in ejection fraction. The accuracy for detection of CAD varies from 80% to 94% depending on the number of vessels involved.

PERICARDIAL DISORDERS

Echocardiography is one of the best non-invasive technique to diagnose pericardial disorders. Some of the indications of echocardiography are:

1. Diagnosis and semi-quantitation of pericardial effusion
2. Diagnosis of pericardial tamponade
3. Diagnosis of post-intervention or post-surgical effusion
4. Constrictive pericarditis
5. Echocardiography guided pericardiocentesis

Normally, the two layers of pericardium contain about 5 to 10 mL of fluid which acts as a buffering medium between the two layers. As the fluid accumulates, echo-wise it is seen as an echo free space between the pericardial layers (**Figure 18**). The semi-quantitation depends on the degree of echo free pericardial space and the distribution of pericardial fluid.

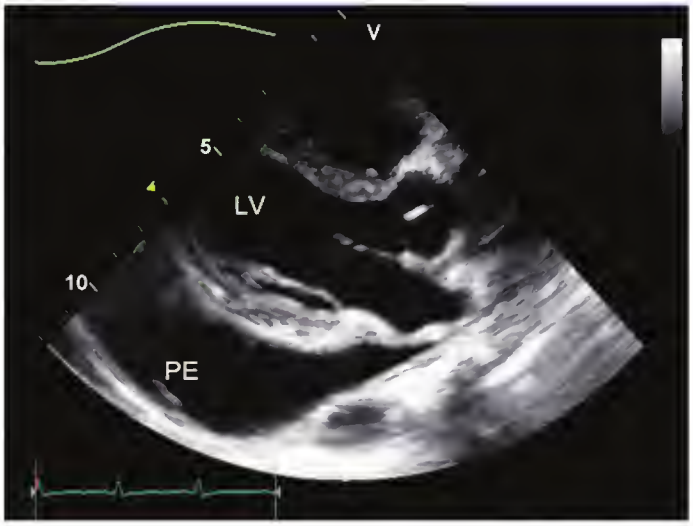

Figure 18: PLAX view showing a large posterior pericardial effusion (PE) as an echocardiogram free space between pericardial layers.

LV = Left ventricle.

An echo free space of >2.0 cm with a diffuse effusion all around the heart indicates a large effusion. The diagnosis of pericardial tamponade and constrictive pericarditis is based on 2D echocardiography features and Doppler findings, e.g. in tamponade there is pericardial effusion, diastolic RV collapse, exaggerated right atrial collapse during atrial systole due to elevated intrapericardial pressure. IVC is enlarged and shows less than 50% inspiratory collapse though it is more sensitive and less specific finding. There are several Doppler findings, but one important finding is more than 25% respiratory variation of atrioventricular valve velocities, the normal variation being less than 15%. The mitral velocity decreases during inspiration and increases following first expiratory beat.

CARDIOMYOPATHIES

The diagnosis of various forms of cardiomyopathies is based on high index of suspicion, clinical features, ECG and X-ray chest, but echocardiography plays a central role in diagnosis. Basically, the different forms of cardiomyopathy are dilated, hypertrophic (both obstructive and non-obstructive) and restrictive. However, RV cardiomyopathy, stress induced cardiomyopathy and LV non-compaction cardiomyopathy are being periodically encountered.

Dilated Cardiomyopathy (DCM)

This is basically characterised by cardiomegaly with global LV hypokinesia. There is impaired systolic and diastolic cardiac functions. Mitral regurgitation is usually present. Echocardiography also plays a role in assessing the prognosis. Some of the determining prognostic factors are: (a) degree of cardiomegaly; (b) degree of LV dysfunction; (c) extent of wall thickness of ventricles; (d) pulmonary hypertension; (e) restrictive filling pattern as assessed by mitral inflow Doppler; and (f) some tissue Doppler imaging parameters.

Hypertrophic Obstructive Cardiomyopathy

Hypertrophic obstructive cardiomyopathy (HOCM) now referred as hypertrophic cardiomyopathy (HCM) with LVOT obstruction is a complex, genetic cardiac disorder with significant heterogeneity in clinical presentation and course. It is a common cause of sudden death in young athletes. Echocardiographically, it is characterised by asymmetrical septal hypertrophy with septal and posterior wall thickness ratio of more than 1.5:1. The septal thickness is more than 15 mm. However, the distribution and severity of hypertrophy can be variable. The LV cavity is small with normal functions. Systolic anterior motion (SAM) of anterior mitral leaflet (AML) is one of the important features of HOCM and leads to varying degree of left ventricular outflow tract (LVOT) obstruction with a gradient more than 30 mm Hg. This is because LVOT is formed by AML and interventricular septum. The degree of LVOT obstruction depends upon the duration for which IVS abuts against the septum. In the echocardiography lab, SAM and LVOT obstruction can be provoked by nitrates (**Figure 19**).

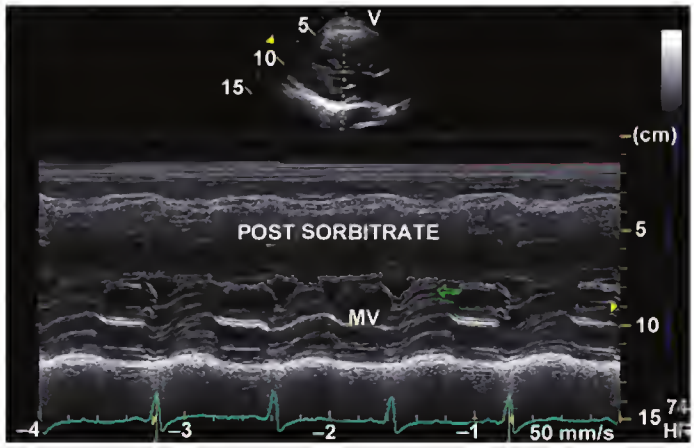

Figure 19: M-mode echocardiogram showing systolic anterior motion (arrow) of mitral valve (MV) following nitrate provocation. The whole LVOT is obliterated by the SAM abutting the interventricular septum.

INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) is an infection of endocardium and intracardiac devices by infective organisms, seen macroscopically as vegetations. Early diagnosis is vital as, despite refinements in medical and surgical therapeutic approaches, the mortality is still between 25% and 30%. No single finding is diagnostic. As such a combination of high index of suspicion, clinical scenario and echocardiography are diagnostic. The role of echocardiography in IE is:

1. Identifying the underlying heart disease including intracardiac devices,
2. Diagnosis of vegetations, if present,
3. Size, mobility and location,
4. Detecting complications of vegetations,
5. Serial evaluation to assess efficacy of therapy or aetiology of worsening,
6. Prognostic stratification. Some adverse prognostic features are large (>10 mm) vegetations, hypermobile vegetations, presence of complications like abscess, leaflet rupture, extension to other areas, systemic embolism, heart failure, etc.

The echocardiography criteria of vegetations are an irregular, mobile mass attached to a free edge of leaflet or a wall. It is attached to the upstream side of the valve, e.g. ventricular side of aortic valve leaflet, atrial side of mitral and tricuspid leaflets and RV side of VSD. The motion of the vegetation is more chaotic and independent of valve motion. It is seen in multiple scan

planes (**Figure 20**). Valvular regurgitation is usually present. As vegetations once develop usually persist, unless they embolise and disappear, hence sometimes there is a difficulty in distinguishing between an active or healed vegetation. Firstly, there should be a clinical correlation as active vegetation will be associated with fever, toxaemia and other manifestations of sepsis, while old, healed vegetation may be routinely detected in virtually an asymptomatic patient. Secondly, a healing vegetations decrease in size and mobility and are more echogenic. Thirdly, a past history of IE may be available.

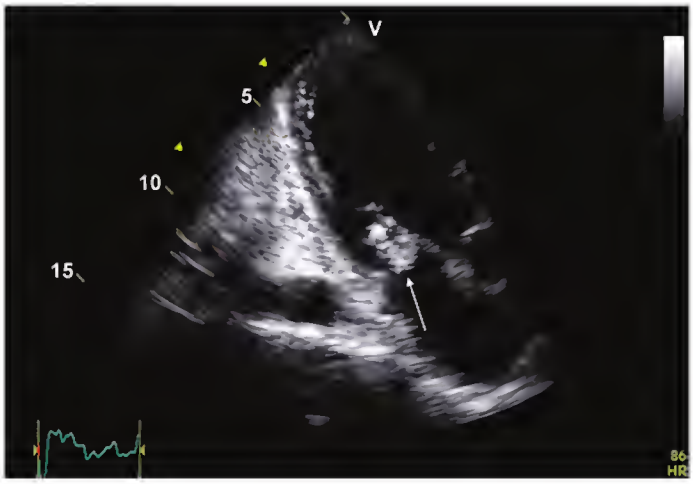

Figure 20: Vegetation seen on the atrial side of the mitral valve (arrow).

HEART FAILURE (HF)

Echocardiography is well suited to meet the growing need for non-invasive imaging of heart failure. The role of echocardiography in heart failure is: (a) diagnosis; (b) prognosis; (c) guiding therapy; and (d) monitoring follow-up.

Because HF patients often have more than one structural and/or functional abnormality contributing to their disease state, echocardiography's versatility in detecting multiple structural lesions including myocardial disorders yield obvious benefits. Assessment of LV ejection fraction is one of the primary measures. A normal EF virtually excludes an advanced myocardial disorder, i.e. systolic HF and then one looks for HFNEF. Doppler measurements provide important haemodynamic information. Some of the adverse prognostic factors in HF can be degree of LV dysfunction, LV end systolic volume of >45 ml/m^2, right ventricular functions, restrictive ventricular filling, myocardial viability, etc. Echocardiography provides important data for therapeutic decision-making like volume status of the patient by IVC parameters as described earlier, need for drugs for LV dysfunction and define candidates for implantable cardiac devices like cardiac resynchronisation therapy or implantable cardioverter defibrillator. One of the major strengths of echocardiography is repeated follow-up, especially in situations of new symptoms, clinical deterioration where it can provide the aetiology.

ROLE OF ECHOCARDIOGRAPHY BEYOND ECHOCARDIOGRAPHY LABORATORY

Since last many years the role of echocardiography has been extended much beyond the echocardiography laboratory. In many situations it has proved to be a life saving technology. Some of the areas are mentioned below:

Critical Care Units

This is the area where echocardiography is extensively employed as a bedside study. The role of echocardiography is critical in diagnosis and guiding therapy. In some areas it gives vital information whether the clinical manifestation is of cardiac or non-cardiac aetiology. Some of the common situations where echocardiography is utilised are: (a) evaluation of chest pain whether it is ischaemic or non-ischaemic; (b) unexplained hypotension/shock. Echocardiography evaluates whether it is cardiac related like acute coronary syndrome, acute valvular insufficiency, severe pulmonary hypertension, pulmonary embolism, etc. Echocardiography can also infer if it is non-cardiac like hypovolaemia, acute sepsis syndrome; (c) evaluation of dyspnoea and heart failure where echocardiography can differentiate between systolic or diastolic failure, pulmonary embolism or a pulmonary aetiology by exclusion; and (d) aetiology of worsening of clinical status in any patient which was showing improvement.

Operating Room

As a routine in large number of cardiac centres intra-operative TEE is routinely utilised especially in monitoring of valvular, congenital or other complex cardiovascular surgical procedures. Besides monitoring cardiac functions, it helps in determining the completeness and success of surgery to avoid any possible redo surgery.

Cardiac Catheterisation Laboratory

There are several non-surgical cardiovascular procedures performed in cardiac catheterisation laboratory or intensive care unit for which online echocardiography monitoring is advantageous. Some of these situations are pericardiocentesis, percutaneous valvuloplasties, closure of ASD, PDA, some VSD's, creation of an atrial septostomy in some complex cyanotic CHD. Occasionally, an emergency echocardiography may be required in catheterisation laboratory to assist in evaluating a patient who has acutely deteriorated during a procedure, to exclude any iatrogenic cardiac tamponade or to reassess intravenous function.

CONCLUSION

The progress in understanding and improvements in equipment has catapulted echocardiogram as a very important tool in diagnosis and functional assessment. The newer innovations of virtual 3D imaging, contrast echocardiography, and tissue perfusion are going to further lend greater importance to echocardiogram.

The echocardiogram helps in, valvular heart disease, congenital heart disease, diseases of myocardium and ischaemic heart disease. In valvular heart disease and congenital heart disease it has obviated the need for invasive testing to a large extent.

The addition of miniature echocardiography may obviate the use of stethoscope in clinical cardiac assessment.

12.6 Cardiac Imaging

Priya Jagia, Sanjiv Sharma

INTRODUCTION

Optimal interpretation of cardiac imaging studies entails a judicious synthesis of imaging evaluation with its significance within the context of clinical decision making. A basic understanding of cardiovascular haemodynamics and electrophysiology is essential for optimal interpretation of imaging information.

Plain chest X-ray is the most routinely used cost effective cardiac imaging modality. It has an advantage that it can be repeated for serial changes and has been standardised since it is the oldest and simplest available cardiac imaging modality.

Non-invasive imaging of cardiac structures is technically challenging due to a variety of reasons. Motion artefacts constitute a major limitation as these degrade the image quality. During cardiac imaging, motion artefacts are produced by cardiac pulsations, counter-clockwise cardiac rotation during different phases of cardiac cycle, diaphragmatic movement and respiratory motion. Optimal profiling of cardiac structures is also compounded by the skewed anatomy of the heart since it is tilted in all three axes and hence routine body axis views are not useful for optimal imaging in disease states. Further, there is a wide variation in the densities of surrounding tissues and these adversely influence the image quality. The haemodynamics within the heart change very rapidly during various phases of the cardiac and respiratory cycles. As a result, the window of opportunity to capture the optimal phase of physiological and biochemical events is very short and difficult to capture for desired anatomic and functional imaging. It is thus obvious that the demands on an optimal technique for cardiac imaging are tremendous. Each modality is discussed.

CHEST X-RAY IN CARDIOVASCULAR DISEASE

For accurate interpretation of chest X-rays, it is imperative to have a systematic and standardised approach, based on an assessment first of anatomy and then of physiology. Any approach must, of course, be based on an understanding of what is normal.

In the standard PA chest study, the overall heart diameter is normally less than 50% of the transverse diameter of the thorax. The heart overlies the thoracic spine, roughly three-fourths to the left of the spine and one-fourth to the right. The mediastinum is narrow superiorly and, normally, the descending aorta can be defined from the arch to the dome of the diaphragm, on the left. Below the aortic arch, the pulmonary hila are seen, slightly higher on the left than the right. On both frontal and lateral views, the ascending aorta (aortic root) is normally obscured by the main pulmonary artery and both atria.

The plain X-ray chest is usually evaluated in frontal projection (PA view) and the distance between the X-ray film and radiation source is 72 inches. It should be systematically evaluated as follows for:

- Position of the patient, fundus of the stomach, domes of the diaphragm, bony abnormalities and the tracheal shadow
- Cardiac size, contour, borders, chambers and great vessels
- Pulmonary vasculature

The proper centring should be assessed looking at distance of medial end of clavicles from midline. The stomach shadow should be seen normally to the left and the right dome is higher than the left. The trachea shadow can be seen dividing at the carina which is at the level of T4 vertebra.

Cardiac Size, Contours, Borders, Chambers and Great Vessels

Cardiac size

The plain film radiographs are still a valuable tool for identifying an enlarged heart that is abnormal. The heart size is assessed by cardiothoracic (CT) ratio which is expressed as the ratio between the maximum transverse diameter of the heart divided by the maximum transverse diameter of the thorax (**Figure 1**). The maximum transverse diameter of the heart is obtained by adding the widest distance of the right heart border from the midline and left heart border to the midline. The midline is drawn through mid point of the spine from the sternum to the diaphragm. The maximum transverse diameter of the thorax is

Figure 1: Cardiothoracic Ratio = r+l / td (where r +l = transverse diameter of the heart and td is transverse diameter of thorax. r and l are measured as the maximum distance from midline of right and left heart borders respectively).

measured as distance between inner borders of thorax obtained above the costophrenic angles. The normal average CT ratio is:

- ≤0.50 in adults
- >0.50 in children
- ≤0.60 in neonates

A normal heart may appear large because of small AP diameter due to pectus excavatum and straight back syndrome.

The heart may appear small even though it is enlarged as in downward displacement of cardiac apex in AR, because of large AP diameter in COPD (**Figure 2**), due to severe dorsal kyphosis in elderly patients or, in Addison disease and anorexia nervosa due to the absence of brown fat.

Figure 2: Chest X-ray PA view of patient with emphysema. Note the tubular appearance of heart with hyperinflated lung fields and low lying diaphragm.

In present day scenario, with use of portable X-rays AP view is done due to which CT-ratio can become abnormal. Moreover, with use of smaller films in digital X-rays the usual measurement parameters used to define cardiac chamber enlargements may not stand true.

Cardiac Contour

Any significant deviation from the normal cardiovascular contour may serve as a clue to the cardiovascular diseases (**Table 1**).

Cardiac Borders, Chambers and Great Vessels

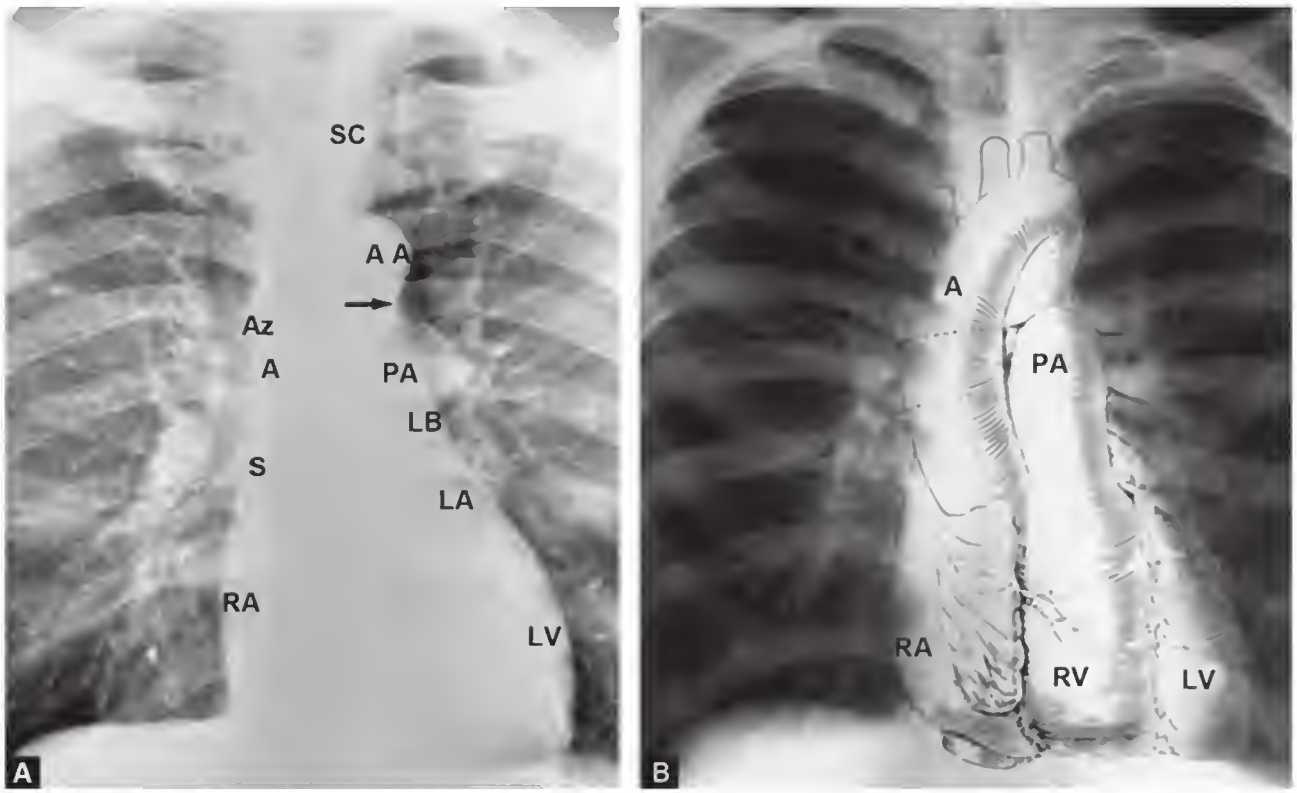
The cardiac borders consist of right and left heart borders (**Figures 3A and B** and **Table 2**).

In frontal projection, RA forms a gentle convexity with the adjacent right middle lobe. The superior border blends above with SVC and inferior border blends below with IVC, meeting the diaphragm at a slightly acute angle. Right atrial enlargement (RAE) commonly occurs in organic tricuspid valve disease and Ebstein's anomaly. Radiographically, RAE is considered:

- When it bulges >5.5 cm to the right of the midline or
- When RA border occupies ≥3 intercostal spaces

The classic signs of right ventricular enlargement are a boot-shaped heart and filling in of the retrosternal airspace. The former is caused by transverse displacement of the apex of the right ventricle as it dilates and leads to an acute cardiophrenic angle. In adults, it is unusual for the right ventricle to dilate without left ventricular dilation, so this boot-shape is not often obvious. It is most commonly seen as an isolated finding in congenital heart disease, classically in tetralogy of Fallot (**Figure 4**). Right ventricular enlargement is often seen in mitral valve disease, secondary to pulmonary hypertension.

LA Enlargement in mitral stenosis may lead to straightening of left heart border. The straightened left heart border occurs due to dilated main pulmonary artery and bulging of the LA appendage (**Figure 5**). The enlarged LA may lead to elevation of left main bronchus, resulting in increase of carinal angle. It may cause a convex shadow of double density in the right portion of cardiac silhouette and may lead to posterior displacement of barium filled oesophagus in lateral and RAO views



Left ventricular enlargement (e.g. in cardiomyopathies, valvular heart diseases, LV aneurysms, etc.) is characterised by a prominent, downwardly directed contour of the apex, as distinguished

Table 1: Abnormal Cardiac Contour

Features of Cardiac Contour	Causes
Mitralisation of left heart border	Mitral stenosis with pulmonary hypertension
Boot-shaped heart	Tetralogy of Fallot
Flask like or money-bag appearance with a smooth featureless cardiac border	Pericardial effusion
Triangular or a large rounded heart with a narrow pedicle	Ebstein's anomaly
Snow man or cottage loaf appearance	Total anomalous pulmonary venous connection
Egg on side appearance (mild cardiomegaly with narrow pedicle)	Transposition of great arteries
Retrosternal double density with a bulge along the cardiac border	Left ventricular aneurysm
Convex double density in the right portion of the cardiac silhouette	Enlarged left atrium

Table 2: Cardiac Borders in Chest X-ray Frontal Projection

Right Heart Border	Left Heart Border
Superior vena cava (SVC)	Aortic knuckle
Right atrium	Main pulmonary artery
	Left atrial appendage (when enlarged)
	Left ventricle

Figures 3A and B: Frontal projection of the heart and great vessels. (A) Left and right heart borders in the frontal projection. (B) Line drawing in the frontal projection demonstrates the relationship of the cardiac valves, rings, and sulci to the mediastinal borders.

A = Ascending aorta; AA = Aortic arch; Az = Azygous vein; LA = Left atrial appendage; LB = Left lower border of pulmonary artery; LV = Left ventricle; PA = Main pulmonary artery; RA = Right atrium; S = Superior vena cava; SC = Subclavian artery.

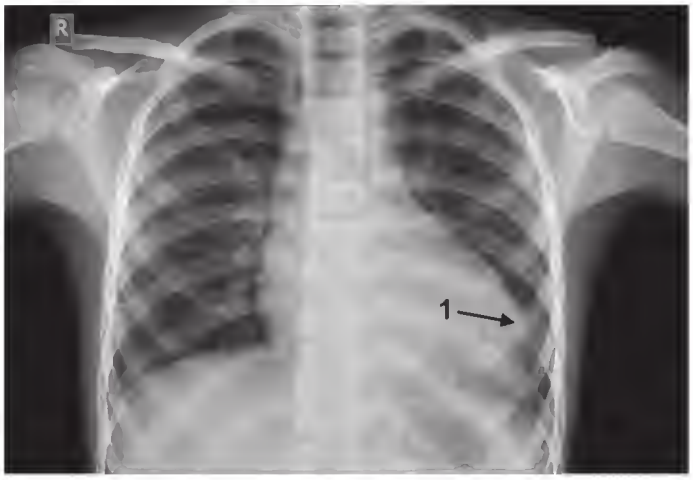


Figure 4: Chest X-ray in a patient of tetralogy of Fallot revealing boot-shaped heart, enlarged right ventricle (1) and oligaemic lung fields.

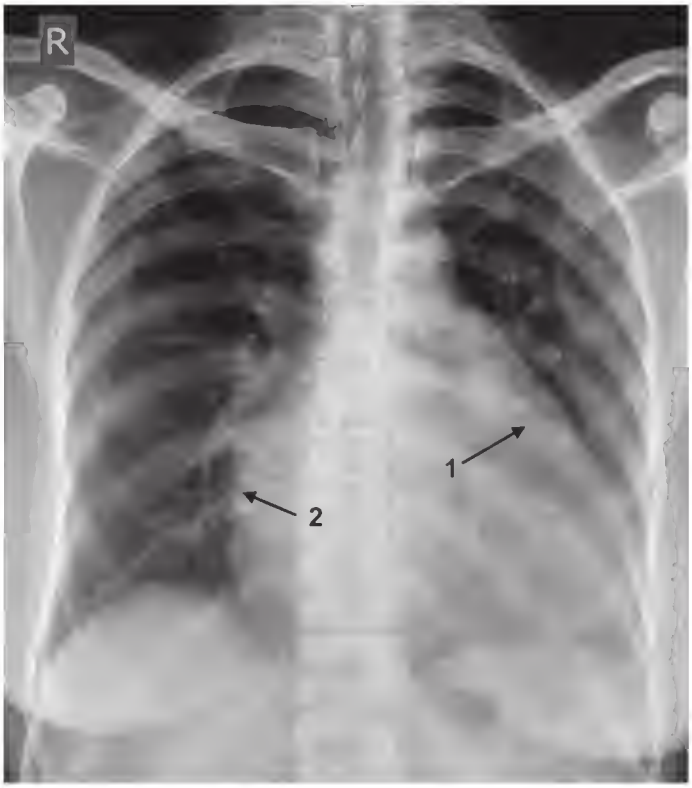

Figure 5: Chest radiograph of severe mitral stenosis. Posteroanterior view shows enlargement of the left atrium [double density shadow (1)], straightening of left heart border (2) (mitralisation) and pulmonary venous redistribution.

from the transverse displacement seen with right ventricular enlargement. Maximal left ventricular enlargement in adults occurs commonly with aortic insufficiency, often with associated aortic root dilation, whereas mitral regurgitation also manifests left atrial dilation. In contrast, aortic stenosis is characterised by left ventricular hypertrophy rather than dilation, and the left ventricle dilates only when aortic stenosis is accompanied by heart failure.

Pulmonary Vascularity

The main pulmonary artery bifurcates into left pulmonary artery (LPA) and right pulmonary artery (RPA) within the mediastinum. The LPA then courses to the left and posteriorly and hence its borders are just visible above the middle of the left hilum. The RPA, which has a horizontal course within the mediastinum, divides into lobar branches proximal to the right hilum. The

transverse diameter of right descending PA (RDPA) is 10 to 15 mm ± 1 mm in males and 9 to 14 mm ± 1 mm in females.

When pulmonary arterial flow is increased, as in patients with a high-output state (e.g. pregnancy, severe anaemia, hyperthyroidism) or left-to-right shunt, the pulmonary vessels are seen more prominently than usual in the periphery of the lung. They are uniformly enlarged and can be traced almost to the pleura, but their margins remain clear. This is typically referred as 'pulmonary plethora' due to increased pulmonary vascularity. It can be seen in acyanotic congenital heart diseases with large left to right shunts like ASD (**Figure 6**), VSD, PDA and in cyanotic patients with admixture lesions like TAPVC, truncus arteriosus, TGA with VSD, etc.

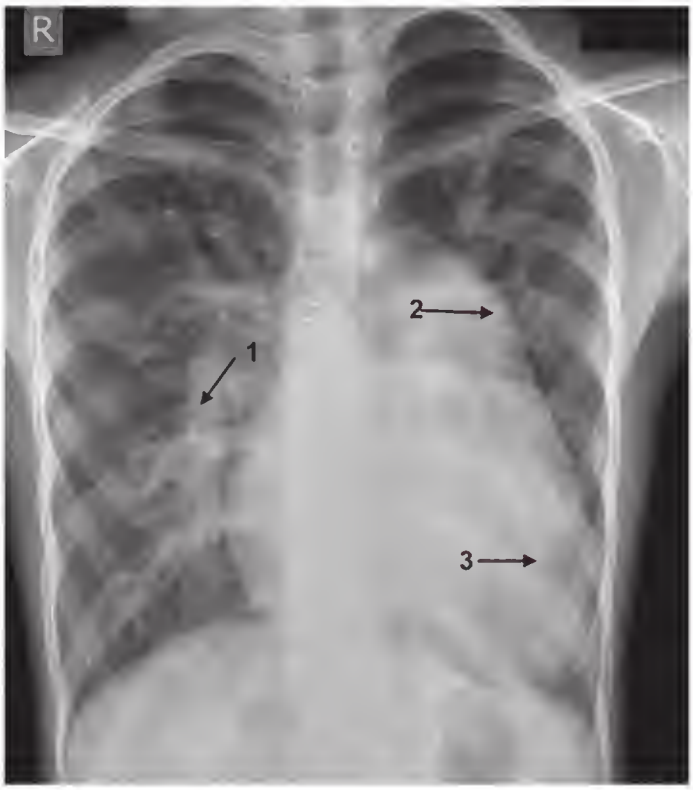

Figure 6: Chest radiograph of patient with atrial septal defect and significant left to right shunt. Marked plethora with dilated right descending (1) and main pulmonary arteries (2) with cardiomegaly (3) can be seen.

When pulmonary arterial hypertension (PAH) develops as in primary pulmonary hypertension or in Eisenmenger's syndrome, it leads to 'pulmonary oligaemia' with prominence of central pulmonary arteries like enlarged main pulmonary artery and its proximal branches. Vascular markings of outer one-third of both lung fields are not present. Pulmonary oligaemia may be seen in conditions with decreased pulmonary flow like TOF, pulmonary atresia, tricuspid atresia, TGA with PS, etc.

In patients with valvular pulmonary stenosis post-stenotic main pulmonary artery dilatation is seen with normal peripheral pulmonary vasculature.

In patients with pulmonary venous hypertension, there is a reasonably good correlation between the pulmonary vascular pattern and pulmonary capillary wedge pressure (PCWP). At a PCWP less than 8 mm Hg, the venous pattern is normal. As the PCWP increases to 10 to 12 mm Hg, there occurs redistribution of pulmonary blood flow with prominent upper lobe veins as compared to lower lobe veins called as 'cephalisation of pulmonary veins'. At pressures of 12 to 18 mm Hg, Kerley B lines appear, which are horizontal, pleuroparenchymal, peripheral linear densities. As PCWP increases acutely above 18 to 20 mm Hg pulmonary oedema occurs, with interstitial fluid present in sufficient amounts to cause a perihilar bat wing appearance.

Aorta

In PA view, the aortic arch is seen as a projection beyond the left margin of the mediastinal shadow, which is known as aortic knuckle or knob. Aortic prominence may be seen on right heart border in patients with AR with dilated aortic root or in those with aortic stenosis with post-stenotic dilatation. In elderly patients with calcified aortic valve, calcification may be visualised on aortic knuckle.

Pericardium

The pericardium is rarely distinctly definable on plain films of the chest, but there are two situations in which it can be seen: effusion and constriction. Classically, the cardiac silhouette has a 'money-bag shape' in the presence of a pericardial effusion, but such a shape is not in itself diagnostic. Pericardial calcification is most often seen in constrictive pericarditis especially of tubercular aetiology. Such calcification is usually thin and linear and follows the contour of the pericardium.

Moreover, the mechanical prosthetic valves (aortic as well as mitral) (**Figure 7**) and devices can be visualised in chest X-ray in post procedural patients.

Recent advances in both computed tomography (CT) and magnetic resonance imaging (MRI) have improved our ability to better image the cardiac anatomy and to some extent define the haemodynamic events within the heart. Comprehensive

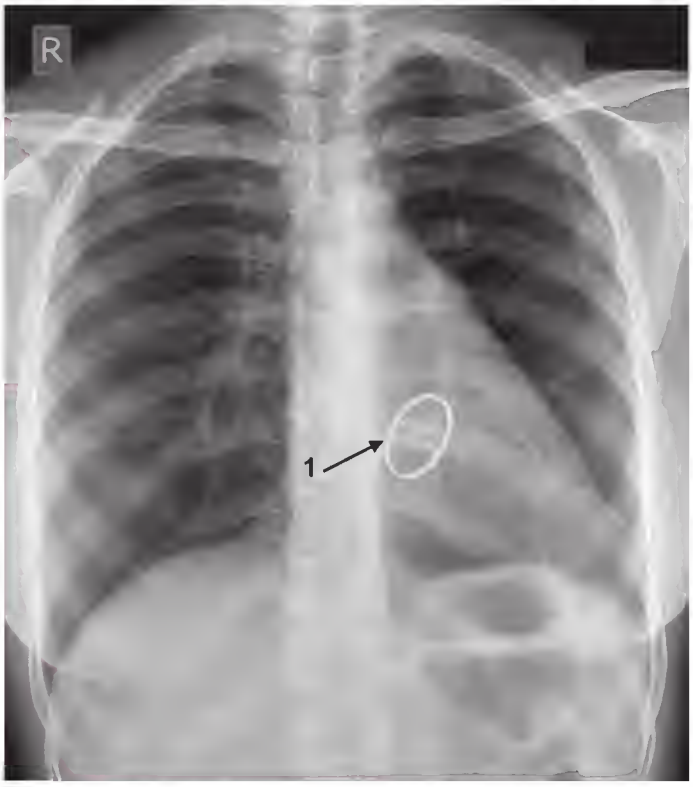

Figure 7: Chest X-ray PA view post-mechanical prosthetic mitral valve (1) replacement.

cardiac imaging includes morphological changes in structure of the heart, identification of the underlying pathoanatomy, functional and haemodynamic consequences of the insult and resultant biochemical changes. The modalities available for cardiac imaging include conventional radiology echocardiography, catheter angiography, radioisotope studies, CT and MRI. An ideal cardiac imaging modality should have very short acquisition time (to minimise motion artefact and freeze capture a biochemical event) and capability for ECG-gated orthogonal imaging to relate the morphological abnormality to a given haemodynamic and biochemical event. For optimal imaging, a large field-of-view to capture all desired structures in an image frame while retaining a high signal-to-noise ratio in the resultant image is desirable. However, at most times, these requirements are mutually contradictory. In view of the large volumes of information required, a fast processing and large storage capacity are essential requirements of an ideal imaging technique for the heart. **Table 3** below lists the diagnostic modalities excluding X-ray chest, and echocardiography useful in various disorders.

Table 3: An Overview of Suitable Techniques for Various Disease States

Congenital heart disease	For morphology – either CT or MRI. If small pulmonary arteries, CT scores over MRI because of high spatial resolution. For functional assessment, including shunt quantification in ASD, VSD, PDA and quantification of flow across shunt/graft/baffle/stenosis, MRI is advisable.
Ischaemic heart disease	For coronary artery assessment – CT angiography. Ventricular analysis and Wall motion abnormality are seen well on both CT and MRI. Perfusion studies and viability are best seen on cardiac MRI.
Cardiomyopathies (Non-ischaemic)	MRI with contrast enhancement for anatomic and functional assessment.
Cardiac masses	MRI with contrast enhancement for anatomic and functional assessment. CT is helpful in detecting calcification in mass. Rest all other features are better seen on MRI.
Pericardial diseases	MRI is more useful in depicting pericardial thickness, effusion and constriction. It helps differentiate constrictive pericarditis from restrictive cardiomyopathy. Cardiac CT shows calcification in pericardium. Pericardial thickness and constriction is also well detected on gated cardiac CT.

ASD = Atrial septal; CT = Computed tomography; MRI = Magnetic resonance imaging; PDA = Patent ductus arteriosus; VSD = Ventricular septal defects.

CARDIAC MRI

MRI offers many advantages in imaging of the heart. These include the lack of ionising radiation, orthogonal imaging capacity and superior temporal and contrast resolution as compared to CT. The relative disadvantages include lower spatial resolution, long acquisition times, inability to change orthogonal planes during post-processing and patient-specific issues such as claustrophobia, pacemaker implantation and pre-existing arrhythmias among others. Recent advances in MRI allow faster acquisition using newer sequences and have helped to obtain comprehensive morphological and functional information of the heart. Its inherent soft tissue contrast obviates the need for contrast injection for simple morphological assessment. All of the above can be obtained on an out-patient basis. Also, MRI is especially useful in post-operative settings. As a result, cardiac MRI (CMR) is fast emerging as a 'one-stop shop' for cardiac evaluation by providing virtually all the information needed for complete assessment of heart disease.

Imaging Sequences

The newer faster sequences allow acquisition of data during breath hold, thus minimising the respiratory artifacts. The sequences are ECG-gated and images are acquired mostly in end-diastole when the heart is most quiescent.

The commonly used sequences include:

1. Dark blood sequences: The flowing blood appears dark in these sequences. These include conventional spin echo, turbo or fast spin echo (TSE, FSE), HASTE, double inversion recovery FSE (Double IR-FSE). These sequences allow morphological assessment of heart and vessels without interference from bright signal from blood. These are useful for cardiac masses, myocardial and pericardial evaluation.
2. Bright blood sequences: Steady state gradient echo images show blood as bright. The sequences are balanced steady state procession sequences and have different trade names for different companies - True FISP, FIESTA, balanced FFE. These sequences are useful for cine imaging whereby images are acquired throughout the cardiac cycle. These cine images are used for functional analysis and to see any turbulent signal produced due to stenotic or regurgitant pathology.
3. Phase contrast imaging sequences: These are used for quantification of stenotic and regurgitant valvular disease, to find out Qp:Qs across a shunt and to do flow analysis across a vessel.
4. Contrast-enhanced MR sequences: These are especially useful for perfusion imaging and viability assessment. They are also indicated in evaluation of cardiac masses, cardiomyopathies and for great vessel visualisation.

Imaging Planes for the Heart

Due to skewed anatomy of the heart which is rotated along all three axes and this rotation varies from patient to patient based on the body build and girth, it is important to acquire images along the axes of 'heart' rather than along the various 'body' axes. Hence, an acquisition technique for images begins with acquiring body axis views-coronal, sagittal and axial, from which two-chamber, four-chamber, short axis, LVOT (Left ventricular outflow tract) and RVOT (Right ventricular outflow tract) views are reconstructed.

Congenital Heart Disease

MRI is useful for morphological assessment in patients with congenital heart disease (CHD). The situs, atrioventricular and ventriculoarterial communications, great vessels especially pulmonary artery size, pulmonary venous drainage, septal defects, etc. are well identified (**Figure 8**).

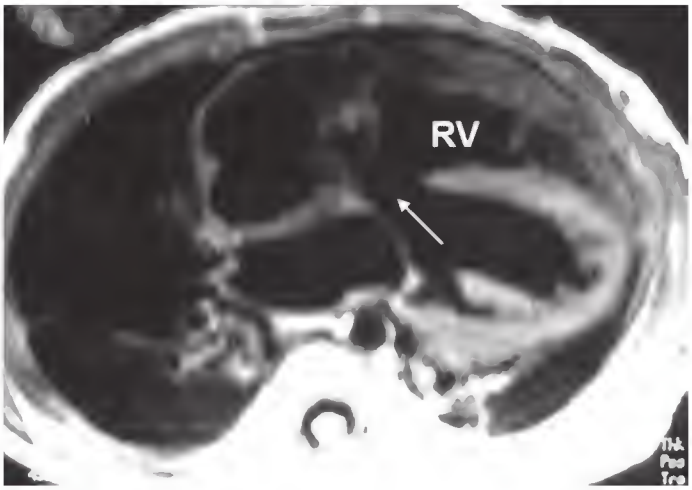

Figure 8: Four chamber T1W spin echo MR image showing perimembraneous VSD (arrow).

Functional information regarding ventricular function, Qp:Qs and quantification of regurgitant and stenotic valves can be obtained. In post-operative cases, the flow across the shunts and baffles can be quantified and gradients across narrowing determined.

For example, in a case of tetralogy of Fallot, CMR can show anatomy of pulmonary arteries, the ventricular septal defect (VSD) with degree of aortic override, pulmonary venous drainage, large aortopulmonary collaterals and ventricular morphology. Functionally, Qp:Qs across the shunt can be determined. RV functional analysis can be done. Post-operatively, flow across shunts or pulmonary regurgitation after total correction can be quantified. Residual VSDs can be picked up easily.

Valvular Heart Disease

Cine MRI in four chamber and long axis view helps pick up turbulent jets produced by the stenotic or regurgitation valvular lesions (**Figure 9**). These can then be quantified using phase contrast sequences, which help classify the severity of valvular lesion according to the flow and gradient across the valve.

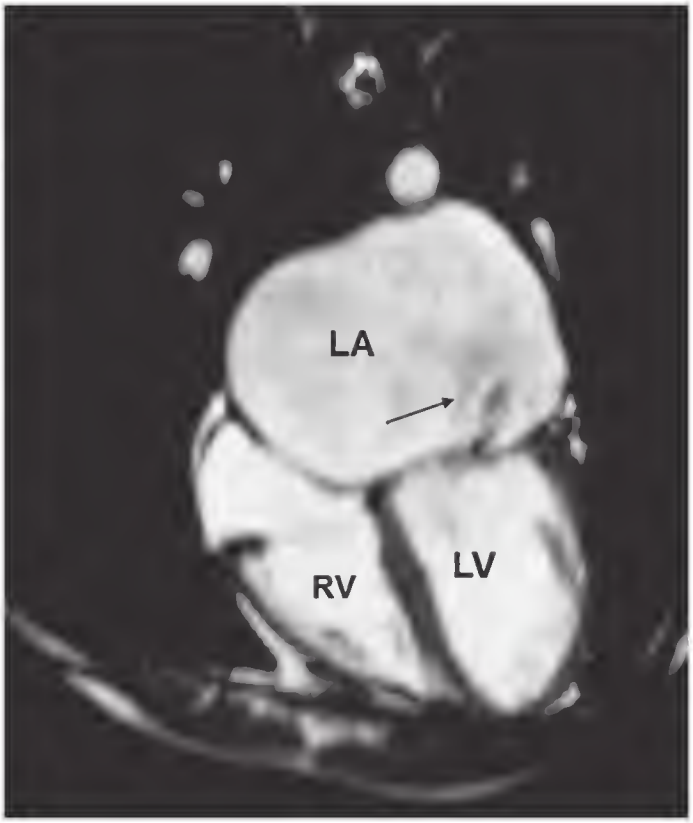

Figure 9: Four chamber bright blood TRUFISP cine MR image showing jet due to mitral regurgitation in dilated LA.

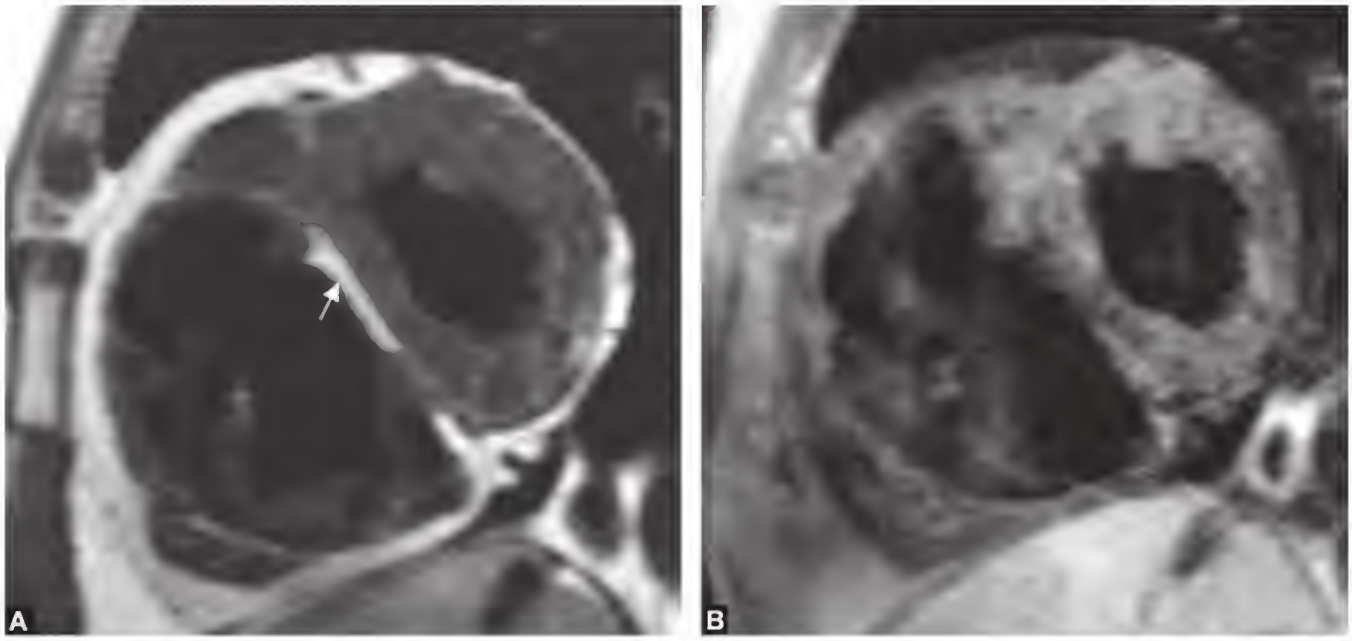


LA = Left atrium; LV = Left ventricle; RV = Right ventricle.

Planimetry for valvular area can be done to measure the stenotic valve area.

CARDIOMYOPATHIES

Arrhythmogenic Right Ventricular Dysplasia

There is fatty or fibrous infiltration of myocardium with or without thinning of myocardium (**Figures 10A and B**). There are

Figures 10A and B: MRI in arrhythmogenic right ventricular dysplasia. (A) Short axis T1W image showing bright fat infiltration (arrow) in RV side of interventricular septum; (B) Corresponding fat saturated T1W image shows bright signal of fat nulled.

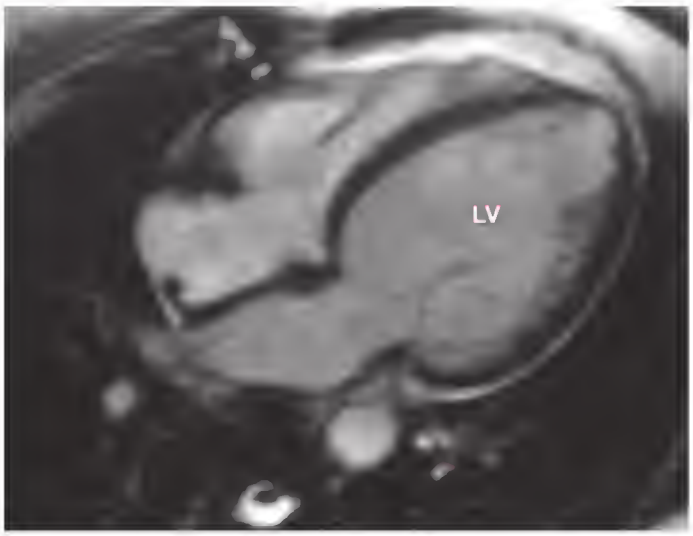
associated wall motion abnormalities of RV, RV outflow tract or LV. MRI, with its inherent soft tissue contrast, is the modality of choice for diagnosing arrhythmogenic right ventricular dysplasia (ARVD). Fat is seen as bright signal on T1 and T2 weighted images and this signal disappears on fat saturation sequence. Cine images show decreased global function, regional wall motion abnormalities or aneurysms. Delayed enhancement images obtained 10 minutes after gadolinium contrast injection shows hyper-enhancement in regions of fibro-fatty replacement. This is very useful in guiding the endomyocardial biopsy.

Dilated Cardiomyopathy

MRI shows biatrial enlargement and increased size of the left and right ventricles (**Figure 11**). Mitral and tricuspid regurgitation, if present, can be well demonstrated. The pattern of enhancement in myocardium helps differentiate LV dysfunction due to dilated cardiomyopathy (DCM) or ischaemic heart disease (IHD). Majority of DCM patients do not have any late contrast enhancement. However, when present, it is in mid myocardium in non-coronary pattern which means that it does not correspond to any coronary artery territory.

Hypertrophic Cardiomyopathy

MRI is especially useful in detecting apical hypertrophy that is not well seen on echocardiography. Cine images demonstrate degree and extent of hypertrophy (**Figures 12A and B**).



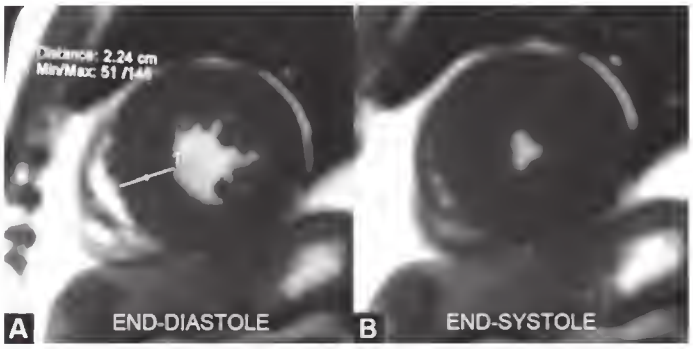


Figure 11: Four chamber bright blood MR image showing dilated left ventricle (LV) with thinned out myocardium in a patient with dilated cardiomyopathy.

Figures 12A and B: Case of hypertrophic cardiomyopathy. (A) short axis cine MR image in end-diastole showing thickened LV myocardium and (B) almost complete obliteration of LV cavity in systolic image.

End-diastolic wall thickness is measured besides quantification of cardiac function and flow dynamics of the ventricular outflow. Systolic anterior motion of mitral valve is well seen on cine MRI and the mitral regurgitation can be quantified. The total myocardial mass can be calculated and used for follow-up studies. Delayed contrast enhancement is, sometimes, seen because of fibrosis in the region of hypertrophy and such patients have higher risk of sudden cardiac death. CMR is useful for monitoring functional and anatomical outcome of surgical and pharmacological septal ablation.

Restrictive Cardiomyopathy (RCM)

There is restrictive filling and reduced diastolic volume of either or both ventricles with near normal systolic function and wall thickness.

On MRI, there is abnormal diastolic ventricular function and biatrial enlargement with normal systolic ventricular function, initially. CMR can characterise tissue, quantify myocardial mass, ventricular volumes and ejection fraction.

Common causes of restrictive cardiomyopathies include sarcoidosis, amyloidosis, haemochromatosis, storage disorders and idiopathic causes.

Amyloidosis

MRI shows thickening of left and right ventricular walls. Increased interatrial septal thickness or of posterior atrial wall greater than 6 mm is quite characteristic for amyloid infiltration. Associated pericardial and pleural effusions help differentiate amyloidosis from myocardial hypertrophy. On delayed enhancement, global subendocardial enhancement, not matching any specific coronary territory, is seen.

Sarcoidosis

CMR can help detect these cases early which is important to initiate early corticosteroid therapy that helps prevent malignant arrhythmias. Focal bright areas with low signal on T2W images suggest sarcoid granuloma. On delayed contrast images, mid wall patchy or focal enhancement is seen.

ISCHAEMIC HEART DISEASE

1. **Ventricular function:** Cardiac MRI is superior to echocardiography for assessment of ventricular function. Dynamic cine MRI images are used for volumetric analysis of ventricles and to see regional wall motion abnormalities.
2. **Myocardial perfusion (Rest and Stress):** Gadolinium contrast is injected intravenously and images are acquired during rest and after achieving pharmacological stress using intravenous adenosine in the dose of 140 µg/kg body weight for 4 to 6 minutes.

   Hibernating myocardium shows perfusion defect on stress that may not be present at rest (**Figures 13A and B**). The regional wall motion abnormality seen at rest improves after stress and there is no delayed contrast enhancement.
3. **Myocardial viability:** On delayed contrast MRI, infarcted or dead myocardium appears bright (**Figure 14**). Potential improvement after revascularisation depends on extent of infarcted wall thickness. Part of myocardium with more than 75% thickness infarcted, has poorest chances of recovery after revascularisation.

Figures 13A and B: Myocardial perfusion imaging. Short axis view showing (A) perfusion defect in inferior wall (RCA territory) on stress MR image which was not seen in (B) rest images suggesting inducible ischaemia on stress.

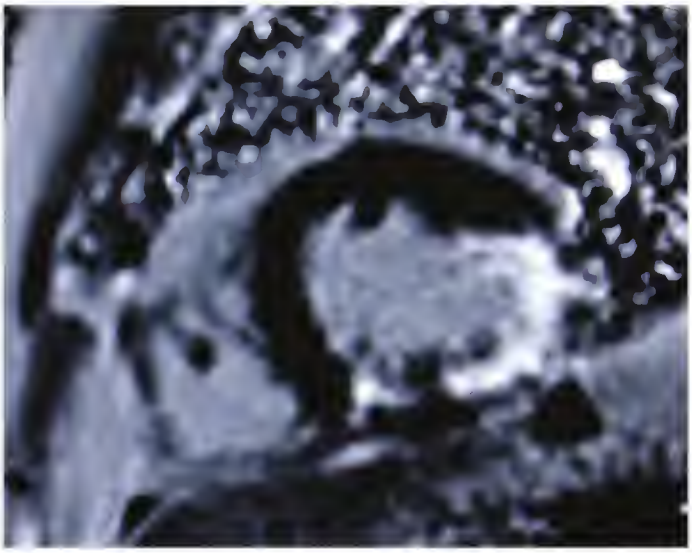

Figure 14: Delayed enhanced MRI in short axis view shows transmural infarct in the lateral wall (left circumflex artery territory).

Thus, cardiac MRI helps detect 'hibernating myocardium' and also helps in prognostication of recovery after revascularisation.

However, coronary arteries are better evaluated on CT angiography since it has a much better spatial resolution.

Pericardial Diseases

MRI is useful to differentiate constrictive pericarditis from restrictive cardiomyopathy, which is a usual diagnostic dilemma. In constrictive pericarditis, cardiac MRI shows pericardial thickness more than 4 mm. There may be associated SVC, IVC dilatation and RA enlargement. On cine MR images, abnormal diastolic septal motion ('septal bounce') is seen suggesting constrictive changes. Calcification is seen as a signal void.

Cardiac and Pericardiac Masses

Cardiac MRI is preferred for evaluation of cardiac masses since it has better soft tissue characterisation. Accurate morphological assessment, tissue characterisation, mobility of mass with cardiac cycle is well seen on MRI. Thrombus is most commonly confused as cardiac mass and it is easy to differentiate on cardiac MRI. The most common benign cardiac tumour is myxoma (**Figure 15**).

CARDIAC COMPUTED TOMOGRAPHY

With the advent of advanced multi-slice CT scanners, it has become possible to image heart with more accuracy in much shorter time. Short acquisition time (4-5 seconds vis-à-vis 45 minutes in MRI) and higher spatial resolution makes CT an investigation of choice for assessment of children with congenital heart disease.

ECG gating is done to acquire motion free images of cardiac chambers and coronary arteries. With latest multi-slice (256 and 320 slice scanners) and dual-source CT scanners available in clinical practice, it is possible to have spatial resolution less than

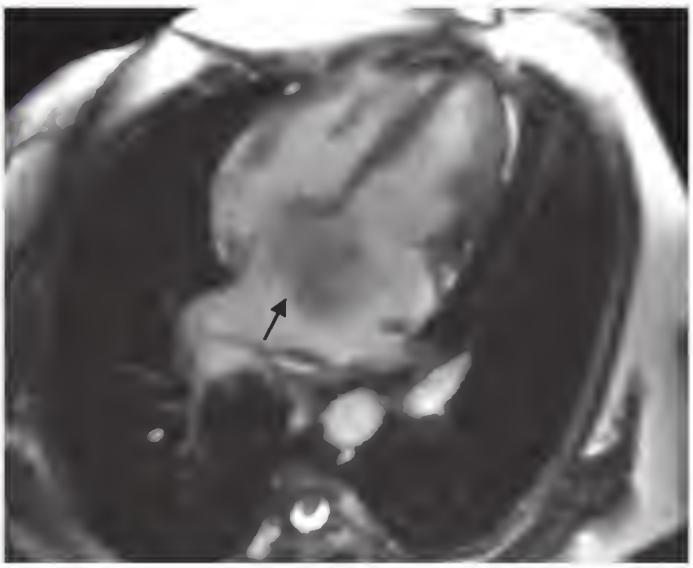

Figure 15: Bright blood MRI image in four chamber view in a case of left atrial myxoma attached to interatrial septum.

0.4 mm and gantry rotation time of 82 ms or lesser and it is no longer mandatory to reduce the heart rate. As long as it is stable, a heart rate of 90 beats per minute too can give reasonably accurate images of coronary arteries on dual source CT. Image acquisition lasts 8–10 seconds only and hence breath hold is easy.

Calcium scoring is used as screening tool in many countries in outpatient department patients. It is done by ECG-gated non-contrast single breath hold scans. A software then calculates the Agatston calcium score taking into account the area and density of calcification. A negative calcium score has a high negative predictive value for ruling out atherosclerosis and stenotic CAD. On the other hand, high calcium score indicates high probability of future hard cardiac events due to CAD. If calcium is concentrated in a single segment and overall score is more than 1,000, the interpretation of underlying coronary arteries becomes an issue and the contrast CT angiography should not be done.

CT angiogram (**Figures 16 to 19**): Sixty to eighty millilitre of non-ionic contrast is injected at the rate of 5-6 mL per second through antecubital vein. ECG-gated images are acquired in different phases of cardiac cycle and reconstructions are made from phases showing least movement.

Pooled data from multiple studies on 64 slice and dual source scanners have demonstrated high sensitivity (89%) and specificity (96%) of coronary CT angiography for evaluation of CAD. It is the modality of choice for evaluation of bypass grafts after coronary artery bypass grafting. In stented arteries, in-stent lumen can usually be well seen in stents greater than 2.5 mm but may vary with stent architecture and design.

Plaque imaging is being done with high-resolution CT angiography and Dual-energy (on Dual-source CT) to differentiate unstable versus stable plaques. Many research projects are currently going on to help identify vulnerable unstable plaque.

Functional assessment of ventricles and planimetry of the stenotic valves (**Figure 20**) can be done using cardiac CT images acquired throughout the cardiac cycle.

Figure 16: Oblique MIP CT image showing mixed plaque with calcification in mid left anterior descending artery (LAD).

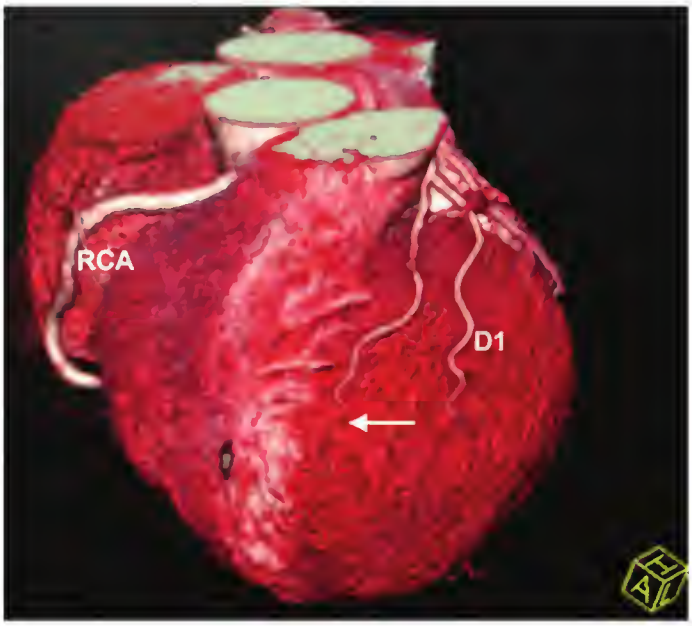

Figure 17: Volume rendered CT image showing Distal LAD Bridging (arrow).

RCA = Right coronary artery; D1 = First diagonal branch.

Figure 18: Oblique MIP-CT image showing patent stent in mid LAD.

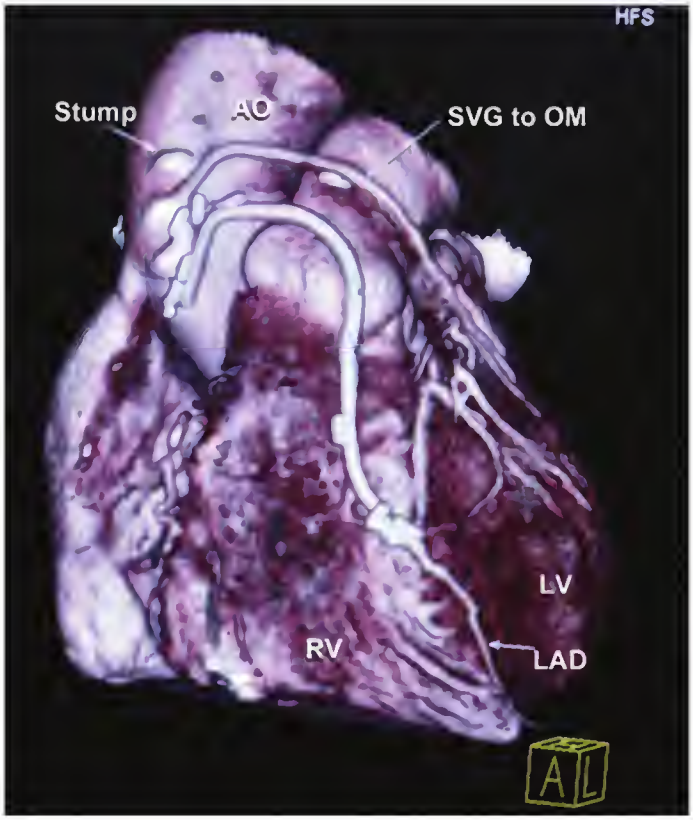

Figure 19: CT angiogram of post-operative CABG patient. Volume rendered image showing patent venous grafts to LAD and OM. A stump of occluded graft to diagonal is also seen.

AO = Aorta; LAD = Left anterior descending artery; LV = Left ventricle; OM = Obtuse marginal; RV = Right ventricle; SVG = Saphenous vein graft.

Overall, optimised cardiac imaging requires an appropriate patient selection. Both CT and MRI share advantages such as being multi-planar, out-patient based and gated acquisition among others. Factors including the speed of examination, image resolution, motion artefacts, feasibility of functional information, radiation exposure and the need for iodinated contrast influence technique selection in a given patient. Whereas claustrophobia, instability and pacemaker limit MRI; body habitus limits, pregnancy, contrast reactions limit use of CT scan. Echocardiography and SPECT may be helpful. In most clinical situations, CT and MRI are complementary in terms of the information that they can provide for optimal diagnosis, treatment planning and surveillance after treatment.

12.7 Nuclear Cardiology

Vikram R Lele, Parag Aland

Nuclear cardiology involves use of radiopharmaceuticals to study the function of the heart (**Table 1**). Radiopharmaceuticals which have affinity for the myocardium are injected intravenously and with the help of a gamma camera, functional images of the heart are obtained. Two technologies are used: single photon emission computed tomography (SPECT) which uses single, dual or triple headed gamma cameras and isotopes of 99mTechnetium, and positron emission tomography (PET) which uses short-lived isotopes of 18F, 14O,13N, and 11C which are produced in cyclotrons and imaged with special PET cameras.

Table 1: The Scope of Nuclear Cardiology

Myocardial function
Myocardial perfusion

Atherosclerosis, apoptosis imaging
Gene therapy imaging

MYOCARDIAL FUNCTION

Nuclear medicine techniques are ideally suited for analysis of myocardial function (**Table 2**). By labelling the patient's red blood cells with radiotracer, and using ECG triggered gating, the blood pool in the heart is imaged. This study called the 'gated blood pool' (GBP) study helps to give accurate quantification of left ventricular ejection fraction (LVEF) and also the wall motion of different walls of the left and right ventricle. Analysis of the electrical conduction can also be made from special computer derived 'phase images' and asynchrony in conduction can be mapped. Diastolic function can also be quantified by analysis of the computer generated LV volume curve.

Diastolic function, estimated from the LV volume curve, gives four parameters of ventricular relaxation and filling. These are peak filling rate (PFR), time to peak filling rate (TPFR), average filling rate (AFR) and atrial contribution to LV filling.

Diastolic function abnormality occurs much earlier than systolic function abnormality in all cardiac disorders including coronary artery disease (CAD) and congestive cardiac failure. The earliest change in CAD is reduction in PFR. With exercise, the expected increment in PFR is blunted. LV function and ventricular volumes are powerful independent prognostic variables in cardiac patients. An LV end systolic volume (ESV) of < 70 mL is related to low mortality while ESV > 70 mL is related to high death rate. In aortic and mitral regurgitation, preoperative ESV > 60 mL/m^2 predicts a high-risk of peri-operative cardiac death.

Exercise induced regional wall motion abnormalities (RWMA) may appear in CAD before development of ECG abnormalities or symptoms of ischaemia. Normal subjects increase their LVEF generally by at least 5% from rest to peak exercise. Patients with significant CAD show no rise, or an actual fall compared to rest LVEF.

The 'gold standard' for LVEF measurements is MRI of the heart due to its most accurate estimation of LV volumes on which LVEF measurements are based. GBP and first-pass studies and myocardial perfusion studies are, however, reproducible, easier to perform and less expensive. GBP are used in follow-up of patients on chemotherapy for detecting early cardiotoxicity and in follow-up of cardiac transplant recipients.

MYOCARDIAL PERFUSION

Myocardial perfusion imaging (MPI) is now a well-established regularly used method in evaluation of a patient with ischaemic heart disease. The procedure involves injection of radiopharmaceutical intravenously during exercise followed by acquisition of post exercise images with a gamma camera (**Tables 3 and 4**). The patient is re-injected at rest followed by resting image acquisition. The stress and rest images are then compared. The radiopharmaceutical, usually Thallium or 99mTc methoxy isobutyl isonitrile (MIBI) is selectively picked up by the myocardium in proportion to blood flow. Areas supplied by stenosed coronary arteries do not get adequate supply of the

Table 2: The Nuclear Techniques for Evaluation of Myocardial Function

Study Name	Isotope Used	Information Obtained	Importance
Gated blood pool and first-pass studies	99mTc-pertechnetate 20 to 30 mL	Left ventricular ejection fraction (LVEF)	Robust parameter of left ventricular function. Altered in various cardiac disorders like myocardial infarction, cardiomyopathy
		Wall motion	Exercise induced wall motion abnormalities are sensitive and specific for ischaemia
		Diastolic function	Earliest to be affected in cardiac disorders
Gated myocardial perfusion scan	99mTc-MIBI/ tetrofosmin	LVEF/Wall motion, wall thickening, diastolic function, perfusion, (myocardial ischaemia, infarct)	Single test combining perfusion and function
	82Rb, $13NH_3$	Absolute quantification of myocardial blood flow, coronary flow reserve (CFR) estimation	Most accurate method for myocardial flow estimation. CFR is of great importance in management decisions

radiopharmaceutical as compared to areas supplied by normal arteries. This is seen as a 'perfusion defect'. If this defect disappears on the resting study, ischaemia is diagnosed. If the defect persists, then infarction is likely to be present.

Coronary blood flow increases several fold during exercise or following adenosine infusion, in the normal coronary vascular bed due to coronary vasodilatation in response to metabolic demand. It fails to increase appreciably in the territory of an obstructed coronary artery or arteries or in arteries with diffuse endothelial dysfunction. The ratio of resting flow to flow after maximal coronary dilatation is called the coronary flow reserve (CFR). Measurement of CFR is being increasingly recognised as vital information for making management decisions about intervention in CAD.

Table 3: Radiopharmaceuticals Used in Myocardial Perfusion Imaging

13N-Ammonia

Table 4: Indications for Performing Myocardial Perfusion Imaging

1. Patients with abnormal baseline ECG (LBBB, LVH, digitalis therapy, WPW syndrome) where treadmill stress test interpretation is difficult.
2. Women: high rate of false positive stress test results.
   Patients unable to perform treadmill stress test (severe arthritis, neurological disorders, lack of motivation. Pharmacological stress test with adenosine/dobutamine can be done).
3. Asymptomatic or mildly symptomatic individuals with risk factors for ischaemic heart disease.
4. Patients with diagnosed coronary artery disease by angiography; for risk stratification and for evaluation of physiological significance of coronary stenosis.
5. Post-angioplasty for evaluation of re-stenosis.
6. Post-coronary bypass surgery for patency of grafts.
7. Post-myocardial infarction for risk stratification and viability assessment.

Based on the scan findings, the results are classified into high, intermediate and low-risk scans. Patients demonstrating 'low-risk scan' pattern can be managed medically even in presence of abnormal coronary angiograms (**Table 5**).

Patients showing 'high-risk scan' pattern should be sent for coronary angiogram (if not already performed) and for revascularisation. **Figures 1 to 3** demonstrate the low, intermediate and high-risk scan patterns. Myocardial perfusion imaging (MPI) thus performs 'gatekeeper' function in CAD management.

It has been demonstrated by large volume of data over last several years that the size and severity and reversibility of perfusion defects demonstrated on a myocardial perfusion have significant prognostic value. Small defects (low-risk scan) indicate <1% probability of cardiac events (myocardial infarct, death) in the following 2 years. Large defects (high-risk scans) indicate >8% probability of cardiac events.

Table 5: The Scan Patterns

Scan patterns
Low-risk scan
Normal perfusion, or
Small perfusion defects <10% of myocardium
Intermediate risk scan
Medium defect 10% to 20% of the myocardium, or
Small perfusion defect + LV dilatation or lung uptake of tracer
High-risk scan
Large defects >20% of myocardium, or
Medium perfusion defect + transient dilatation of LV or lung uptake of tracer

Higher the quantity of ischaemic myocardium (>12.5% of total myocardium), the better the results from interventional treatment strategies (CABG, angioplasty) rather than medical management.

Thus, MPI identifies patients who should be managed by medical versus revascularisation strategies.

PET technology allows absolute quantification of myocardial blood flow in mL/g/min and also estimates the CFR.

Coronary angiography is blind to vessels <400 microns in diameter. A significant portion of disease involves these vessels. The only way to assess these vessels is through the estimation of CFR (**Table 6**).

Table 6: The Utility of Estimating CFR

Potential clinical applications of PET MPI and CFR estimation
Impaired CFR in early coronary atherosclerosis
Hypertension
Hyperlipidaemia
Diabetes
Smoking
Impaired CFR in coronary stenosis and advanced coronary atherosclerosis
Evaluation of functional significance of coronary lesions (intermediate lesions)
Detection/delineation of multi-vessel CAD
Track disease progression/regression
Impaired CFR in non-atherosclerotic microvascular disease
Syndrome X, cardiomyopathies (HCM, DCM), hypertensive heart disease

CFR is found to be impaired in patients with hypertension, hyperlipidaemia, diabetes, and in smokers long before they develop manifest atherosclerosis and coronary disease. Corrective measures have shown normalisation or improvement in CFR.

In some patients with so called 'balanced triple vessel disease' where there is similar degree of stenosis in all three coronary arteries, a SPECT myocardial perfusion scan will look spuriously normal since the tracer will go equally badly in all stenosed territories and there will be no relative hypoperfusion in a particular territory. In this situation, an absolute quantification

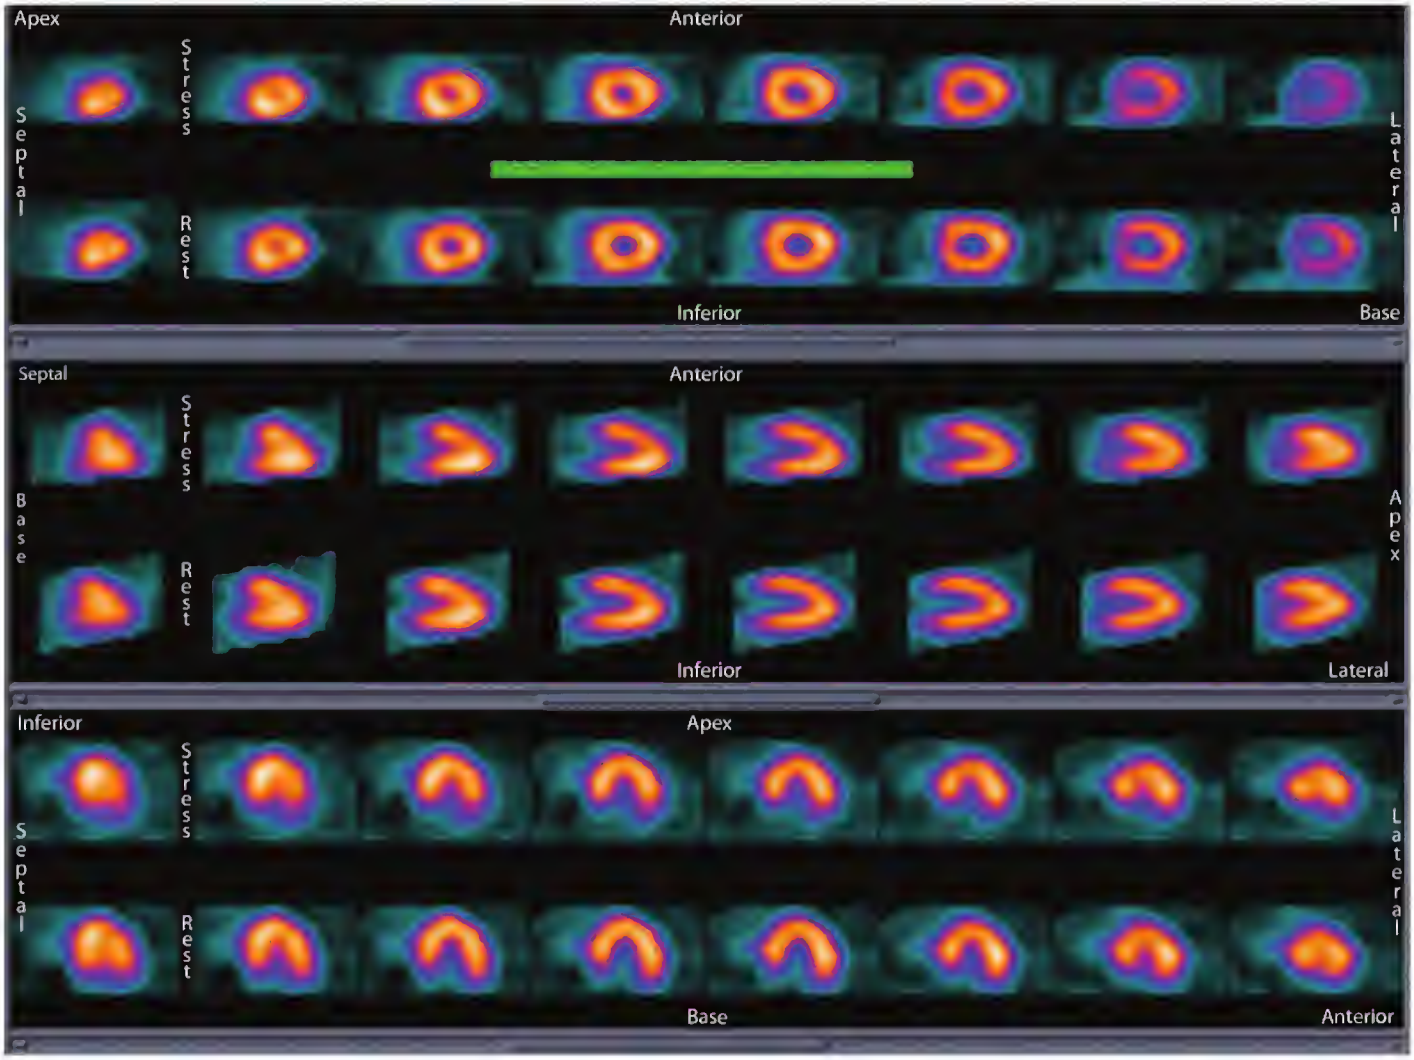

Figure 1: Shows a normal myocardial perfusion scan. Top two rows show matched short axis slices from apex to base: upper row post-stress and lower row during rest. The middle two rows show vertical long-axis slices from septum to lateral wall (upper post-stress, lower resting). The lower two rows show horizontal long axis slice from inferior to anterior wall. Note the homogenous perfusion in all areas with no perfusion defects.

of blood flow will show low values in all territories and the CFR will show low reserve.

This underscores the importance of PET scans in evaluation of MPI and CFR. Limited at the moment due to its high cost and limited availability, PET MPI and CFR will in future become the main tests in evaluation of ischaemic heart disease.

MYOCARDIAL METABOLISM

The normal myocardium predominantly uses fatty acids for its metabolic needs, to produce energy for contraction. In ischaemic conditions, the metabolism switches to the use of glucose in order to produce ATP. This is an inefficient way of producing energy, but the only way available for the myocardium in times of ischaemia.

It is possible with SPECT and PET techniques to evaluate myocardial metabolism of fatty acids as well as glucose (**Table 7**).

Evaluation of glucose metabolism has become the mainstay in detection of viable myocardium.

The switch in metabolism from fatty acids to glucose metabolism can be used to diagnose myocardial ischaemia. If a fatty acid tracer is injected during stress, ischaemic areas would show reduced uptake of fatty acid tracer. If 18F-FDG is injected during stress, ischaemic areas would show increased uptake of the glucose tracer. The normal areas would show no uptake of 18F-FDG. Stress FDG imaging is undergoing clinical studies. Hence, in patients coming to hospital with acute chest pain, a fatty acid tracer would immediately identify if there is ongoing ischaemia, showing reduced uptake of the tracer in ischaemic areas.

Table 7: Available Techniques for Imaging Myocardial Metabolism

Evaluation of myocardial metabolism with SPECT and PET

PET tracers
Fatty acid metabolism
11C-Palmitate
Glucose metabolism
18F-FDG (Fluoro-deoxy-glucose)

Many times after a large myocardial infarction with a resultant low left ventricular ejection fraction, it is necessary to know if there is viable myocardium in the infarct zone. It has been conclusively shown that revascularisation provides better

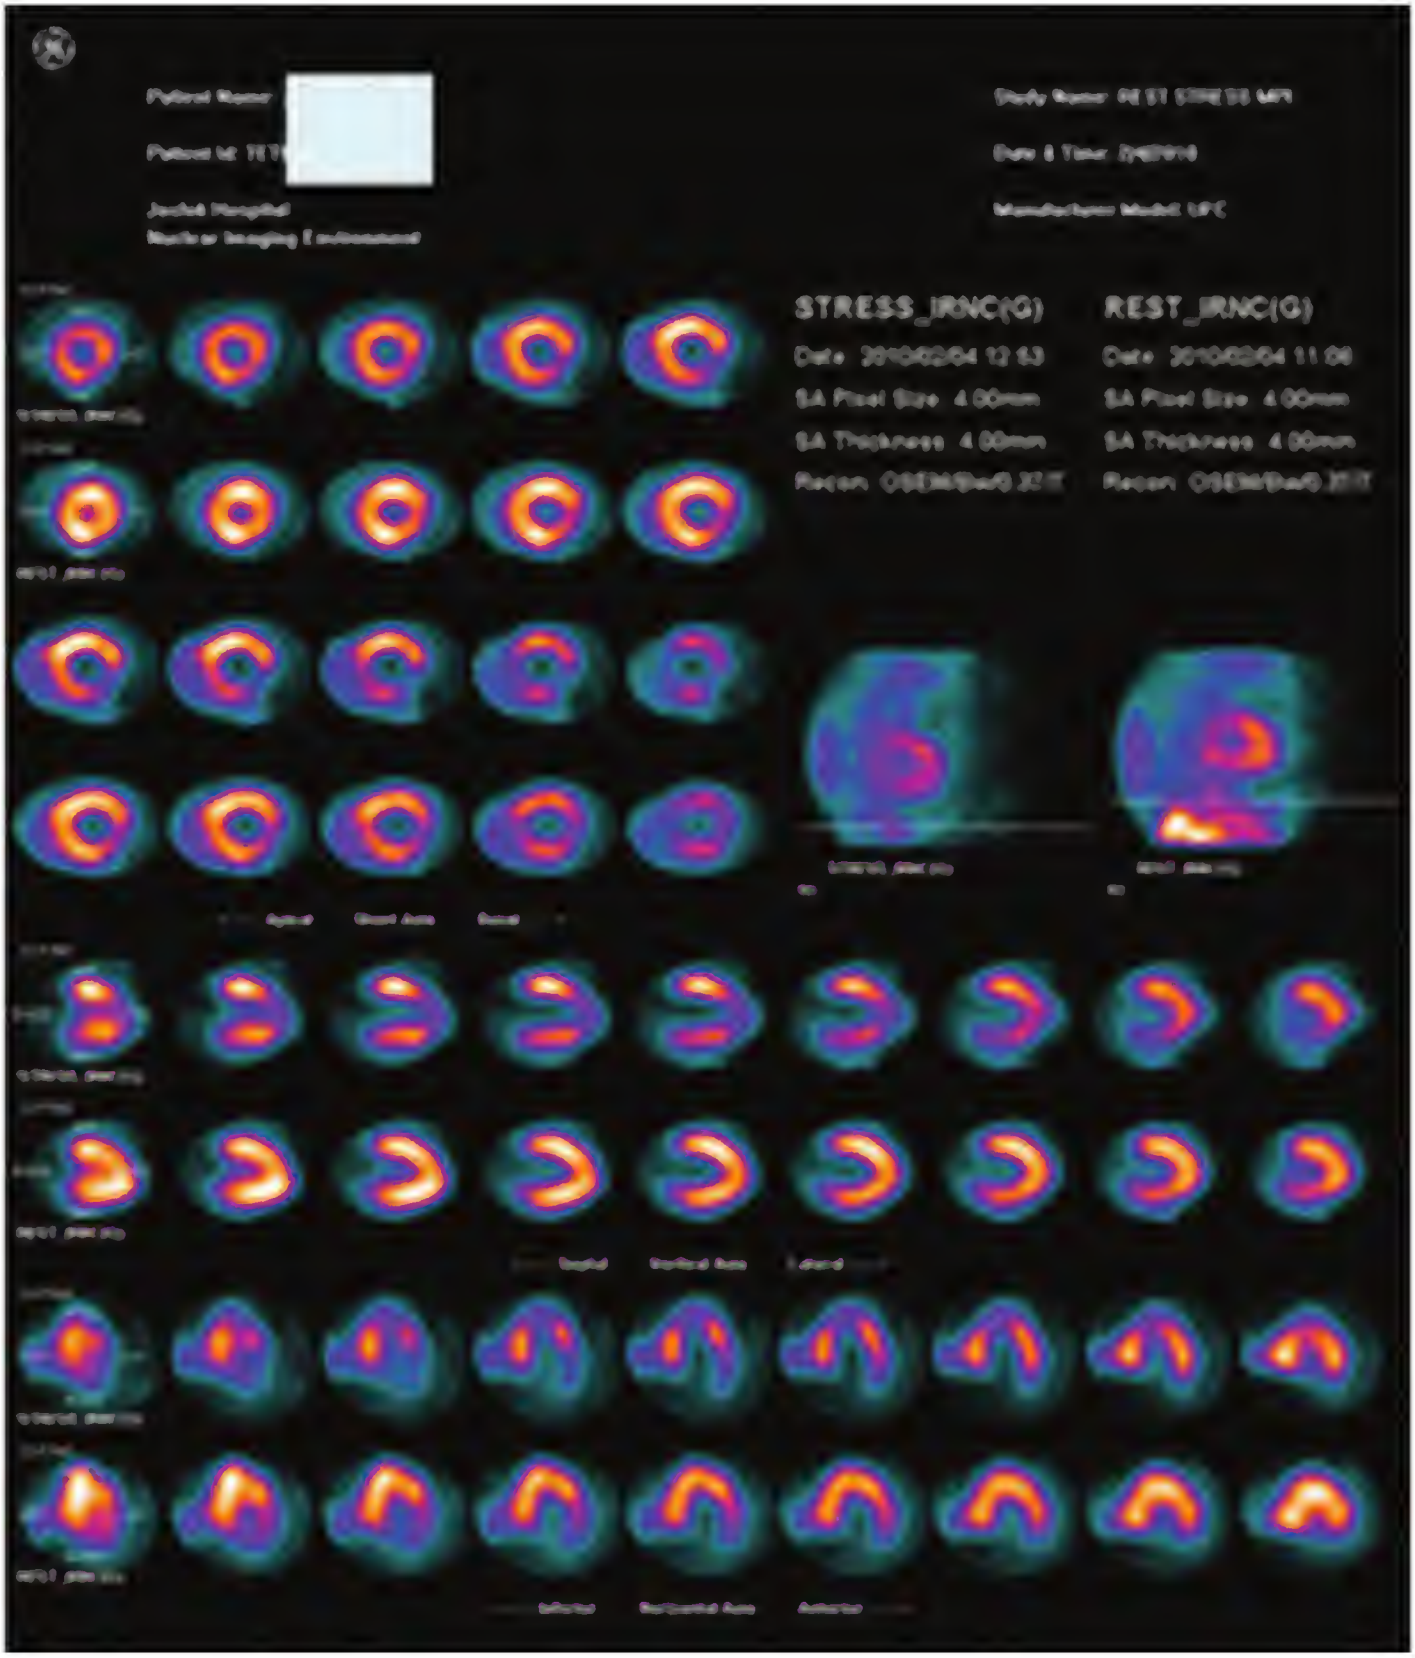

Figure 2: Shows an intermediate risk scan pattern showing medium sized perfusion defects in apex, and lateral wall.

clinical outcomes in terms of survival and symptomatic improvement in patients with viable myocardium as compared to medical therapy. Therefore, identification of viable myocardium is of great importance post myocardial infarction. Several techniques are available for this identification, namely low-dose dobutamine stress echocardiography, delayed enhanced MRI, and 18F-FDG myocardial PET. Currently, 18F-FDG PET remains the 'gold standard' for detecting myocardial viability. Viable myocytes retain capability of metabolising glucose. Dead myocytes or scar tissue cannot metabolise glucose. Hence, if a resting myocardial perfusion shows a severe perfusion defect and an FDG scan shows uptake of tracer in the same area (perfusion-metabolism mismatch), then viability is present.

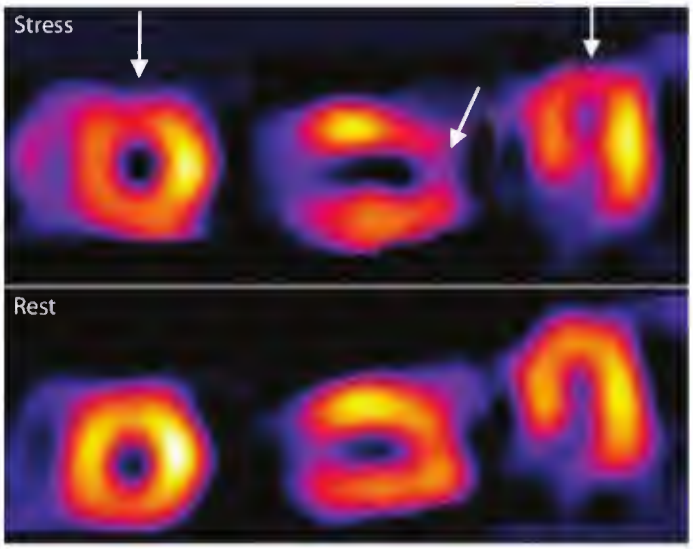

Figure 3: Shows a high-risk scan pattern with transient LV dilatation and large reversible defects in apical and anterior segments.

MYOCARDIAL INFARCTION

On standard MPI, an area of infarction is seen as a persistent perfusion defect on both the stress and rest images (fixed defect). Tracers have been developed which would be concentrated in infarcted tissue.

Glucaric acid localises in necrotic (not normal or ischaemic) tissue. Acute MI can be visualised within 1 to 2 hours of the onset of pain, in patients with or without thrombolytic therapy. Infarcts older than 2 to 3 days are not likely to show up on imaging. Tc-glucaric acid imaging will provide an important triage function in the emergency room in the evaluation of acute coronary syndromes. It will also detect peri-operative infarcts following CABG.

MYOCARDIAL RECEPTORS

Non-invasive assessment of cardiac pre-synaptic sympathetic nerve activity is possible with 123I-MIBG SPECT and 11C meta hydroxyephedrine (HED) PET. Myocardial receptor imaging has a potential diagnostic and prognostic role in patients with heart failure and cardiomyopathies. Regional uptake and washout of the radiotracer are expressed as heart to upper mediastinum (H/M) ratio in the early and late images of 123I-MIBG SPECT. A low H/M ratio strongly predicts poor outcome. Other applications include detection of diabetic autonomic neuropathy, cardiac transplant, re-innervation and re-entrant arrhythmias post-myocardial infarction.

Regional heterogeneities in β-adrenergic receptor number and reuptake occur in subjects with sudden cardiac death, and may be predictive for future events. Genetic variations in β-adrenergic receptors have major implications in terms of future development of CHF and early associated mortality. As newer third generation beta blockers like carvedilol become available, it will become increasingly important to identify markers predictive of drug efficacy for individual heart failure patients, based on sympathetic nerve imaging.

APOPTOSIS IMAGING

Pathological insults can induce apoptosis in various cardiovascular disorders, e.g. infarction and reperfusion injury, myocarditis, heart failure, heart transplant rejection. Identification of apoptosis is possible by imaging with 99mTc-annexin. The usefulness of serial imaging has been demonstrated clinically in early detection of cardiac transplant rejection by positive scans. Upon immunosuppressive therapy with cyclosporine the scans become negative within two days.

ATHEROSCLEROSIS AND GENE THERAPY IMAGING

For ensuring success of gene and cell based therapies, it is of prime importance to develop technology for non-invasive monitoring of the location and duration of gene expression, distribution and targeting of therapeutically engineered cells and vector particles *in vivo*. A number of advances have been achieved in high resolution, *in vivo* imaging methods, such as bioluminescence imaging, MRI, PET and various fluorescence imaging techniques, including fluorescence-mediated tomography (FMT) and near infrared fluorescence (NIRF) reflectance imaging.

Identifying patients at high-risk for an acute cardiovascular event such as myocardial infarction or stroke and assessing the total atherosclerotic burden are clinically important. Currently available imaging modalities can delineate vascular wall anatomy and, with novel probes, target biologic processes important in plaque evolution and plaque stability.

CONCLUSION

Nuclear cardiology has established itself as a very important diagnostic tool in the management of heart disease. By its unique ability to study physiological processes and their alteration in health and disease, it provides important diagnostic and prognostic information vital for making appropriate management decisions. Information from anatomical modalities should be combined with physiological information from nuclear cardiology techniques for full understanding of disease pathophysiology and appropriate management.

12.8 Cardiac Catheterisation and Angiocardiography

Lekha Adik Pathak, NO Bansal

INTRODUCTION

The introduction of cardiac catheterisation ushered in the era of modern cardiology with marked improvement in the diagnostic capabilities of cardiac ailments and followed in turn, with the key-hole approach to treatment of a large majority of the cardiac patients since the 1980s. Even today angiography is considered 'gold standard' in the diagnosis of coronary artery disease (CAD).

HISTORY

Cardiac catheterisation opened the way for the study of anatomy and physiology of heart. The development of cardiac catheterisation has had profound impact on the diagnosis and treatment of CAD and congenital and valvular heart diseases. The noted 19th century French physiologist Claude Bernard catheterised and measured pressure in the various cardiac chambers and great vessels of the animal heart. The first catheterisation of the living human heart was performed by a young surgeon, Werner Forssmann (on himself) in 1929 in Eberswald, Germany. Cardiac catheterisation paved the way for coronary arteriography. The first coronary angiogram was performed by F. Mason Bones on October 30, 1958; since then it has revolutionised our understanding and treatment of CAD. The coronary angiogram not only provided objective evidence to support or refute the clinical diagnosis of angina pectoris but, more importantly, led to first studies of the natural history of patients with CAD. The coronary angiogram provided the road map necessary for the successful development of coronary angioplasty. On 16 September 1977, Andreas Gruentzig performed the first coronary angioplasty in an awake human, a 37-year-old insurance salesperson with proximal LAD lesion and thus described a new way of achieving coronary revascularisation by the endovascular dilation of an obstructing lesion, that he referred to as percutaneous transluminal coronary angioplasty (PTCA).

CARDIAC CATHETERISATION PROCEDURE

Cardiac catheterisation procedure involves:

1. Pressure measurements: To calculate pressure, gradients and valve areas.
2. Oximetry data: To measure oxygen saturation and for calculation and directions of shunts.
3. Contrast injections for opacification of cardiac chambers and coronary angiograms.

Indications

The decision to perform cardiac catheterisation must be based on a careful balance of the risk of procedure against the anticipated benefit to the patient. Indications of cardiac catheterisation are enumerated in **Table 1**.

Contraindications

There is no absolute contraindication to cardiac catheterisation. Relative contraindications are given in **Table 2**.

Technique

Cardiac catheterisation is performed in adults and older children under light sedation and local anaesthesia with xylocaine. However, in smaller children and infants, general anaesthesia is required. The portals of entry commonly employed are as under:

Table 1: Indications of Cardiac Catheterisation

Diagnostic	
	To define cardiovascular anatomy in patients with congenital or acquired heart diseases
	To define coronary artery anatomy
	To assess ventricular function
	To determine intracardiac/intravascular pressures and measure flow (cardiac output) for calculation of physiological parameters
	To determine transvalvular gradients across cardiac valves and to quantify valvular regurgitation when there is disparity between clinical and echocardiographic findings
	For electrophysiologic (EP) studies to localise the site of heart block and the nature and pathway of cardiac arrhythmias
	To perform endomyocardial biopsies
Therapeutic	
	Percutaneous coronary interventions (PCI)
	Valvular dilations such as balloon mitral valvuloplasty (BMV), balloon pulmonary valvuloplasty (BPV), balloon aortic valvuloplasty
	Device closure of atrial septal defects (ASD), ventricular septal defects (VSD), patent ductus arteriosus (PDA) and other uncommon congenital defects such as coiling or device closure of ruptured sinus of Valsalva aneurysm (RSOV), and coiling of coronary artery fistulas
	Balloon atrial septostomy as in patients with transposition of great arteries (TGA)
	Radiofrequency ablation (RFA) of foci of cardiac arrhythmias and pathways of aberrant conduction
	Local thrombolysis in patients with pulmonary artery embolism
	Alcohol septal ablation in HOCM

Table 2: Relative Contraindications of Cardiac Catheterisation

Uncontrolled ventricular irritability (increased risk of ventricular tachycardia/fibrillation)
Digitalis toxicity
Electrolyte imbalance (e.g. uncontrolled hypokalaemia)
Uncorrected hypertension
Concurrent febrile illness
Decompensated heart failure
Severe renal insufficiency, unless dialysis is planned
Severe allergy to radiographic contrast agent
Prothrombin time >18 or INR >2 or bleeding diathesis

Femoral route

The femoral artery and vein are the most commonly used vessels for cardiac catheterisation. It is important to puncture these vessels at correct level, i.e. 1 cm to 2 cm below the inguinal ligament (and not the inguinal skin crease) which runs from the

anterior superior iliac spine to pubic tubercle. Though earlier puncture was done using Seldinger technique with a Seldinger needle, nowadays most of the cardiac catheterisation laboratories use a single wall puncture needle. Once the needle is in the vessel, it is stabilised with the left hand and a guide wire (0.035 or 0.038 inch) with J tip is inserted via the needle into the vessels, while making sure that there is no resistance felt during its advancement. The needle is then removed and a skin nick (if not already done) is made. An appropriate sized sheath is then threaded over the guide immediately after sheath insertion. The catheters are then guided under fluoroscopic control to appropriate site, through the sheath (**Figure 1**).

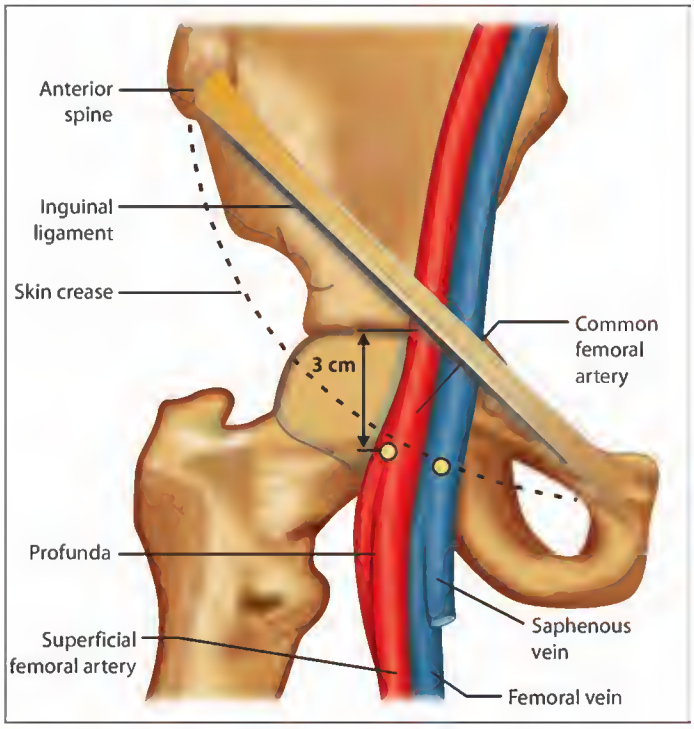

Figure 1: Regional anatomy relevant to percutaneous femoral arterial and venous catheterisation. Schematic diagram showing the right femoral artery and vein coursing underneath the inguinal ligament, which runs from the anterior superior iliac spine to the pubic tubercle. The arterial skin nick should be placed approximately 1 cm to 3 cm below the ligament and directly over the femoral arterial pulsation, and the venous skin nick should be placed at the same level but approximately one finger-breadth more medially. Although this level corresponds roughly to the skin crease in most patients, the anatomical localisation relative to the inguinal ligament provides a more constant landmark.

Radial artery route

This approach is especially useful for those with peripheral arterial disease and morbid obesity. The preferred site of puncture is approximately 1 cm to 2 cm proximal to the radial styloid. Radial artery cannulation is done using a micropuncture needle (21 gauge). Using the technique as described above, an appropriate sized sheath (5 or 6 F) is inserted into the vessel. Anticoagulation (usually, heparin) and cocktail of vasodilators (NTG 100 mg to 200 mg, verapamil 1.25 mg to 2.5 mg) is administered immediately after sheath insertion. As the risk of post-procedural radial artery occlusion is up to 3%, palmar arch patency must be assessed prior to the procedure. This is done by Allen's test. Both the radial and ulnar arteries are compressed while the patient is asked to make and open fist 3 to 4 times. Ulnar artery compression is then removed and the time taken for the palm to get flushed is noted. Absent or delayed flushing suggests inadequate palmar arch blood flow. A modification of Allen's test (first developed by Hovagim and validated by Gerard Barbeau) can also be done. This method involves placing a pulse oximeter probe on the thumb while compressing the radial artery. Adequacy of palmar arch blood flow is confirmed by the presence of an arterial waveform (even if with reduced amplitude or delayed appearance) and oxygen saturation of >90%. The patency of radial and ulnar arteries is best confirmed by Doppler study. The major advantages of radial artery approach are faster time to ambulation and rare access site bleeding complications. Limitations include smaller artery size and inability to take venous access.

Other sites

Brachial artery can be approached over the antecubital fossa by both percutaneous technique and surgical cut-down. Axillary artery can be entered over the head of humerus. In the new born, umbilical artery can be used for catheterisation.

GENERAL PRINCIPLES

Figure 2 outlines the hardware and machine used for cardiac catheterisation.

Certain general principles should be followed during cardiac catheterisation. Haemodynamic measurements should precede angiographic studies, so that the pressure and flow measurements are made as close as possible to the basal state. Measurements of pressure and cardiac output should be made as simultaneously as possible. Cardiac output can also be measured using thermodilution techniques.

Limit total contrast volume for the study (in paediatric patients, this should not exceed >5 mL/kg). Currently, most contrast media used are non-ionic with low osmolality. Nowadays, 10% to 30% of coronary angiograms and angioplasties are done via radial route and it is increasing still further in view of great patient comfort and less bleeding. The blood samples need to be acquired with the patient breathing (or being ventilated with) air or a gas mixture containing no more than a maximum of 30% oxygen.

INTERPRETING TRACINGS

Atrial Tracings

Atrial tracings have three positive waves namely 'a', 'c' and 'v' and two descents namely 'x' and 'y'. The 'c' wave is often missing. Left atrium (LA) tracings differ from those of right atrium (RA) in the form that 'v' wave is taller than 'a' wave in the former (**Figure 3**) Also pressures are generally higher in the LA tracing. Tall 'a' waves in the RA tracing suggest tricuspid stenosis (TS), pulmonary stenosis (PS), and significant pulmonary hypertension (PH). Tall 'a' waves in the LA tracing suggest mitral stenosis (MS) and left ventricular hypertrophy (LVH) due to any cause. In atrial fibrillation (AF), 'a' wave is absent. Tall 'v' waves in the RA tracing suggest tricuspid regurgitation (TR) and in the LA suggest mitral regurgitation (MR). A well marked 'y' descent rules out significant stenosis of the respective AV valve. In cardiac tamponade, the 'x' descent is present but 'y' descent is absent. A rapid 'x' and 'y' descent (M or W sign) is seen in constrictive pericarditis.

Ventricular Tracings

Left ventricular end-diastolic pressure (LVEDP) is somewhat higher than right ventricular end-diastolic pressure (RVEDP) reflecting the greater stiffness of LV. High right ventricular systolic pressure (RVSP) is seen in PS and PH due to any cause. Raised

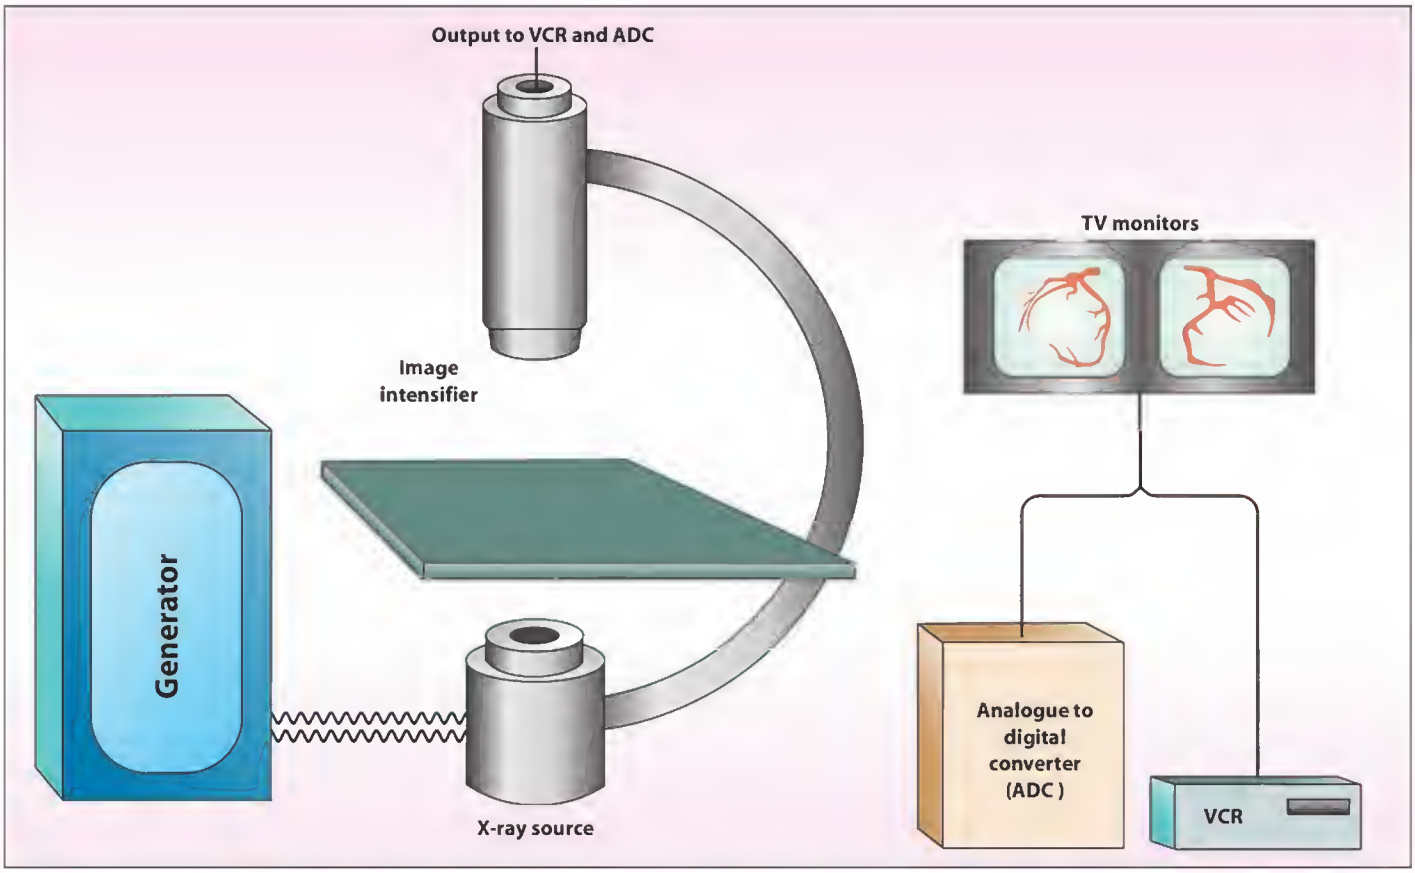

Figure 2: Cineangiography equipment. The major components include a generator, X-ray tube, image intensifier attached to a positioner such as a C-arm, optical system, video camera, videocassette recorder (VCR), analog to digital converter (ADC), and television monitors. The X-ray tube is the source of the X-ray beam, which passes superiorly through the patient.

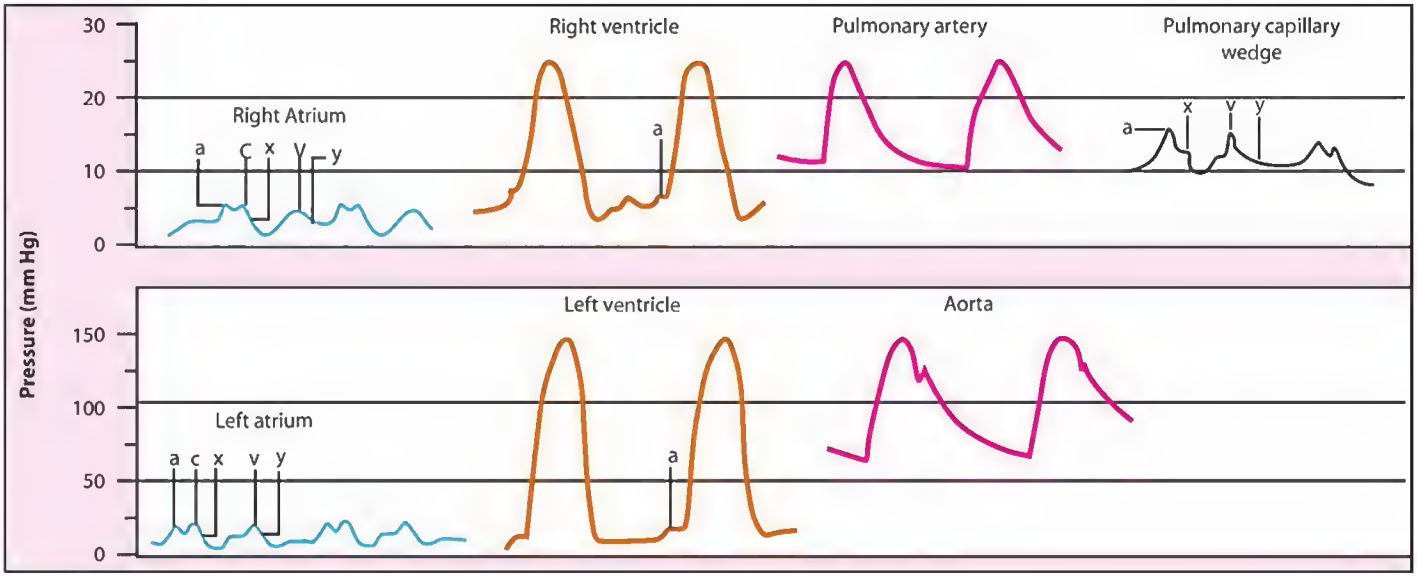

Figure 3: Normal right- and left-heart pressures recorded from fluid-filled catheter systems in a human.

left ventricular systolic pressure (LVSP) is seen in systemic hypertension and left ventricular outflow tract obstruction (LVOTO) due to any cause (aortic stenosis, hypertrophic obstructive cardiomyopathy). Higher ventricular end-diastolic pressures reflect ventricular dysfunction or restrictive physiology.

Arterial Tracings

In severe aortic regurgitation (AR), the arterial pulse pressure is wide with a high systolic pressure and lower diastolic pressure. With significant aortic stenosis (AS), there is decapitation of systolic pressure. Similar changes are seen in respective pulmonary artery tracings in those with PR or PS. Pulmonary arterial wedge pressure obtained by wedging the right heart catheter far out into a pulmonary artery branch reflects the LA pressure in individuals without any vascular lung disease or pulmonary venous obstruction. It is, thus, a measure of LV diastolic pressure in those with normal functioning mitral valve.

Pressure recordings provide an important clue to the presence of valvular stenosis. With significant stenosis of semilunar valves, a systolic pressure gradient is present between the respective great artery and the ventricular chamber (**Figure 4**). Stenosis across the AV valves results in pressure gradients in diastole between the respective atrial and ventricular chamber. (**Table 3** gives normal pressure values of chambers and across valves).

Table 3: Haemodynamic Data

Chamber	Normal Values
RA pressure	Mean 1 to 5 mm Hg
RV systolic pressure (RVSP)	15 to 30 mm Hg
RV end diastolic pressure (RVEDP)	1 to 7 mm Hg
PA systolic pressure (PASP)	15 to 30 mm Hg
PA diastolic pressure (PADP)	4 to 12 mm Hg
PA mean	9 to 19 mm Hg
PCWP	Mean 4 to 12 mm Hg
LA pressure	Mean 2 to 12 mm Hg
LV systolic pressure (LVSP)	90 to 140 mm Hg
LV end diastolic pressure (LVEDP)	5 to 12 mm Hg
Aorta systolic pressure	90 to 140 mm Hg
Aorta diastolic pressure	60 to 90 mm Hg
Mean aortic pressure (MAP)	70 to 105 mm Hg
Systemic vascular resistance	1170 ± 270 dynes sec/cm^{-5}
Pulmonary vascular resistance	67 ± 30 dynes sec/cm^{-5}
Oxygen consumption	125 mL/m^2
AV oxygen difference	30 to 50 mL/L
Cardiac output	4 to 8 L/min

Valve Area

Calculation of valve area is based on the hydraulic formula usually referred to as the 'Gorlin formula'. The calculation depends on obtaining estimates for valve flow in mL/s during the time that the valve is open.

Normal mitral valve area in adults is 4 to 5 cm^2. When it is less than 1 cm^2, it becomes critical MS. In adults, the normal aortic valve area is 3 to 4 cm^2 and critical AS is said to be present when valve area is less than 0.8 cm^2.

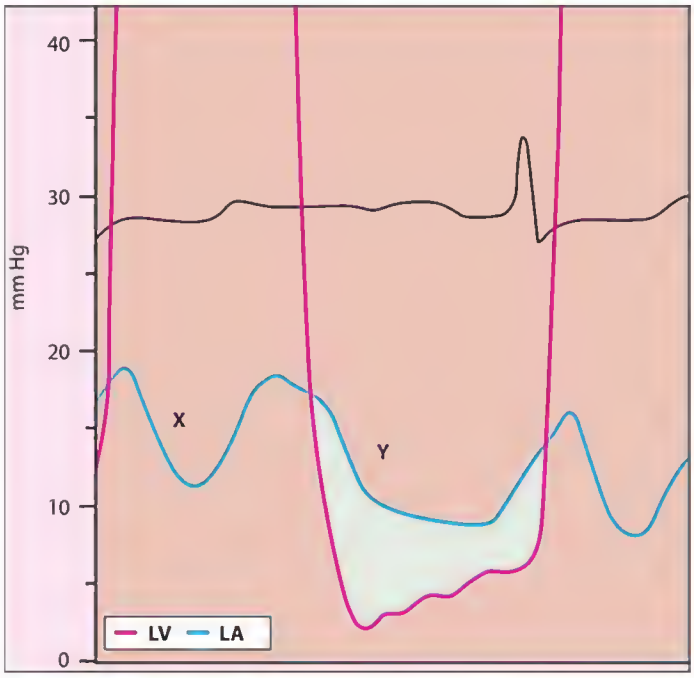

Figure 4: Pressure gradient in a patient with mitral stenosis. The pressure in the left atrium (LA) exceeds the pressure in the left ventricle (LV) during diastole, producing a diastolic pressure gradient (green shaded area).

Shunt Detection

Cardiac catheterisation data are also used to detect, localise and quantify left to right shunt or right to left shunts. For example, a step-up in oxygen saturation from 65% in the RA to 80% in pulmonary artery is indicative of large left to right shunt that may be due to ventricular septal defect. Pulmonary to systemic flow ratio (Qp:Qs) can be calculated as it provides a simple and reliable estimate of the extent to which pulmonary flow is increased or reduced and provides a useful insight into the severity of the haemodynamic disturbance in most cases. It is also very simple to perform, employing the oxygen saturation data. The formula is:

$$Qp:Qs = \frac{Sat\ AO - Sat\ MV}{Sat\ PV - Sat\ PA}$$

where Sat AO is aortic saturation, Sat MV is mixed venous saturation; Sat PV is pulmonary vein saturation, and Sat PA is pulmonary artery saturation.

Calculation of pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR) is very important in cases of shunts to decide further treatment options.

ANGIOGRAPHY (CONTRAST INJECTION)

The goal of coronary angiogram is to examine the entire coronary anatomy including the native vessels and bypass grafts, if any. The coronary artery can be delineated by opacifying it with contrast material which is injected via a catheter that is engaged to the respective coronary artery sinus. Images of the coronary artery are recorded by filming with digital cineangiography systems at 10 to 30 frames/s. Each coronary artery is visualised in several views and analysed for the anatomy, number and severity of stenosis (commonly expressed as % stenosis relative to normal segment) (**Figures 5 to 7**).

VENTRICULOGRAM

A ventriculogram can be performed by rapid injection of radio-opaque contrast agent into the chamber to be assessed. A power injector injects the contrast agent at a pre-selected flow rate, volume and pressure. The catheter used is usually an end-hole catheter with multiple side-holes (pigtail catheter) as it can

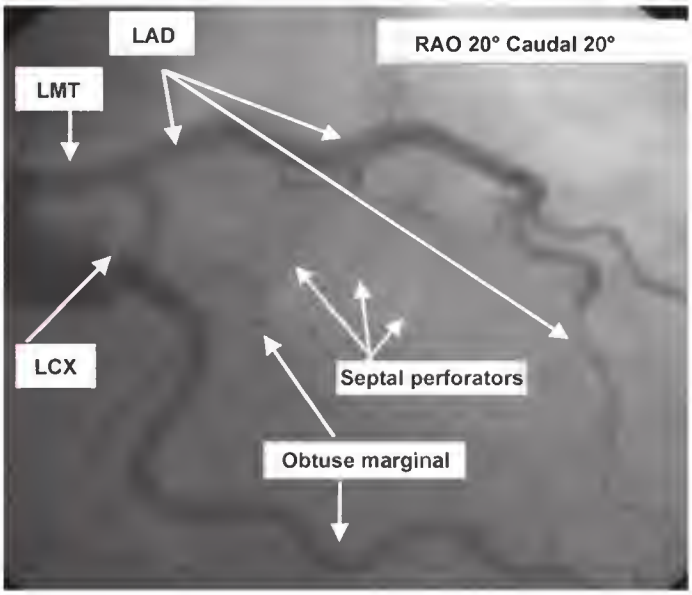

Figure 5: Left coronary angiogram in right anterior oblique (RAO) caudal view, showing left main trunk (LMT), left anterior descending (LAD) and left circumflex arteries (LCX) and their branches.

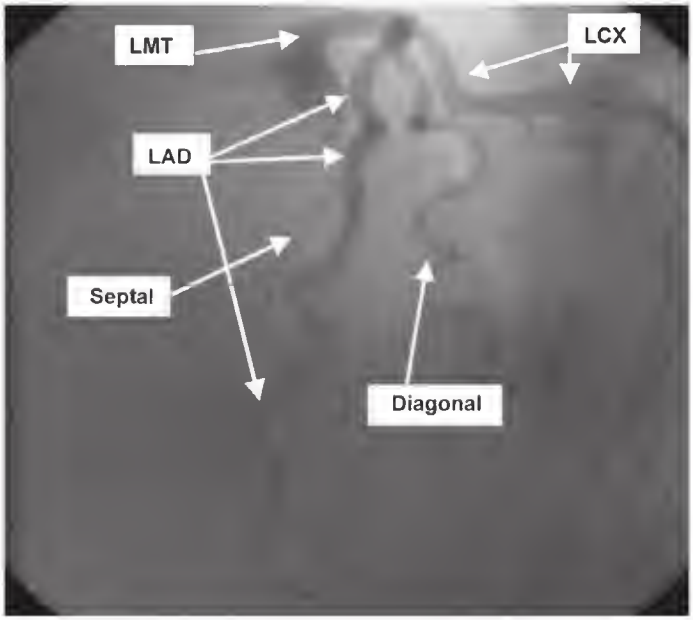

Figure 6: Left coronary angiogram in left anterior oblique (LAO) cranial view.

LMT = Left main trunk; LAD = Left anterior descending; LCX = Left circumflex artery.

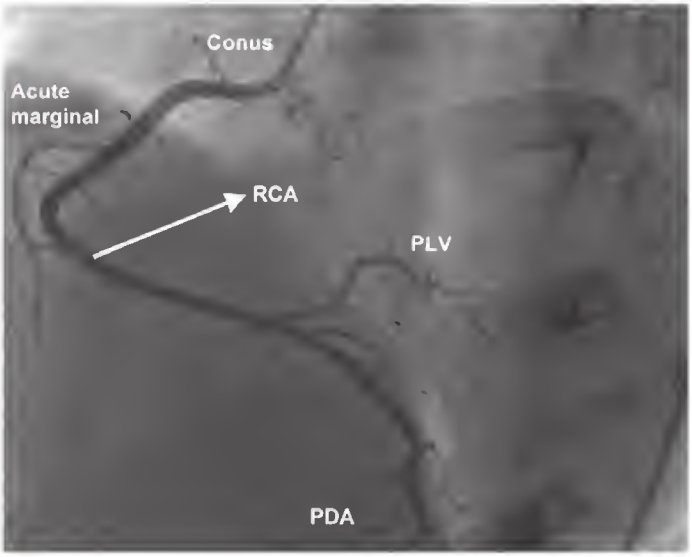

Figure 7: Right coronary angiogram in right anterior oblique (RAO) view, showing right ventricular, posterior left ventricular (PLV) and posterior descending (PDA) branches.

RCA = Right coronary artery.

rapidly deliver a bolus of the contrast agent without recoil. Ventricular wall contraction can be visually assessed by ventriculogram. Regional abnormalities of wall motion include diminished inward motion of myocardial segment (hypokinesia), absence of movement of myocardial segment (akinesia) and paradoxical systolic expansion of regional myocardial segment (dyskinesis). Also ventricular end-diastolic pressures can be determined. Ventricular systolic function can also be assessed by calculating ejection fraction, dp/dt or stroke work.

Besides aortography may be performed when indicated (as in quantification of aortic regurgitation, identification of aortic aneurysm and/or aortic dissection) to define the size of aortic root and thoracic aorta.

Various procedures, like balloon valvuloplasties of AV valves can be easily done, by percutaneous route, with the help of contrast ventriculograms (**Figure 8**).

Figure 8: Balloon mitral valvuloplasty showing the inflated Inoue balloon across the mitral valve.

COMPLICATIONS

Serious complications of cardiac catheterisation include death, myocardial infarction (MI), or stroke. Their incidence is < 1%. The risk of vascular injury requiring transfusion or surgical repair is <2%. Perforation of heart or great vessels may occur, especially when using the trans-septal technique. Vasovagal reactions are common and respond well to atropine. Major arrhythmias occur in 1% patients and include ventricular tachycardia/fibrillation and bradyarrhythmias. Because cardiac catheterisation is inherently a sterile procedure, infection is extremely unusual. Iodinated contrast agents may trigger allergic reactions. At least 5% of patients experience a transient rise in serum creatinine (contrast induced nephropathy) following coronary angiography; however, nowadays non-ionic low osmolar contrast agents are widely used which have significantly lower incidence (1%) of allergic reaction. Hypotension and heart failure may occur sometimes especially in those with extensive CAD or depressed LV function.

12.9 Pharmacotherapy of Cardiovascular Disorders

J C Mohan, Vipul Mohan

INTRODUCTION

It is well known that cardiovascular diseases are the number one cause of mortality in the world. Cardiovascular pharmacotherapy has been a tremendous success story. Underlying this success has been knowledge of the neuro-endocrine signal transduction pathways, receptors, enzymes, cytokines and ion channels involved in pathogenesis of disease process.

MANAGEMENT OF ANGINA AND MYOCARDIAL ISCHAEMIA

Angina results from an imbalance between myocardial perfusion and myocardial metabolic demands. Heart rate (HR) reduction can alter both elements of this imbalance beneficially. The resulting increase in diastolic filling time should improve myocardial perfusion; myocardial oxygen demand varies directly with HR. It is essentially due to demand-supply mismatch of oxygen at mitochondrial level. There is, however, a weak relationship between severity of pain and degree of oxygen deprivation in the heart muscles.

About five million patients in India use anti-anginal drugs. Anti-anginal efficacy is documented by improved exercise tolerance, reduction in angina attack rate and short-acting nitrate use, and anti-ischaemic efficacy by reduction in exercise-induced electrocardiogram (ECG) ST-segment depression.

Pharmacological Approach in Ischaemia/Angina

Pharmacological treatment of angina encompasses both the prevention of the complications of coronary atherosclerosis and the relief of symptoms. Progress of atherosclerosis can be retarded by statins, anti-RAAS agents and blood pressure lowering drugs. Modes of relief of ischaemia are shown in **Table 1**.

Table 1: Modes of Relief of Ischaemia

Reduce energy expenditure (mainstay)
Increase oxygen delivery (increase myocardial blood flow)
Increase oxygen efficiency (complimentary)
Combined

Drugs which reduce myocardial contractility, HR and/or systolic blood pressure are the mainstay of anti-anginal therapy (**Table 2**). These include beta-adrenergic receptor blockers, calciumchannel blockers and direct sinus node inhibitors.

Nitrates

Sublingual nitrates work rapidly, i.e. within minutes, and the effect lasts for about 30 to 45 minutes. Profound relief of symptoms is the result of venodilatation, after-load reduction and coronary dilatation. Many nitrate delivery systems have been developed for chronic prophylactic use (**Table 3**). It has become clear, however, that patients can develop at least partial tolerance to this therapy. The use of nitrate-free interval between dosing is an effective means of overcoming the development of tolerance; although in some cases, a rebound of symptoms may occur at this time. Eccentric dosing of oral nitrates is a recognised way of reducing nitrate tolerance. This can be obviated by the concomitant use of another class of anti-anginal agents. Nitrates do not influence morbidity or mortality.

Table 2: Major Classes of Anti-anginal Drugs

Organic nitrates (reduce pre-load and increase coronary blood flow)
Pure negative chronotropic agents (direct sinus node inhibitors, like ivabradine, cilobradine, etc.)
Negative chronotropic and negative inotropic agents (beta-adrenergic receptor blockers and phenylalkylamine and benzothiazepine calcium channel blockers, like verapamil, diltiazem, etc.)
Vasodilatory non-chronotropic calcium channel blockers (nifedipine, nitrendipine, amlodipine, etc.)
Delayed sodium current (phase I sodium channel blockers) modifiers, like ranolazine
Nitric oxide donors, like nicorandil and nebivolol
Metabolic modulators (trimetazidine, perhexiline maleate, diacetoacetate, etc.)

Table 3: Different Types of Nitrates

Short-acting nitrates: Nitroglycerine, amyl nitrate
Intermediate-acting nitrates: Isosorbide dinitrate
Long-acting nitrates: Isosorbide mononitrate

Calcium antagonists

Calcium antagonists cause coronary and peripheral vasodilation. Furthermore, smooth muscle relaxation and reduction of after-load together with the negative inotropic effects of some of the agents will reduce myocardial oxygen consumption. While various formulations of the two prototype papaverine-like and benzothiazepine-like calcium antagonists, verapamil and diltiazem are widely available, most current development involves analogues of the nifedipine-like dihydropyridine class. The calcium antagonists are a structurally heterogeneous group of compounds with important differences in pharmacological action.

Verapamil slows conduction through the atrioventricular node and has important negative inotropic effects as well as causing smooth muscle relaxation which leads to an increase in coronary blood flow and a reduction in after-load. The dihydropyridines, such as nifedipine and amlodipine, also cause smooth muscle relaxation but have no effect on cardiac pacemaker tissue which may result in a reflex increase in the HR. In common with other calcium antagonists, these drugs have negative inotropic effects, which are, however, less marked than those of verapamil. The effect of diltiazem is

similar to those of verapamil though it has a less potent effect of left ventricular function.

Beta-adrenergic receptor blockers

Catecholamines stimulate largely type 1 beta-receptors present in myocardium. Although this activation of beta-1 receptors provides inotropy, chronotropy and lusitropy which is extremely useful in acute situations, chronic overstimulation creates a state of energy starvation, calcium overload, mechanical inefficiency, hypertrophy, inhibition of repair, extracellular matrix synthesis, state of inflammation and hypokalaemia and aggravates angina and ischaemia (**Table 4**). Beta-receptor antagonists counteract these deleterious effects by occupying the receptors and displacing catecholamines.

Table 4: Mechanisms of Anti-Ischaemic Action of Beta-Blockers

Reduced energy expenditure by slowing the heart rate
Reduced energy expenditure by negative inotropy
Improved myocardial flow by prolonging diastolic filling period
Improvement in mechanoenergetics
Reverse remodelling of the dysfunctional ventricular myocardium

Usually, beta-adrenergic receptor blocking agents are used orally for chronic prophylaxis and can be administered once or twice a day in progressively increasing doses till resting heart rate reaches about 60 beats per minute or adverse effects appear. Usual doses of atenolol (100 mg per day), metoprolol (200 mg per day), bisoprolol (10 mg per day), nebivolol (5 to 10 mg per day), carvedilol (50 mg per day) are sufficient for this purpose. Intravenous propranolol, atenolol and metoprolol have been used during rest angina, especially when associated with tachycardia (**Figure 1**).

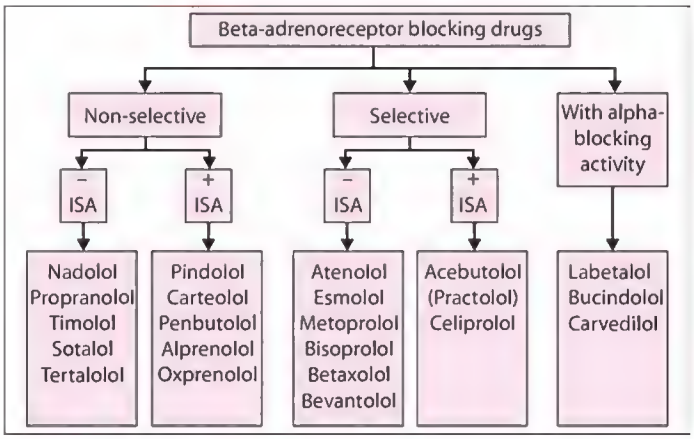

Figure 1: Classification of beta-adrenoreceptor blockers on the basis of cardio-selectivity and intrinsic sympathomimetic activity (ISA).

Metabolic modulators

Metabolic modulators are the agents that may reduce symptoms without affecting haemodynamics, inotropy and/or chronotropy. Glucose oxidation is the key step to be influenced in a metabolic approach to the treatment of ischaemia/reperfusion diseases, such as angina. Free fatty acids are the main fuel for the healthy heart, with a lesser contribution from the oxidation of glucose and lactate. Myocardial ischaemia alters fuel metabolism, causing an accelerated rate of glucose conversion to lactate and a switch from lactate uptake by the heart to lactate production. Metabolic modulators produce a switch in substrate utilisation by the heart. Glucose is 16% more oxygen efficient, and hence, switching from free fatty acids to glucose will relieve ischaemia in a strained heart.

Most commonly used metabolic modulator as an anti-ischaemic agent is trimetazidine in a maximum dose of 60 mg per day. It is the mitochondrial enzyme long-chain 3-ketoacyl coenzyme A thiolase, inhibition of which triggers a balancing increase in pyruvate oxidation and reduces the accumulation of lactate.

MANAGEMENT OF ACUTE CORONARY SYNDROME

Besides the usual measures like bed rest, hospitalisation, oxygen therapy, pain relief and use of above-mentioned anti-ischaemic drugs, it needs to be stratified into a risk category based upon well-established scoring systems and algorithms. High-risk patients need a combination of pharmacotherapy with catheter-based interventions while non-high-risk patients are usually managed conservatively with potent anti-platelet and anti-thrombotic drugs along with plaque stabilisers, like statins and anti-RAAS agents. Drug therapy for acute coronary syndrome is summarised in **Table 5**.

Table 5: Drug Therapy for Acute Coronary Syndrome

Dual oral anti-platelet therapy
Anti-thrombotic therapy
Thrombolytic therapy for ST-elevation myocardial infarction
Anti-ischaemic therapy with emphasis on beta-blockers, calcium channel blocking agents and nitroglycerine
Plaque stabilising therapy like statins in high doses and beta-receptor blocking agents
Anti-RAAS agents after stabilisation
Potent intravenous anti-platelet agents for catheter-based interventions

Aspirin has been thoroughly evaluated as an anti-platelet drug and was found to prevent vascular death by approximately 15% and non-fatal vascular events by about 30% in a meta-analysis of more than 100 randomised trials in high-risk patients. The best characterised mechanism of action of the drug is related to its capacity to inactivate permanently the COX activity of prostaglandin H-synthase-1 and -2 (also referred to as COX-1 and COX-2). The saturability of the anti-platelet effect of aspirin at low doses, the lack of dose-response relationship in clinical studies evaluating its anti-thrombotic effects, and the dose dependence of its side effects all support the use of as low a dose of aspirin as has been found to be effective in the treatment of various thromboembolic disorders.

Dual anti-platelet therapy has become the standard of care for all cases of acute coronary syndrome because of their synergistic and additive benefits. Initially, it was used to be aspirin (75 to 300 mg per day) along with ticlopidine but now it is aspirin with clopidogrel (75 to 150 mg per day). Newer drugs like prasugrel and ticagrelor may replace clopidogrel in near future at least in high-risk cases. **Table 6** shows the anti-platelet drug therapy currently being used in patients with acute coronary syndrome.

Dual anti-platelet treatment is required for at least one year after an episode of acute coronary syndrome or percutaneous coronary intervention. Selected cases may, however, require longer treatment. Subsequent to one year, aspirin alone or clopidogrel alone in aspirin-intolerant patients is sufficient.

Table 6: Anti-Platelet Drugs

Cyclooxygenase-1 inhibitors	
	Aspirin
Adenosine diphosphate receptor inhibitors	
	Clopidogrel
	Elinogrel
	Prasugrel
	Ticlopidine
	Ticagrelor
	Cangrelor (both oral and intravenous)
Phosphodiesterase inhibitors	
	Cilostazol
Glycoprotein IIB/IIIA inhibitors (intravenous use only)	
	Abciximab
	Eptifibatide
	Tirofiban
	Defibrotide
Adenosine reuptake inhibitors	
	Dipyridamole

Glycoprotein IIB/IIIA Inhibitors

Platelet membrane glycoprotein (GP) IIb/IIIa receptors constitute the final common pathway of platelet aggregation, the integrin GPIIb/IIIa antagonists prevent cross-linking of platelets. The inhibitors of GP-IIb/IIIa include monoclonal antibodies against the receptor (Abciximab), naturally occurring Arg-Gly-Asp sequence (RGD) containing peptides isolated from snake venoms, synthetic RGD- or Lys-Gly-Asp sequence (KGD) containing peptides, and peptidomimetic and non-peptide RGD mimetics (eptifibatide and tirofiban) that compete with fibrinogen, von Willebrand factor, and/or perhaps other ligands for occupancy of the platelet receptors.

Anti-thrombotic Agents

Anti-thrombotic agents includes only those drugs which affect the coagulation cascade are described in **Table 7**.

Table 7: Anti-Thrombotic Agents Used in Acute Coronary Syndrome

Non-selective indirect thrombin Inhibitors	
	Unfractionated heparin
	Low-molecular weight heparins
Direct thrombin inhibitors	
	Hirudin
	Bivalirudin
	Argatroban
	Dabigatran
	Ximelagatran
Selective factor Xa inhibitors	
	Fondaparinux
	Rivaroxaban
	Apixaban

Unfractionated heparin is still the most commonly used anti-thrombotic agent with a bolus dose of 50 to 100 units/kg of weight followed by 10 to 15 units/kg per hour infusion for at least 48 hours and may be even longer.

Unfractionated heparin preparations contain molecules of widely varying sizes (3,000-30,000 Daltons; mean 15,000 Daltons), but anticoagulant activity is limited to the relatively small proportion of molecules (approximately 30%) whose structures include the pentasaccharide sequence. This active fraction of heparin preparations is non-selective in its ability to enhance anti-thrombin III-mediated inhibition of both thrombin and factor Xa, demonstrating equipotent activities in anti-factor IIa (thrombin)-specific and anti-factor Xa-specific assays.

Heparin is heavily sulphated, causing it to bind non-specifically to various plasma and cellular proteins. This contributes to heparin's unfavourable pharmacokinetic properties, including a complex clearance mechanism and a relatively short, dose-dependent half-life. It also leads to reduced bioavailability and consequently, an unpredictable anticoagulant response in different individuals, which requires frequent laboratory monitoring of activated partial thromboplastin time to ensure adequate anticoagulation without enhanced bleeding risk. Heparin's high degree of non-specific binding is directly responsible for a number of undesirable complications that represent major drawbacks to unfractionated heparin therapy; these complications include changes in platelet function that contribute to bleeding complications, heparin resistance, osteoporotic changes, and most important, heparin-induced thrombocytopaenia.

Low molecular weight heparin preparation

Short chains containing the pentasaccharide sequence predominate, but longer chains that contain the pentasaccharide sequence as well as thrombin-binding structures are included in all low molecular weight heparin (LMWH) preparations to varying degrees. Thus, LMWH that shares the same mechanism of anti-thrombin III-mediated inhibition as unfractionated heparin, targets factor Xa preferentially but also exerts some anti-factor IIa activity, based on the degree to which longer chains are present in different commercial LMWH preparations.

As a therapeutic agent, LMWH is rapidly absorbed into plasma and has a longer half-life relative to that of unfractionated heparin. The higher bioavailability of LMWH compared with that of unfractionated heparin leads to a more predictable dose response and, therefore, a reduced need for routine laboratory monitoring of haemostatic variables; this renders LMWH relatively easy to use in clinical practice. Dalteparin, enoxaparin, tinzaparin, nadroparin, reviparin and certoparin are approved for use.

Advantages of LMWH are subcutaneous twice daily administration, no monitoring and somewhat better efficacy. Usually, enoxaparin or dalteparin are used for 5 to 7 days. Classic indications are conservative management of acute coronary syndrome, following thrombolysis and in a few selected cases after catheter-based interventions.

Thrombolytic Agents

Thrombolytic agents are used in patients with ST-elevation myocardial infarction (MI) (other indications being submassive pulmonary embolism, prosthetic valve thrombosis, selected cases of thrombotic stroke, proximal deep vein thrombosis, etc.). Time to reperfusion remains a key modifiable determinant of mortality in ST-elevation MI. Despite many years of medical advances, the time from symptom onset until the start of pharmacological reperfusion treatment remains largely unchanged, with a median of approximately 2.5 to 3 hours.

Thrombolytic drugs dissolve blood clots by activating plasminogen, which forms a cleaved product called plasmin. Plasmin is a proteolytic enzyme that is capable of breaking cross-links between fibrin molecules, that provide the structural

integrity of blood clots. Due to these actions, thrombolytic drugs are also called 'plasminogen activators' and 'fibrinolytic drugs'.

Streptokinase (1.5 M units over one hour) and urokinase are inexpensive and used as infusion. Alteplase is used as bolus followed by short infusion (100 mg dose). Reteplase (5 units double bolus) and tenecteplase (50 to 60 mg rapid bolus) can be given as bolus and hence are of great use in pre-hospital thrombolysis. Their efficacy is similar to or better than alteplase. Thrombolysis is always followed by 5 to 7 days of anti-thrombotic therapy to prevent rebound thrombosis.

MANAGEMENT OF SYSTEMIC ARTERIAL HYPERTENSION

See the chapter on Essential Hypertension

MANAGEMENT OF HEART FAILURE

Over the last 20 years, enormous progress has been made in the pharmacotherapy of chronic heart failure. Large, randomised, control trials of inhibition of the renin-angiotensin-aldosterone system and sympathetic nervous system have led to substantial improvements in both morbidity and mortality.

The primary goal of drug therapy in heart failure (HF) is to improve cardiac function and to reduce the clinical symptoms associated with HF (e.g. oedema, shortness of breath, exercise intolerance). Improving cardiac function along with reducing blood volume can dramatically improve the clinical symptoms. The treatment of HF caused by systolic dysfunction follows clear clinical guidelines based upon numerous clinical trials. Diastolic dysfunction, however, is more difficult to treat and there is no clear consensus regarding the best therapeutic options other than targeting clinical symptoms related to fluid retention. In addition, drugs that can adversely affect patients with HF due to systolic dysfunction should be avoided or withdrawn. These include non-steroidal anti-inflammatory drugs, most anti-arrhythmic drugs, and the non-dihydropyridine calcium channel blockers (i.e. diltiazem and verapamil). Drug therapy for systolic HF is grouped in four categories as shown **Table 8**.

Diuretics, especially loop diuretics, are the most efficacious in relieving clinical symptoms of shortness of breath and signs of peripheral oedema. The diuretic-induced reductions in ventricular filling pressures and ventricular cavity size, decreases in mitral regurgitation and resulting increases in forward cardiac output, all may be favourable in HF. Digoxin reduces hospitalisations for HF in patients with sinus rhythm. It maintains a role in those with advanced chronic HF and atrial fibrillation, where rate control may improve symptoms.

Angiotensin-converting enzyme (ACE)-inhibitors are an important component of standard HF therapy (Class I) in patients with current or prior symptoms of HF and depressed left ventricular systolic function. The mechanism of action consists of improvement in left ventricular geometry, ejection fraction and filling pressures. Randomised trials have shown that ACE-inhibitor therapy leads to symptomatic improvement, reduced hospitalisation and enhanced survival in patients with HF and systolic dysfunction. Angiotensin receptor blockers provide a unique pharmacological mechanism for inhibiting the RAS and these are mostly used in ACE-I intolerant patients.

Although seemingly paradoxical, beta-receptor blocking drugs have been able to reduce HF mortality by about 35% in various randomised trials. The strategy for administering all β-blocking agents in the setting of chronic heart failure is to start at extremely low doses and increase the dose gradually. The pharmacological half-lives of metoprolol tartrate, carvedilol, and bucindolol dictate twice-daily dosing, whereas bisoprolol and metoprolol succinate CR can be given once daily.

Aldosterone antagonists like spironolactone and eplerenone have been used in HF with impressive mortality benefits.

MANAGEMENT OF CARDIAC ARRHYTHMIAS

There are four main classes in the Vaughan-Williams classification of anti-arrhythmic agents as described here:

Table 8: Drugs for the Prevention and Treatment for Chronic Heart Failure

Drug	Initial Daily Dose(s)	Maximum Total Daily Dosage
Angiotensin-converting enzyme inhibitor		
Captopril	6.25 mg three times	50 mg three times
Enalapril	2.5 mg two times	10 mg two times
Lisinopril	2.5-5.0 mg once	20-35 mg once
Ramipril	1.25-2.5 mg two times	2.5-5 mg two times
Perindopril	2 mg once	8-16 mg once
Fosinopril	5-10 mg once	40 mg once
Angiotensin-receptor blocker		
Trandolapril	0.5 mg once	4 mg once
Valsartan	40 mg two times	160 mg two times
Candesartan	4 mg once	32 mg once
Losartan	12.5 mg once	50 mg once
Beta-receptor blocker		
Carvedilol	3.125 mg two times	25 mg two times (50 mg two times if more than 85 kg)
Bisoprolol	1.25 mg two times	10 mg once
Metoprolol succinate CR/XL	12.5-25 mg once	200 mg once
Spironolactone	12.5-25 mg once	25-50 mg once
Eplerenone	25 mg once	50 mg once
Combination of hydralazine-isosorbide dinitrate	10-25 mg/10 mg three times	75 mg/40 mg three times
Fixed dose of hydralazine-isosorbide dinitrate	37.5 mg/20 mg (one tablet) 3 times	75 mg/40 mg (two tablets) 3 times
Digoxin	0.125 mg once	0.375 mg once

Class I Agents

The class I anti-arrhythmic agents interfere with the sodium (Na^+) channel. These are grouped by what effect they have on the Na^+ channel and what effect they have on cardiac action potentials.

These agents are also called membrane stabilising agents. The 'stabilising' is the word used to describe the decrease of excitogenicity of the plasma membrane which is brought about by these agents (Also noteworthy is that a few class II agents like propranolol also have a membrane stabilising effect).

Class I agents are divided into three groups (1a, 1b and 1c) based upon their effect on the length of the action potential.

1. 1a lengthens the action potential (right shift), e.g. quinidine, procainamide, disopyramide.
2. 1b shortens the action potential (left shift), e.g. lignocaine, bretylium, mexiletine.
3. 1c does not significantly affect the action potential (no shift), e.g. flecainide, encainide, ajmaline, propafenone.

Class II Agents

Class II agents are conventional beta-blockers. They act by blocking the effects of catecholamines at the β_1-adrenergic receptors, thereby decreasing sympathetic activity on the heart. These agents are particularly useful in the treatment of supraventricular tachycardias. They decrease conduction through the AV node. Class II agents include atenolol, esmolol, propranolol and metoprolol.

Class III Agents

Class III agents predominantly block the potassium (K^+) channels, thereby prolonging repolarisation. Since these agents do not affect the Na^+ channel, conduction velocity is not decreased. The prolongation of the action potential duration and refractory period, combined with the maintenance of normal conduction velocity, prevent re-entrant arrhythmias. Typical examples are amiodarone, sotalol, dofetilide and dronedarone.

Class IV Agents

Class IV agents are slow calcium channel blockers. These decrease conduction through the AV node and shorten phase two (the plateau) of the cardiac action potential. Thus, these reduce the contractility of the heart, so may be inappropriate in HF. However, in contrast to beta-blockers, these allow the body to retain adrenergic control of HR and contractility. Class IV agents include verapamil and diltiazem.

Others

These include the following:

1. Digoxin decreases conduction of electrical impulses through the AV node and increases vagal activity via its central action on the central nervous system.
2. Adenosine
3. Magnesium sulphate has been used for *torsades de pointes*.

MANAGEMENT OF PULMONARY HYPERTENSION

The drugs used for the management of pulmonary hypertension are:

1. Calcium channel blockers (only in patients with demonstrable vaso-reactivity)
2. PDE-5 inhibitors (sildenafil, tadalafil)
3. Endothelin receptor antagonists (bosentan, ambrisentan, sitaxentan)
4. Prostaglandins (iloprost, epoprostenol, treprostinil)
5. Oral anticoagulants

MANAGEMENT OF CARDIOGENIC SHOCK

Circulatory shock is a life-threatening emergency that results in death in approximately half of all patients.

Intravenous vasopressors provide inotropic support increasing perfusion of the ischaemic myocardium and all body tissues. However, extreme heart rates should be avoided because they may increase myocardial oxygen consumption, increase infarct size, and further impair the pumping ability of the heart. No particular vasopressor has been shown to be superior to another except recent data which suggest some superiority of norepinephrine over dopamine. Carefully chosen combinations of vasopressors may be useful.

Dopamine may provide vasopressor support. With higher doses, it has the disadvantage of increasing the HR and myocardial oxygen consumption. Intravenous (IV) continuous infusion of 5 to 20 mcg/kg per minute; increase by 1 to 4 mcg/kg per minute q 10 to 30 minutes to optimal response (>50% of patients have satisfactory responses with doses <20 mcg/kg per minute).

Dobutamine, inamrinone (formerly amrinone), or milrinone may provide inotropic support. In addition to their positive inotropic effects, inamrinone and milrinone have a beneficial vasodilator effect, which reduces pre-load and after-load. Some of these drugs are described below:

Milrinone: Loading dose, 50 mcg/kg IV over 10 min; continuous infusion: 0.375 to 0.75 mcg/kg per minute IV.

Norepinephrine: Norepinephrine infusion must be considered in refractory cardiogenic shock, though it significantly increases after-load but is less arrhythmogenic (Dosage: 0.5 to 1 mcg/min IV infusion initially, titrated to effect; not to exceed 30 mcg/minute).

Levosimendan: Levosimendan, though not approved for use in the USA, can be considered in conjunction with vasopressors. It should be used with caution as it can cause hypotension. When used with vasopressors, levosimendan may improve haemodynamics and improve coronary blood flow. However, there are no trials with this drug in patients with cardiogenic shock.

In summary, these are exciting times for cardiovascular pharmacotherapy. Novel molecules are being developed. Older drugs are undergoing reappraisal. Polypharmacy-based one type of system is being challenged. Combination therapy and fixed-drug combinations are gaining ground. Targets for drugs are being redefined. It would not be long before many of today's dogma shall become obsolete.

12.10 Heart Failure

Donald Kikta, Veronica Franco

INTRODUCTION

Heart failure (HF) is defined as the inability of the heart to pump blood forward at a rate sufficient to meet the metabolic demands of the body, or the ability to do so only if the cardiac filling pressures are abnormally high. It most commonly results from myocardial or extra-myocardial abnormalities which interfere with normal left ventricular function. It may result from a sudden overwhelming cardiac load, as with an acute hypertensive crisis, or a chronic cardiac stressor such as systemic hypertension. Chronic HF that results predominantly from an abnormality of ventricular emptying, due to impaired contractility or excessive afterload, is often termed systolic HF. Heart failure that results from an abnormality of ventricular filling was previously referred to as diastolic HF. Heart failure with preserved ejection fraction is now the preferred term, as the physiologic abnormalities in this condition are not solely restricted to either diastole or systole. HF may be the final and most severe manifestation of nearly every form of cardiac disease including coronary atherosclerosis, valvular disease, hypertension, congenital heart disease and the cardiomyopathies. The mortality rate in patients with HF has remained unacceptably high despite improvements in therapy, making early detection of susceptible persons, who would benefit from preventive measures imperative.

PATHOPHYSIOLOGY

The heart normally accepts blood at low filling pressures during diastole and then propels it forward at higher pressures in systole. In a healthy individual, the cardiac output is matched to the body's total metabolic need through adjustments in heart rate and ventricular stroke volume. Stroke volume is a function of ventricular preload, afterload and contractility. Within a physiologic range, ventricular output increases in relation to the preload or stretch on the myocardial fibres before contraction. The ventricular wall stress that develops during systolic ejection, or afterload, reflects the resistance the ventricle must overcome to empty its contents. This pressure determines the end-systolic volume of the left ventricle independent of the preload. Myocardial contractility accounts for changes in the force of contraction independent of the preload and afterload, and can be augmented by increasing the cycling rate of actin-myosin cross-bridge formation in the cardiac myocyte. Heart failure aetiologies can be grouped into those with impaired contractility, increased afterload or impaired ventricular filling.

Systolic HF results from diminished capacity of the affected ventricle to eject blood because of impaired myocardial contractility or excessive afterload. Loss of contractility may result from destruction of myocytes, abnormal myocyte function or fibrosis. Conditions associated with impaired contractility include dilated cardiomyopathy, chronic volume overload due to valvular insufficiency and myocardial ischaemia or infarction. Pressure overload impairs ventricular ejection by significantly increasing resistance to flow. These conditions result in a reduced stroke volume as systolic emptying ceases at a higher end-systolic volume than normal. When normal pulmonary venous return is added to the increased end-systolic volume that has remained in the ventricle because of incomplete emptying, the diastolic chamber volume increases resulting in a higher than normal end-diastolic volume and pressure. Conditions resulting in excessive afterload include uncontrolled systemic hypertension and aortic stenosis. Although an increase in preload induces a compensatory rise in stroke volume via Frank-Starling mechanism, impaired contractility or increased afterload cause the end-diastolic volume to remain elevated. During diastole, the persistently elevated left ventricular pressure is transmitted to the left atrium through the open mitral valve and to the pulmonary veins and capillaries. An elevated pulmonary capillary hydrostatic pressure results in transudation of fluid into the pulmonary interstitium and symptoms of pulmonary congestion.

Heart failure with preserved ejection fraction results from impaired ventricular filling resultant from mechanical obstruction or impaired diastolic relaxation. Left ventricular hypertrophy, hypertrophic cardiomyopathy, restrictive cardiomyopathy and myocardial ischaemia result in reduced chamber compliance and diastolic dysfunction. Mitral stenosis and pericardial constriction obstruct normal ventricular filling necessitating elevated diastolic pressures. Filling of the ventricle occurs at higher than normal pressures and is transmitted retrograde to the pulmonary and systemic veins.

Isolated right ventricular failure is less common and usually reflects increased right ventricular afterload due to disease of the lung parenchyma or pulmonary vasculature. When the right ventricle fails, the elevated diastolic pressure is transmitted retrograde to the right atrium with subsequent congestion of the systemic veins. The most common cause is actually left-sided HF, where elevated pulmonary vascular pressures resultant from left ventricular dysfunction lead to excessive right ventricular afterload.

NEUROHORMONAL MODEL FOR HEART FAILURE

Clinicians have used a variety of increasingly complex model systems to describe the syndrome of HF. It was initially viewed as a problem of excessive salt and water retention caused by renal blood flow abnormalities. Later, haemodynamic studies revealed that HF is associated with a reduced cardiac output and excessive peripheral vasoconstriction. Although the cardiorenal and cardiocirculatory models for HF explain the excessive salt and water retention that patients experience and provide a rational basis for the therapeutic use of diuretics, inotropes and vasodilators, neither of these models explain the relentless disease progression that occurs in this syndrome. It is increasingly apparent that HF can no longer be described in

simple haemodynamic terms. Some experts suggest that HF should be viewed as a neurohormonal model, in which it progresses as a result of the overexpression of biologically active molecules that are capable of exerting deleterious effects on the heart and circulation.

Heart failure is a progressive disorder that is initiated after an index event either damages the heart muscle, with a resultant loss of functioning cardiac myocytes, or alternatively disrupts the ability of the myocardium to generate a force, thereby preventing the heart from contracting normally. The index event may have an abrupt onset, as in the case of a myocardial infarction; it may have a gradual or insidious onset, as in the case of haemodynamic pressure or volume overloading; or it may be hereditary, as in the case of the genetic cardiomyopathies. In most instances, patients will remain asymptomatic or minimally symptomatic for a prolonged period. This is likely due to a number of compensatory mechanisms which become activated in the setting of cardiac injury and appear to modulate left ventricular (LV) function within a physiological range such that the functional capacity of the patient is preserved or only minimally depressed.

The principal neurohormonal systems involved in the response to HF are the sympathetic nervous system, the renin-angiotensin-aldosterone system, anti-diuretic hormone, endothelin, natriuretic peptides and nitric oxide. Neurohormonal activation is acutely beneficial in patients with HF since the elevations of cardiac contractility, vascular resistance and renal sodium retention tend to restore the cardiac output and tissue perfusion towards normal. The deleterious effects, however, predominate over the long-term leading to pulmonary and peripheral oedema, increased afterload, pathologic myocardial remodelling and more rapid progression of myocardial dysfunction. The major pathophysiologic process in the progression of HF appears to be cardiac remodelling, often referred to as progressive chamber enlargement over time and obligatory reduction in ejection fraction. The ability of ACE inhibitors and beta-blockers to improve survival and slow progression of this disease in clinical trials is compatible with this hypothesis. Clinical studies have additionally shown that other medical and device therapies have favourable effects on cardiac remodelling, resulting in stabilisation or reversal of LV chamber mass and dilation. Although the precise cellular and molecular mechanisms that are responsible for this "reverse remodelling" are not fully known, recent studies have demonstrated that improvement in ventricular function is associated with favourable changes in myocardial gene expression.

EPIDEMIOLOGY

The magnitude of HF is difficult to assess with precision since reliable, population-based estimates of its prevalence, incidence and prognosis are lacking. Large differences exist among studies in their definition of the condition and the methods used to establish its presence. HF affects nearly twenty-three million people worldwide. There is an increase in prevalence due to ageing of the population and improved survival of patients due to modern therapeutic interventions. The worldwide prevalence and incidence rates of HF are approaching epidemic proportions, as evidenced by the relentless increase in the number of hospitalisations, the growing number of HF-attributable deaths and the spiralling costs associated with the care of HF patients.

The prevalence of HF increases exponentially with age. Data suggest the lifetime risk in the United States of developing HF is 20%. Investigations using echocardiography estimate that only 50% of patients with LV dysfunction are symptomatic. Half of the patients who develop HF have a normal or preserved LV ejection fraction. The Framingham Heart Study estimated the prevalence of symptomatic HF in the United States as 0.8% and 6.6% in the sixth and ninth decades of life.

The population-attributable risk for HF was prospectively estimated to be 62%, 17%, 10%, 8%, 3%, and 2% for coronary artery disease, cigarette smoking, hypertension, obesity, diabetes mellitus and valvular heart disease respectively, in the US. Ischaemic cardiomyopathy is the most common cause of systolic HF in the western world, whereas hypertension and valvular heart disease have become less common due to improvements in detection and therapy. The exact cause cannot be determined in 20% to 30% of cases and is, therefore, classified as idiopathic. Ageing, female gender, hypertension, diabetes mellitus, LV hypertrophy, coronary artery disease and infiltrative cardiomyopathies are associated with diastolic dysfunction.

The prevalence or risk of developing HF in emerging nations is less defined due to a lack of population-based studies. Hypertension has the greatest impact on the development of this syndrome and is estimated to account for 39% of events in men and 59% in women. A recent study at an urban African hospital demonstrated that 88% of *de novo* presentations for HF were attributed to uncontrolled hypertension, idiopathic dilated cardiomyopathy or right-sided heart failure. Valvular heart disease only accounts for 7% to 8% of cases. Pathologies associated with a high cardiac output, such as anaemia, are seldom responsible for the development of HF in a normal heart. However, in the presence of underlying structural heart disease, the additional work required in high output conditions may contribute to overt congestive failure. Rheumatic heart disease remains a major cause of HF in Africa and Asia. Chagas disease is still an important aetiology in South America. As developing nations undergo socio-economic development, the epidemiology of HF is becoming similar to that of Western Europe and North America.

CLINICAL MANIFESTATIONS

Heart failure is a bedside diagnosis that is defined by clinical assessment. The clinical manifestations result from impaired forward cardiac output and/or elevated venous pressures and relate to which of the ventricles has failed. The cardinal symptoms of chronic LV failure are dyspnoea, exercise intolerance and fatigue. Elevated pulmonary venous pressures cause transudation of fluid into the lung parenchyma, increasing work of breathing due to reduced pulmonary compliance, increased airway resistance and stimulation of juxtacapillary receptors. Accumulation of lactic acid due to low cardiac output may contribute to this sensation.

As HF advances, dyspnoea occurs with progressively less strenuous activity and ultimately is present even at rest. The New York Heart Association (NYHA) functional classification, although somewhat vague, remains the most commonly used standard to describe severity of signs and symptoms. Additional common symptoms related to left ventricular congestion include orthopnoea, nocturnal cough and paroxysmal

nocturnal dyspnoea. Orthopnoea is the sensation of laboured breathing while lying flat and is relieved by sitting upright. Orthopnoea and nocturnal cough result from redistribution of fluid from the splanchnic circulation and lower extremities into the central circulation during recumbency, with a resultant increase in pulmonary capillary pressures. Paroxysmal nocturnal dyspnoea is severe, sudden nocturnal breathlessness which occurs hours after going to bed. It results from gradual reabsorption of lower extremity interstitial oedema into the circulation with subsequent intravascular volume expansion and increased venous return to the heart and lungs. Common symptoms related to chronic right ventricular congestion include abdominal discomfort, anorexia, nausea, peripheral oedema and weight gain. Elevated systemic venous pressures result in abdominal discomfort due to hepatic engorgement and capsular distention. Anorexia and nausea may result from oedema within the gastrointestinal tract. Weight gain and peripheral oedema result from the accumulation of interstitial oedema within the dependent portions of the body. Common symptoms related to low cardiac output include fatigue, weakness, dulled mental status and nocturia. These result from impaired skeletal muscle, cerebral and renal perfusion.

The physical signs of HF depend on the severity and chronicity of the condition and again can be divided into those due to left or right cardiac dysfunction. Common signs of left-sided HF include pulmonary rales, wheezing, increased intensity of S2, S3 or S4 gallop and a mitral regurgitation murmur. Pulmonary rales result from the popping open of small airways which had been closed off by oedema fluid before inspiration, while 'cardiac asthma' results from compression of larger airways. An early diastolic sound, or S3, signifies increased left ventricular end-diastolic pressure in patients with decreased left ventricular function. A late diastolic sound, or S4, may result from forceful atrial contraction into a stiffened LV. Left ventricular dilation can result in incomplete closure of the mitral valve during systole and functional mitral regurgitation. Common signs of right-sided HF include distention of the jugular veins, hepatic enlargement, dependent oedema, right ventricular heave or gallop and tricuspid regurgitation murmur. Signs of impaired peripheral perfusion, cardiac cachexia, diaphoresis, tachycardia, tachypnoea and narrow pulse pressures are often signs of advanced disease.

PROGNOSIS

Morbidity and mortality after the onset of symptomatic HF are extremely high despite improvements in therapy. This is a progressive condition, beginning with predisposing factors and leading to the development and worsening of clinical illness. The latest American College of Cardiology and American Heart Association (ACC/AHA) guidelines have classified HF using a new staging system that emphasizes the evolution and progression across a continuum. Stage A patients are at high-risk for developing heart failure without structural heart disease. Stage B patients have structural heart disease but have not yet developed symptoms of HF (post-myocardial infarction, hypertension, valvular disease or asymptomatic LV dysfunction). Stage C patients had past or current symptoms of HF associated with underlying structural heart disease. Stage D patients have end-stage disease requiring specialised advanced therapy. It is important to note that a patient classified as Stage B has a better prognosis than one with Stage C NYHA class I symptoms.

A major challenge in the management of HF is the accurate identification of those patients who have a poor prognosis and would, therefore, be most likely to benefit from intensive medical therapy. Although multiple variables have been identified as predictors of survival within a large population, their ability to predict survival in individual patients is limited. Many factors affect patient outcomes including co-morbid medical conditions, psycho-social factors and intensity of medical care. The most frequently predictors of adverse outcome directly or indirectly reflect the severity of cardiac dysfunction. Prospective studies have demonstrated a one-year mortality of 5% for patients in NYHA functional class I, 15% in classes II-III and 64% in class IV. Exercise variables such as maximal oxygen consumption and six-minute walk testing provide the most objective assessment of functional capacity in patients with heart failure and are an important component in the evaluation of patients for advanced heart failure therapies.

Need for hospitalization is an important marker for poor prognosis. In-hospital, 30-day and one-year mortality after index hospitalisation are estimated to be 6%, 11% and 30% in the US. Additional univariate predictors of survival in systolic HF include signs of congestion or reduced tissue perfusion on physical examination; severe LV systolic dysfunction; concomitant diastolic dysfunction or right ventricular dysfunction with associated pulmonary hypertension; attenuated response to diuretics or lack of haemodynamic improvement with therapy; echocardiographic evidence of left ventricular remodelling; ventricular dyssynchrony resulting from conduction system defect; severe ventricular ectopy after exercise; evidence of neurohormonal activation including hyponatraemia, elevated brain natriuretic peptide (BNP), reduced heart rate variability and sinus tachycardia; ischaemic cardiomyopathy; concomitant paroxysmal atrial fibrillation, sleep-disordered breathing, renal insufficiency or anaemia; elevated serum troponin or markers of inflammation; low serum cholesterol or weight loss.

The prognosis in HF patients with preserved ejection fraction is less well-defined. Although once thought to be better than those with systolic dysfunction, recent evidence suggests similar mortality rates. The two main causes of death in patients with HF are sudden death due to arrhythmias and progressive pump failure. It has been postulated that progressive pump failure, sudden death due to arrhythmia and sudden death during episodes of clinical worsening each account for one-third of cardiovascular mortality in this population.

12.11 Heart Failure Management

Veronica Franco, Ragavendra Baliga

Therapy for heart failure (HF) is divided into 2 distinct clinical scenarios and approaches: acute decompensated HF and, chronic stable HF (**Table 1**). The goals of therapy are different: in decompensated HF it is to stabilise the patient, improve organ perfusion and filling pressures; in chronic stable HF, the aim is to extend survival, good quality of life and delay disease progression. Approach therapy for patients with chronic HF is based on their stage classification. Diuretics, vasodilators and positive inotropic agents are used to improve symptoms. Neurohormonal inhibitors are used to reduce mortality and delay disease progression.

Table 1: Treatment of Heart Failure

Decompensated Heart Failure	Chronic Stable Heart Failure
Diuretics	**Diuretics**
Loop diuretics (IV)	Loop diuretics (po)
Thiazides (IV)	Thiazides (po)
Vasodilators	antagonists
Nitrovasodilators (IV)	**Vasodilators**
Direct acting nitrates (po)	Nitrovasodilators (po)
Calcium channel blockers (IV; in the setting of angina or hypertension)	Direct acting nitrates (po)
Natriuretic peptides (nesiritide)	**Positive inotropic agents**
Positive inotropic agents	Digitalis
Beta-adrenergic receptor agonists	**Neurohormonal inhibitors**
Phosphodiesterase inhibitors	Angiotensin converting enzyme inhibitors
Phosphodiesterase inhibitors with calcium sensitizer action	Angiotensin receptor blockers
	Beta-adrenergic blockers

NON-PHARMACOLOGICAL THERAPIES

These therapies apply to patients with decompensated and chronic HF, at all stages.

Diet

1. Dietary instruction regarding sodium intake is one of the cornerstones of HF treatment. It plays a very important role in the prevention of acute recurrent events.
2. Sodium restriction (2 to 3 g daily) is recommended for all patients, regardless of their left ventricular ejection fraction (LVEF). Further restriction (<2 g daily) is recommended for those with moderate to severe HF.
3. Fluid intake less than 2 litre daily is recommended for patients with serum sodium less than 130 mEq/L and patients with volume retention.
4. Prealbumin and caloric evaluation is recommended for patients with cardiac cachexia and unintentional weight loss.

Other Therapies

1. Continuous positive airway pressure if there is a diagnosis of sleep apnoea has been shown to improve symptoms of dyspnoea.
2. Oxygen supplementation is seldom needed in HF patients. If oxygen saturation is low, evaluation for pulmonary disease or residual pulmonary oedema is recommended.
3. Treatment of depression with appropriate therapy is very important. Selective serotonin re-uptake inhibitors (SSRIs) are preferred.

Routine Healthcare

1. Limit daily consumption of alcohol to less than 2 drinks in men and less than 1 drink in women. In patients with alcoholic cardiomyopathy, total abstinence is recommended.
2. Pneumococcal and influenza vaccinations are indicated.
3. Endocarditis prophylaxis is not recommended based on the diagnosis of HF alone.
4. Nonsteroidal anti-inflammatory drugs are not recommended due to associated fluid, salt retention and acute renal failure.
5. Exercise training, with the goal of 30 minutes of moderate exercise activity at least five times per week.

PHARMACOLOGICAL THERAPIES

Two classes of agents have become the cornerstone of therapy to delay or halt progression of cardiac dysfunction and improve mortality: angiotensin converting enzyme (ACE) inhibitors and beta-blockers.

ACE-Inhibitors

They block the renin-angiotensin-aldosterone system (RAAS) and should be used in all patients with HF and LVEF less than 40%. They block the conversion of angiotensin I into angiotenin II, as well as degradation of bradykinin. Kinins are responsible for the cough and angioedema present in 5% of patients. There has been evidence of 'angiotensin II escape', however this has not been translated into clinical trials and ACE inhibitor remain the prefer red medication, over angiotensin receptor blockers (ARBs).

Foetal angiotensin I receptors are growth stimulators, therefore should not be used in pregnant patients. They have an anti-adrenergic effect secondary to decrease in norepinephrine production. Finally, angiotensin II produces efferent arteriolar vasoconstriction to improve glomerular filtration rate (GFR) and after decrease in production of angiotensin II, renal function could worsen.

ACE inhibitors have been shown in double-blind, placebo-controlled trials to produce clinical benefit, increase LVEF and improve survival. Should be started at the lowest dose and titrated as tolerated to doses used in clinical trials (**Table 2**), during concomitant uptitration of beta-blockers. Patients should not receive an ACE inhibitor if they have experienced life-threatening side effects (angioedema or anuric renal failure).

They should be used with extreme caution if the patient is hypotensive, have bilateral renal artery stenosis, potassium greater than 5.5 meq/L, or creatinine greater than 3 mg/dL. Renal function and potassium should be checked within 1 to 2 weeks.

Table 2: Medication Dosage in Chronic HF

Medication	Usual Dosage	Target Doses in HF
Loop diuretics		
Frusemide	10 to 360 mg/day	
Bumetanide	0.5 to 20 mg/day	
Torsemide	2.5 to 200 mg/day	
Thiazide diuretics		
Chlorothiazide	50 to 100 mg/day	
Hydrochlorothiazide	25 to 50 mg/day	
Chlorthalidone	25 to 100 mg/day	
Metolazone	5 to 10 mg/day	
K^+ sparing diuretics		
Eplerenone	25 to 50 mg/day	50 mg/day
Spironolactone	12.5 to 25 mg/day	25 mg/day
ACE-inhibitors		
Captopril		50 mg tid
Enalapril		10 mg bid
Lisinopril		20 mg qd
Ramipril		10 mg qd
Trandolapril		4 mg qd
Fosinopril		80 mg qd
Quinapril		80 mg qd
Angiotensin receptor blockers		
Candasartan		32 mg qd
Losartan		150 mg qd
Valsartan		160 mg bid
Beta-blockers		
Bisoprolol		10 mg qd
Carvedilol		25 mg bid
Metoprolol succinate (XL)		200 mg qd
Other vasodilators		
Fixed dose of Hydralazine/nitrates		75 mg hydralazine + 40 mg isosorbide dinitrate, tid
Hydralazine		75 mg qid
Isosorbide dinitrate		40 mg qid

Alternative for ACE-inhibitors

Angiotensin receptor blockers (ARBs) are recommended for those patients intolerant to ACE inhibitors. Both drugs have similar effect on renal function, potassium and blood pressure. Angioedema has been reported very infrequently with ARBs and patients that experience that side effect with ACE inhibitors, should have a trial with ARBs. If a patient is intolerant to ACE inhibitors and ARB, then the combination of hydralazine/nitrates could be used. There is no evidence to support the routine use of ARBs in combination with ACE inhibitors.

Beta-Blockers

Beta-blockers interfere with the actions of the sympathetic nervous system and have been shown to be effective in clinical trials in reducing morbidity and mortality. Only metoprolol succinate, bisoprolol and carvedilol are approved in HF therapy. They are recommended for all HF patients with reduced LVEF, with or without previous myocardial infarction. It can also be used in patients with recent decompensation of HF, after optimization of volume status and successful discontinuation of IV diuretics/inotropes. If possible, beta-blockers should be initiated in the hospital setting to evaluate tolerability. These are indicated even in patients with diabetes mellitus, peripheral vascular disease and/or asthma and chronic obstructive lung disease. It should be used with caution if recurrent hypoglycaemic episodes or resting limb ischaemia is present. These are contraindicated in active bronchospasm. Beta-blockers should be initiated at low doses and titrated up to optimal doses every 2 weeks (**Table 2**). Beta-blockers should be continued in patients experiencing a symptomatic exacerbation, unless they develop cardiogenic shock or refractory volume overload.

Diuretics

These drugs improve congestion, dyspnoea and retard adverse remodelling in the ventricle due to reduced wall stress. Diuretics do not improve survival, except for aldosterone antagonists, and should not be used as monotherapy.

Diuretics are prescribed for patients with previous or current fluid retention. Intravenous formulations should be used if significant volume overload. In patients with difficult to treat HF, combination of diuretics acting by different mechanisms often works synergistically. Non-steroidal anti-inflammatory drugs can inhibit the natriuretic effect of many diuretics and produce renal failure.

Loop diuretics

This class of diuretics includes: furosemide, bumetanide, torsenide, ethacrynic acid and piretanide. The most commonly used is furosemide. Its half-life is 1.5 hours and total duration of action 4 to 6 hours. The effect can be as fast as 10 minutes if given intravenously. Acutely (within minutes), they not only produce venodilation and decrease wedge pressure, but also cause neurohormonal activation. Side-effects include hypochloraemic metabolic alkalosis, hypokalaemia, hyponatraemia, hypocalcaemia, increased uric acid and higher risk of gout.

Loop diuretics are the preferred therapy in HF, because of better fluid clearance (20% to 25% increase in sodium excretion compared to 5% to 10% seen with thiazides) and effectiveness despite renal insufficiency. The optimal doses are detailed in **Table 2**. Importantly, loop diuretics can induce a sulfa-like toxicity in those patients with a sulfa allergy (skin photosensitivity, blood dyscrasias, hepatitis, pancreatitis, interstitial nephritis and pneumonitis).

Thiazide diuretics

This class of diuretics includes chlorthalidone, hydrochlorothiazide and metolazone. The total duration of action is 16 to 24 hours. Side effects include hypokalaemia, hyponatraemia, mild metabolic alkalosis, hypercalcaemia and increase in uric acid and higher risk of gout. Metolazone is the only thiazide effective in patients with renal failure.

Thiazide diuretics are the preferred therapy in hypertension, because these are effective for almost 24 hours. High doses of thiazide diuretics (50 to 200 mg daily) will be more helpful in the treatment of HF and volume overload, however they produce more metabolic adverse effects like hyperglycaemia, high triglycerides and low-density lipoproteins (LDL).

These effects are rarely seen with low-dose (12.5 mg or 25 mg daily).

K^+ sparing diuretics

This includes triamterene, amiloride and mineralocorticoid receptor antagonists (spironolactone and eplerenone). The main side effects is hyperkalaemia. These are weak diuretics because in HF, the sodium retention occurs before the collecting ducts and they not effective in achieving a negative sodium balance if used alone. Spironolactone produces gynaecomastia, impotence and menstrual irregularities in up to 10% of patients. These effects have not been observed with eplerenone because these are more selective. These diuretics are contraindicated if creatinine greater than 2.5 mg/dL, GFR less than 30 mL/min or potassium greater than 5.0 mEq/L.

Vasodilators

Systemic vascular resistance (SVR) is increased in HF as a result of neurohormonal activation. Vasodilators increase cardiac output and blood flow to organs (**Table 3**). Vasodilators are more important in the treatment of acute decompensated HF and only hydralazine/nitrates combinations have been approved for chronic HF therapy. Importantly, pure vasodilators (without a neurohormonal effect) have not demonstrated a reduction in mortality and, in fact, powerful vasodilators, like the prostacyclin epoprostenol, increase mortality in HF.

Nitrovasodilators

Nitroglycerin: These are powerful venodilators, mainly in epicardial coronary flow (used in acute coronary syndromes). No effect on mortality. In acute decompensated HF, they lower filling pressures and increase cardiac output. The main limitation is the development of tolerance after 24 hours. Hydralazine can attenuate nitrate tolerance.

Nitroprusside: It has a very quick onset of action and, therefore, preferred in decompensated HF. Complications include cyanide toxicity and coronary steal. It should be used only for a short period of time.

Table 3: Vasodilators

Medication	Site of Action: Vein	Site of Action: Arteriolar
Nitrates	+++	+
Hydralazine	+	+++
CCBs	+	+++
Minoxidil	++	+++
Prostacyclins	+++	++
Nesiritide	+++	+
ACE inhibitor, ARB	++	+

Nesiritide

It is a vasodilator and has a direct natriuretic effect on the kidneys. Nesiritide is less arrhythmogenic than dobutamine. Titration or boluses are no longer recommended because of potential hypotension and acute renal failure.

Positive Inotropic Agents

Digoxin

Weak positive inotrope used to improve symptoms in patients LVEF ≤ 40% and recurrent admissions for HF exacerbation, despite optimal therapy. Digoxin does not improve mortality or is beneficial if preserved LVEF. The usual dose is 0.125 mg daily with a goal level less than 1.0 ng/mL. The narrow safety profile and significant drug interactions are the main reasons why digoxin is utilized rarely. Side effects include cardiac arrhythmias, heart block, gastrointestinal symptoms, neurological complaints (visual disturbances, disorientation and confusion). Digoxin toxicity could be precipitated by hypokalaemia, hypomagnesaemia, renal failure or hypothyroidism.

Beta-adrenergic agonists

These have a positive inotropic and chronotropic effect (**Table 4**). They have a short half-life (minutes) and that is one of their advantages over phosphodiesterase (PDE) inhibitors. Dobutamine is preferred over dopamine for most patients with decompensated HF who have not responded well to intravenous diuretics. The limitations of dobutamine are: (1) It does not work as well if patient has desensitisation of beta-receptors as happens with end-stage HF; (2) It cannot be effectively used with high levels of beta-blockers; (3) It only modestly reduces elevated pulmonary arterial pressure and pulmonary vascular resistance (PVR). Epinephrine is a vasodilator and vasoconstrictor, utilised in cases of concomitant septic and cardiogenic shock. Norepinephrine is a powerful vasoconstrictor not recommended in HF.

Phosphodiesterase inhibitors (Milrinone)

They are good inotropes without the associated chronotropic effect. Their vasodilator properties are both a strength and weakness of this medication. These work particularly well in patients with secondary pulmonary hypertension due to HF. Problems by its use are: (1) hypotension; (2) prolonged half-life and (3) 80% of the medication is renally excreted and should be used with caution in patients of renal failure, (for detail therapy see chapter pharmacotheraphy of cardiovascular disorders).

Table 4: Adrenergic Agonists.

Medication	β1 affinity	β2 affinity	α affinity
Dobutamine	+++++	+++	+
Dopamine	+++++	+++	+++++
Epinephrine	++++	++++	++++++
Norepinephrine	++++	+++	++++
Isoproterenol	++++	++++	0
Phenylephrine	0	0	++++++

ACUTE DECOMPENSATED HEART FAILURE

In acute HF, the aim of therapy is to provide immediate symptomatic relief of pulmonary oedema and rescue patients from imminent cardiorespiratory collapse by optimising the haemodynamic status. The emphasis is on agents given intravenously (**Table 1**). The hallmark of therapy is intravenous loop diuretics. If the patient exhibits signs of normal cardiac output, nitrates or nesiritide could be used to assist with vasodilation. If there is low cardiac output and end-organ damage, inotropic agents could be used, however, there is no evidence that these give long-term benefit, and in fact, could cause more harm and increase mortality. Reduction of hospitalisations for acute HF is important to reduce morbidity and mortality.

CHRONIC HEART FAILURE: THERAPIES BY HEART FAILURE STAGE

The objectives of therapy are: (1) to prevent progressive damage to the myocardium (prevention); (2) to prevent or reverse further enlargement of the heart (reverse remodeling); (3) to improve the quality of life by relief of symptoms; and (4) to prolong life. While the era of device therapy for HF is currently expanding at a tremendous rate, the clinician should be aware of the importance of achieving specific pharmacologic goals in their HF patients. The pathophysiology of symptoms in chronic HF is not well understood, but in contrast to acute HF is not directly related to high left atrial pressure.

Stage A—Preventive Therapy

Recognition that many risk factors can be modified and that treating HF is difficult and costly has focused attention on preventive strategies for HF. Treatment of systemic hypertension, with or without hypertrophy, reduces the development of HF. Myocardial infarction confers an 8- to 10-fold increased risk for subsequent HF. Early identification and treatment of risk factors is the most significant step in limiting the public health impact of HF. See previous chapter for more details as well as **Tables 5 and 6**. Routine evaluation of B-type natriuretic peptide (BNP) for asymptomatic patient evaluation is not recommended. ACE-inhibitors are recommended for prevention of HF in patients at risk.

Table 5: Indications to Suspect Heart Failure (Perform History and Physical)

Conditions	Test findings
Hypertension	Arrythmias
Diabetes mellitus	Abnormal ECG (LBBB, LVH, Q waves)
Elevated BMI	Cardiomegaly in chest X-ray
Coronary artery disease	
Atherosclerotic disease (peripheral vascular disease or cerebrovascular disease)	
Valvular heart disease	
First degree relative with HF	
Cardiac toxins exposure	
Obstructive sleep apnoea	

Table 6: Indications to Assess Cardiac Structure by Echocardiogram

Coronary artery disease
Valvular heart disease
First degree relative with HF
Supraventricular tachycardia: Atrial fibrillation or flutter
Abnormal ECG (LVH, LBBB, Q waves)
Ventricular tachycardia or fibrillation
Cardiomegaly on chest X-ray

Stage B

These patients will have cardiac structural changes but have not developed HF symptoms yet. It is important to determine the aetiology of HF, with particular attention to reversible causes including coronary ischaemia. Coronary angiography should be considered when pre-test probability is high. Laboratory testing for unusual aetiologies of HF is recommended if no cause is identified. Endomyocardial biopsy is only recommended in cases of rapidly progressive clinical HF with severe heart block or arrhythmias. Also important is to identify any exacerbating factors for HF, co-morbidities that could influence therapy and barriers to adherence. Treatment recommendations include smoking cessation, optimal blood pressure control, avoiding deconditioning and alcohol abstinence if previous history of excessive alcohol intake is present. Pharmacological therapies for asymptomatic patients with LVEF less than 40% include: ACE-inhibitors and beta-blockers.

Stage C

This category includes patients with structural changes that have developed symptoms. All recommendations for Stage B HF patients apply to patients with symptoms. The New York Heart Association (NYHA) functional classification, determines the pharmacological and device therapy in HF patients. The degree of volume excess is a key consideration in the treatment of HF. ACE-inhibitors and beta-blockers are recommended for all patients, aldosterone antagonist and digoxin should be reserved for those with NYHA class III-IV.

The utilisation of implantable cardioverter defibrillatory (ICD) for primary prevention of sudden cardiac death in HF patients improves survival significantly. The recommendations for ICD are: (1) patients with LVEF ≤ 35% and NYHA class II-III symptoms (ischaemic and non-ischaemic cardiomyopathies); (2) patients undergoing cardiac resynchronisation therapy (CRT) implantation; (3) survivors of cardiac arrest from ventricular fibrillation or haemodynamically unstable ventricular tachycardia that is not due to a reversible aetiology like acute myocardial infarction. If there is severe refractory HF and the life expectancy is less than 1 year, an ICD is not recommended.

Biventricular pacing seeks to improve and synchronize ventricular contraction, which results in less mitral regurgitation and increase diastolic filling time. Cardiac resynchronization therapy is indicated in: (1) patient with LVEF ≤35%, QRS ≥120 ms plus NYHA class III symptoms despite optimal medical therapy; (2) selected ambulatory NYHA IV patients in sinus rhythm, with LV dysfunction and QRS ≥120 ms; (3) may be considered in patients with NYHA class I or II symptoms, LV dysfunction and QRS ≥150 ms; and 4) may be considered in patients with LV dysfunction in whom frequent chronic pacing is expected (i.e. complete heart block).

Stage D

While there has been a significant positive impact on HF outcomes with the advent of new pharmacologic approaches to treatment, the disease remains burdensome. End-stage HF patients have poor quality of life, frequent hospitalisations, and higher mortality, despite optimal medical management. They also produce major economic stress on the healthcare system. The possibility of salvage by medical therapy at this stage is remote.

The goals of therapy differ from those in stages A, B and C and will include palliation of symptoms and hospice, reducing rates of hospitalisations, and in subjects that are eligible, cardiac transplantation and/or left ventricular assist devices (LVADs). In patients with recurrent admissions, inotropic therapy should be considered as a bridge to transplantation/LVAD or as part of the hospice period. The indications for transplantation are listed on **Table 7**.

Table 7: Indications for Heart Transplantation or LVAD Evaluation

Absolute indications

- For haemodynamic compromise due to HF
  - Refractory cardiogenic shock
  - Inotrope dependent
- Peak VO_2 <10 mg/kg/min with achievement of ventilator threshold
- Severe symptoms of ischaemia and refractory angina, not amenable to revascularisation
- Recurrent symptomatic ventricular arrythmia

Relative indications

- Peak VO_2 11 to 14 mg/kg/min (or 55% predicted) and major limitation in performance of daily activities
- Recurrent instability of fluid balance/renal function not due to patient non-compliance with medical regimen

Not appropriate indications

- Low left ventricular ejection fraction
- Functional class III or IV heart failure
- Peak VO_2 >15 mg/kg/min (and >55% predicted) and no other indications

Heart failure has worse prognosis than many cancers and premature death from progressive acute decompensated HF or sudden cardiac death is common. Hospice services should be implemented after the patient has been evaluated at a specialised centre and determination that LVAD or transplantation is ill-advised. It is important to allow adequate time (weeks to months) for medications and other therapies to exert a beneficial effect before considering these advance therapies.

12.12 Acute Rheumatic Fever

R Krishna Kumar

INTRODUCTION

Acute rheumatic fever (RF) is an immune-mediated non-suppurative consequence of pharyngitis due to group-A beta-haemolytic *Streptococcus* (GABHS). The morbidity resulting from an episode can be considerable and rarely, an episode of RF may result in death. However, the major concern relating to RF is often not the episode itself but the long-term consequences of damage to heart valves, rheumatic heart disease (RHD) that often results from recurrence of RF. For this reason, RF and RHD are often clubbed together in discussions on epidemiology. RF-RHD continues to be a major public health problem in many parts of India. The impact of the disease through disability, premature deaths and economic losses is substantial at all levels. It is important for physicians to be thoroughly familiar with the diagnosis and management of RF as well as preventive strategies both for the individual as well as for the population.

In the past four to five decades, there have been modest advances in our understanding of the disease process. There have been minor changes in the diagnostic criteria and management practices for RF have also largely remained unchanged for the last 20 to 30 years. However, there have been important changes in the epidemiology both in India and the rest of the world. There appears to have been a sharp decline in RF and RHD in parts of India that have shown improving indices of human development. Physicians living in these parts of India need to be mindful of the prospect of over-diagnosis of RF. For most of India, however, the disease is still quite common and it is important to not miss the initial episode of RF because secondary penicillin prophylaxis still remains the most effective way of preventing RHD.

In this chapter, the existing information on aetiopathogenesis, diagnosis and management of RF will be summarised. There will be additional emphasis on the epidemiology of the disease and an effort will be made to focus on data from India over the last several years.

EPIDEMIOLOGY

There is an undeniable relationship between the incidence of RF and of living standards. A sharp decline in RF and RHD occurred in industrialised nations all over the world with improving living standards and with introduction of penicillin. Industrialised nations now have an average annual RF incidence of less than 0.5 per 100,000 and RHD prevalence of less than 0.05 per 1,000. Improved living standards translate into reduction in overcrowding, better access to healthcare and more widespread use of antibiotics, all of which allow prompt treatment of streptococcal infections and help abort epidemics. However, the small but significant resurgence of the RF in parts of the US during the mid-eighties suggested that additional factors also contribute to occurrence of RF, albeit in a small way. Selected populations in Australia, New Zealand and the Pacific islands also appear to have a very high occurrence of RF and RHD that is perhaps in part explained by a genetic predisposition.

A number of studies have attempted to document RF incidence and RHD prevalence in India. School surveys are traditionally considered useful for this purpose because the denominator is clear. However, school surveys will miss older patients with RHD. In areas where RF and RHD are on the decline most patients with RHD tend to be older. Population-based registries have the potential to capture all age groups but are heavily dependent on referral mechanisms. Hospital-based statistics have serious limitations because only the most seriously affected are represented.

It is important to recognise, however, that data from these highly selected regions are not representative of the country as a whole. The parts of the country with the highest prevalence today are also those regions with the poorest healthcare infrastructure. Most comparative studies have reported a substantially higher prevalence in rural regions. Because of serious limitations in the healthcare delivery systems, the magnitude of the problem remains unrecognised in many poorly-served regions. Very few systematic surveys are available from rural populations with a poor healthcare infrastructure, urban slums and tribal colonies. Given the extraordinary variations in indices of human development across the country and even within regions, it is difficult to make generalisations for the entire country. **Table 1** summarises the results of selected studies from India over the last 50 years.

Table 1: Rheumatic Fever/Rheumatic Heart Disease Status in India

Authors	Place	Year	Age (yrs)	Population Studied	RHD Prevalence (per 1000)	RF Incidence (per 1000/yr)
Padmavati	Delhi (urban)	1984-94	5 to 10	40,000	3·90	0·38
Lalchandani *et al*	Kanpur	2000	7 to 15	3,963	4·54	0·75
Jose *et al*	Vellore	2001-02	5 to 18	2,29,829	0.68*	—
Soman *et al***	Ernakulam	2002-04	5 to 16	25,033	0.12*	0.08

RHD = Rheumatic heart disease; RF = Rheumatic fever.

AETIOLOGY

Rheumatic fever is an excellent example of a condition where all three components of the classic epidemiologic triad: agent, host and environment interact to result in the development of the disease.

The Agent

The role of preceding group-A beta-haemolytic streptococcal pharyngeal infection in the development of RF was suspected and firmly proven in the early 1930s and this association remains undisputed to this day. The clearest evidence of causality was provided by the demonstration of efficacy of penicillin prophylaxis dramatically reducing recurrences of RF. Further, mass penicillin prophylaxis terminated epidemics of RF in closed populations and in civilian populations as well. Streptococcal pharyngeal infections also result from other streptococci (groups B, C, G and F), but these do not result in RF.

Notwithstanding the clear demonstration of the association between GABHS and RF some aspects of this association that are unclear. The occurrence of group-A beta-haemolytic streptococcal pharyngeal infection has remained unchanged in various parts of the world including developed nations. Yet in most of these nations RF fever has declined substantially. Certain aspects of the association between GABHS and RF have been defined:

Epidemics of streptococcal infection are far more likely to cause RF than endemic streptococcal infections. The frequently quoted figure of 3% for epidemics and 0.3% for endemic infections are derived from studies in the 1950s on adult military recruits and civilian medical practice respectively. The risk of RF increases dramatically in recurrent attacks of GABHS infections in children and adults with a previous episode of RF.

The intensity of antigenic stimulus as suggested by the anti streptolysin-O (ASO) antibody titres correlate with attack rates of RF.

There is a carrier state for GABHS infections. This refers to the isolation of GABHS from asymptomatic patients. This does not translate into a risk of development of RF and does not require treatment.

The molecular basis of rheumatogenic potential of GABHS is unclear. There is also no clear relationship between specific serotypes and the propensity to produce RF. The virulence of streptococcus is closely linked to its rheumatogenic potential. The M protein is responsible for the ability of GABHS to resist phagocytosis. However, there appears to be no consistent relation between specific M protein serotypes and the incidence of RF after GABHS infection.

Host Factors

The first attack of RF typically occurs between 5 and 15 years with a peak at 8 years. Attacks are uncommon below 5 years and rare below 3 years. Virulent GABHS epidemics can result in RF occurring for the first time in young adults. There are anecdotal reports of initial attacks in the fourth or fifth decades.

While both sexes are equally predisposed to develop RF, chorea is strikingly uncommon in post-pubertal males. Interestingly, selected large community surveys from India on RHD have shown a striking female preponderance.

Genetically-programmed determinants of host susceptibility to RF have been studied extensively. These determinants include a variety of genes in the HLA-DR loci and B-cell alloantigens. Loose associations have been identified for different racial-ethnic groups. The available information seems to indicate that heredity plays a small role, if at all, in the development of RF.

Environmental Factors

Trends in RF and RHD over the last one-and-a-half centuries, in both the developed and developing countries, all point towards environmental factors such as poor living conditions, overcrowding and access to healthcare as the most significant determinants of disease distribution. Indeed, global, and to a substantial extent regional, distributions of RF and RHD are still largely influenced by socio-economic indices. Parts of India that have good human development indices (HDI), such as Kerala, have a much lower incidence of RF when compared to parts of India with low HDI, such as Chhattisgarh or Orissa. It is generally believed that crowded living conditions, with close interpersonal contacts, contribute to the rapid spread and persistence of virulent streptococcal strains. However, population density does not correlate well with RF incidence. Variations within India are best explained by education and access to health care including perhaps antibiotic usage. Seasonal variations in the incidence of RF (i.e. high incidences in early autumn, late winter and early spring) closely mimic variations in streptococcal infections in temperate climates. Such variations are not significant in the tropics.

PATHOGENESIS AND PATHOLOGY

The fact that RF represents an immunologic consequence of GABHS infection is largely uncontested. However, significant gaps remain in our understanding of many of the specific pathways involved. This together with the absence of a reliable and consistently reproducible animal model has come in the way of developing a suitable vaccine for the disease.

Pathology of Rheumatic Carditis

All components of the cardiac tissue are affected. Acute pericarditis occurs in 18% of cases and results in adhesions because of its fibrinous nature. Small-to-moderate effusions are also common. However, large effusions and tamponade is distinctly rare. Pericarditis is self-limiting and does not result in constriction unlike tuberculous or pyogenic pericarditis. Acute endocardial and valvular inflammation is characterised by tiny vegetations that neither embolise nor are infected.

Valvular involvement alone has long-term consequences. The valve heals with fibrosis and results in incompetence or stenosis. Not uncommonly, during acute RF one or more chordae of the mitral valve may rupture resulting in a flail leaflet and severe mitral regurgitation. Myocardial involvement is typically confined to the interstitium and does not result in myocardial damage or dysfunction.

The histological hallmark of rheumatic carditis is the Aschoff body. This is a granulomatous lesion, less than 1 mm in size, found in the endocardium, subendocardium and in the perivascular regions of the interstitium. It consists of a central area of fibrinoid necrosis surrounded by cardiac histiocytes (Aschoff cells or Anitschkow myocytes).

Pathology of Arthritis and Chorea

Synovial thickening and fibrinous exudates without any pannus formation are typical of rheumatic arthritis. Joint lesions heal

without any permanent damage. The pathologic basis of chorea is unclear. A variety of changes have been described in the cortex, cerebellum and basal ganglia (especially the caudate nucleus). The specificity of these changes is not established.

Pathogenesis of Rheumatic Heart Disease following Rheumatic Fever

Among the tissues affected during an episode of RF, only heart valves suffer permanent damage. All other affected tissues typically heal with no residual sequelae. Thus, pericarditis resolves completely without constriction, chorea resolves without long-term neurologic consequences and arthritis does not leave behind any disability. The reasons why heart valves are permanently damaged by one or more episodes of RF have not been fully understood. The following hypothesis appears most plausible.

Histopathological findings indicate widespread vascular disease throughout the body during an acute episode of RF. The immunological findings suggest that RF predominantly damages the vascular endothelium and mesothelium. The adjacent subendothelial and submesothelial tissues are affected to a very limited depth. Despite the diffuse collagen – vascular involvement, one of the mysteries of the pathology, of RF is the remarkable tendency for the disease to heal rather than to scar the tissues it affects, with the exception of cardiac valves. The damaged endothelium gets replaced by a new endothelium within days after injury without significant scarring. The valves are structurally unfortunate in having a small core of connective tissue covered by two layers of endothelium.

It is likely that the endothelium suffers initial damage due to a humoral immune response, the damage resulting in VCAM-1 being expressed on the endothelium. This is followed by activation of cellular immune response. As a result, CD4+, CD8+, T lymphocytes and macrophages get attached to the valvar endothelium and migrate to the connective tissue core. This sets up an inflammatory response. The inflammation is accompanied by neovascularisation of the valve substance. The endothelium of the newly formed vessels may serve as a substrate for additional inflammation and perhaps setup a vicious cycle of inflammation, neovascularisation and further damage resulting eventually in a permanently scarred valve.

DIAGNOSIS AND CLINICAL MANIFESTATIONS OF ACUTE RHEUMATIC FEVER

Jones Criteria

Duckett Jones introduced specific criteria in 1944 as a set of clinical guidelines for the diagnosis of rheumatic fever (RF) and carditis. The clinical features of RF were divided into major and minor categories, based on the prevalence and specificity of manifestations. The criteria needed to be sensitive enough to limit under-diagnosis and specific enough to limit over-diagnosis. Over the years, there have been modifications and revisions proposed by the American Heart Association (AHA) to improve the specificity of these criteria largely dictated by the declining incidence of RF in industrialised nations. In 1988 and subsequently in 2002-2003, WHO introduced specific modifications to the Jones criteria to allow wider application in today's developing world.

For the diagnosis of a primary episode of RF, it is recommended that the major and minor clinical manifestations of RF, the laboratory manifestations, and evidence of a preceding streptococcal infection should all continue according to the 1988 WHO recommendations. In the context of a preceding streptococcal infection, two major manifestations, or a combination of one major and two minor manifestations, provide reasonable evidence for a diagnosis of RF. The WHO has continued to maintain that a diagnosis of a recurrence of RF in a patient with established RHD should be permitted on the basis of two minor manifestations plus evidence of a recent streptococcal infection.

INDIVIDUAL MANIFESTATIONS OF RHEUMATIC FEVER

Major Manifestations

Carditis

Valvulitis is always seen in patients with carditis and is often clinically evident. Rheumatic pericarditis and myocarditis do not occur without accompanying valvulitis.

The initial symptom of carditis is often the pain of pericarditis or symptoms of heart failure typically manifesting about 2 to 3 weeks after the onset of RF. Symptoms may be subtle in children with nausea and vomiting resulting from gastric congestion, right upper quadrant pain because of hepatic capsule distension or non-productive cough from pulmonary congestion. Carditis may be present particularly with insidious onset in young children under the age of 6 years. This is identified as a separate category (insidious or chronic carditis) and is typically not accompanied by arthritis.

Signs and symptoms of carditis can be classified depending on the pathology.

Pericarditis

Pericarditis results in chest pain and is identified through auscultation of a friction rub. This may or may not be accompanied by a small pericardial effusion that is identified by echocardiography. In presence of mitral and/or aortic valve lesions, a pericardial friction rub strongly suggests acute RF. Pericarditis is equally diagnostic in primary episode or a recurrence of RF.

Myocarditis

Left ventricular function is rarely affected in acute rheumatic fever and heart failure is almost always the result of acute valvular regurgitation. Disproportionate tachycardia and a soft first heart sound are accompanying features of rheumatic carditis.

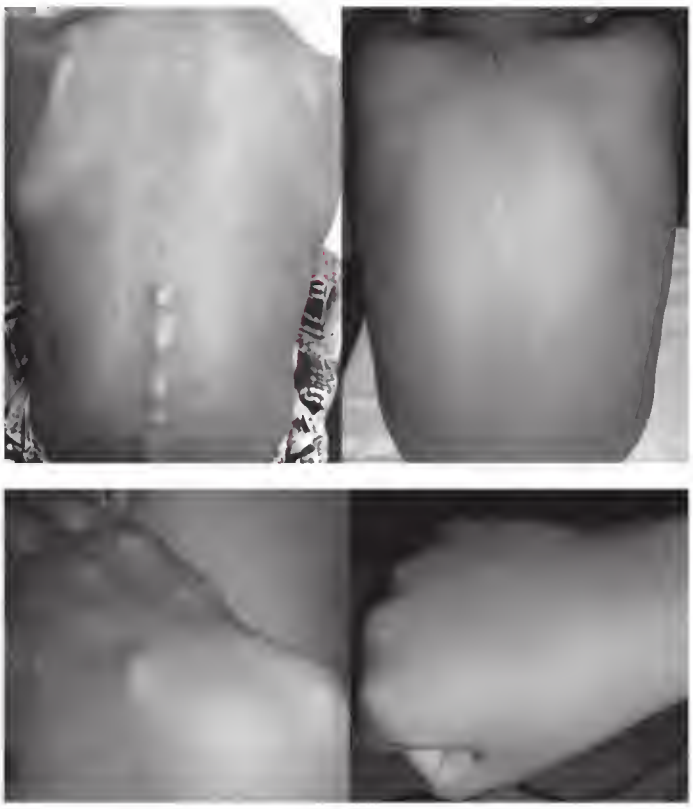
Endocarditis/Valvulitis

For patients who do not have a history of RHD, the presence of apical holosystolic murmur of mitral regurgitation (with or without apical mid-diastolic murmur, Carey Coomb's) or basal early diastolic murmur strongly supports the diagnosis of acute RF. For patients with previous RHD, a definite change in the character of any of the murmurs or the appearance of a new significant murmur suggests the presence of carditis. Mitral regurgitation may disappear (58% to 74%) in time but aortic involvement is usually permanent.

Arthritis

Arthritis is the most frequent major manifestation of RF, occurring in up to 75% of patients in the first attack of RF. It

occurs early in the course of the disease, as the presenting complaint. Arthritis is often the only major manifestation in adolescents as well as in adults. The articular manifestations in RF typically present as migratory polyarthritis, most often in the larger joints (commonly in the knees and ankles); the wrists, elbows, shoulders and hips are less frequently involved; and the small joints of the hands, feet, cervical and thoracic or lumbar spine are rarely affected. Inflamed joints are characteristically warm, red and swollen, and an aspirated sample of synovial fluid may reveal a high average leucocyte count. Tenderness in rheumatic arthritis may be out of proportion to the objective findings and severe enough to result in excruciating pain on touch. The term 'migratory' reflects the sequential involvement of joints with each completing a cycle of inflammation and resolution, so that some joint inflammation may be resolving while others are beginning. Many cases of rheumatic arthritis do not conform to this characteristic description. Monoarthritis may occur, for example, typically when anti-inflammatory therapy is initiated before RF is fully expressed. Frequently, several joints may be affected simultaneously, or the arthritis may be additive rather than migratory. Inflammation in a particular joint usually resolves within two weeks and the entire bout of polyarthritis in about a month if untreated.



Chorea

Sydenham's chorea occurs in fewer than 10% patients with rheumatic fever.

Chorea occurs primarily in children and is rare after the age of 20 years. It occurs primarily in females and almost never occurs in postpubertal males. Sydenham's chorea is characterised by emotional lability, uncoordinated movements, and muscular weakness. The onset may often be difficult to determine, as initially the child may become fretful, irritable, inattentive to schoolwork, fidgety or even severely disturbed. Physical incoordination soon becomes apparent, perhaps manifested as clumsiness and a tendency to drop objects, which progresses to spasmodic, uncoordinated movements. On physical examination, the movements are abrupt and erratic. All muscle groups may be affected, but erratic movements of the hands, feet and face are most evident. Facial movements include grimaces, grins and frowns. When the tongue is protruded, it resembles a 'bag of worms' and speech is jerky and staccato. Handwriting becomes illegible and the patient may stumble when attempting to walk. When the hands are extended, the dorsum assumes a 'spoon' or 'dish' configuration due to flexion of the wrist and hyperextension of the metacarpophalangeal joints. When raising the hands above the head, the patient may pronate one or both hands ('pronator sign'). Patients with chorea are unable to sustain a titanic contraction; therefore, when asked to grip the examiner's hand, their irregular, repetitive squeezes have been termed 'milkmaid grip'. Although the choreiform movements are usually bilateral, they may be unilateral (hemichorea). The choreiform movements disappear during sleep, decrease with rest and sedation, and can be briefly suppressed by volition. They may be accentuated by asking the patient to perform several voluntary movements at once. Neither sensory deficits nor pyramidal tract involvement are present. The latent period between the onset of the initiating streptococcal infection and the onset of Sydenham's chorea may be as long as several months. There is no definitive laboratory test for establishing a diagnosis of Sydenham's chorea, and the diagnosis is largely clinical.

Subcutaneous Nodules and Erythema Marginatum

Subcutaneous nodules and erythema marginatum are rare; usually, present in fewer than 10% of cases. Because the skin over them is not inflamed, they may easily be missed if not carefully sought on physical examination. Subcutaneous nodules are found over extensor surfaces of joints, are seen most often in patients with long-standing rheumatic heart disease and are rare in patients experiencing an initial attack. They are invariably associated with carditis and typically occur six weeks after the initial attack (**Figure 1**).

During acute rheumatic fever 6 weeks later

Figure 1: Subcutaneous nodules in rheumatic fever: These pictures have been obtained from an 8-year-old boy who had characteristic subcutaneous nodules in a number of locations including the back and dorsum of the hand as shown in the figure. Six weeks after presentation, following administration of anti-inflammatory medications that included a course of steroids, the nodules disappeared completely.

Erythema marginatum is an extremely uncommon manifestation. It is a macular eruption with rounded borders – usually concentrated on the trunk with serpiginous margins. It is only noticeable in fair-skinned individuals and tends to be very evanescent.

Minor Criteria

The minor criteria are non-specific and may be present in many clinical conditions. Fever occurs in almost all rheumatic attacks at the onset, usually ranging from 101°F to 104°F (38.4°C to 40.0°C). Diurnal variations are common, but there is no characteristic fever pattern. Arthralgia without objective findings is common in RF. The pain usually involves large joints, may be mild or incapacitating and may be present for days to

weeks, often varying in severity. Abdominal pain and epistaxis may occur in only about 5% of patients with RF.

Interpretation of Jones Criteria

To fulfil the Jones criteria, two major criteria, or one major criterion and two minor criteria, plus evidence of an antecedent streptococcal infection (see below) are required. The latter may be provided by recovery of the organism on culture or by evidence of an immune response to one of the commonly measured group A streptococcal antigens (e.g. antistreptolysin O, antideoxyribonuclease B, and anti-hyaluronidase). Insidious or chronic carditis and chorea can occur several weeks after GABHS infection, and therefore, do not require the essential criteria of evidence of streptococcal infection for the diagnosis of RF.

Interpretation of Laboratory Data

Antistreptolysin O test

Although widely used, ASO test has important limitations that need to be understood. ASO is positive in 85% of RF patients. The antibody levels in the normal population are influenced by several variables such as age, geographic location, socio-economic status, season of the year and genetic factors. Attempts to define normal values in Indian children indicate considerable variability. Several normal children had strikingly high titres.

In the absence of normative data for a given geographic region, ASO in excess of 240 for adults and 320 for children are considered to be abnormal. However, ASO titres have to be interpreted with caution in patients with suspected RF. Mere elevation of ASO in the presence of non-specific symptoms should not be labelled as RF. Penicillin prophylaxis should not be initiated on this basis. If necessary, a repeat titre should be obtained after a week. ASO antibodies appear after 7 to 10 days, peak at 2 to 3 weeks following GABHS infection and drop steadily thereafter.

Other streptococcal antibody tests

Other antibodies to extra-cellular streptococcal antigens (AntiDNAse B, antihyaluronidase, antistreptokinase and antistreptococcal esterase) can be used to improve sensitivity. If some of these tests are combined with ASO, the overall sensitivity can be improved to more than 95%. However, these tests are not generally available, particularly in smaller clinics in the developing world.

Throat culture

Throat swabs should be obtained carefully and inoculated within 5 hours of being obtained or should be transferred using appropriate transport methods. Throat swab culture does not differentiate between carrier and an active infection. Delays in obtaining throat swabs are common in the field setting and many patients receive antibiotics before samples can be obtained.

Rapid antigen detection

Rapid detection of streptococcal antigens from throat swabs using latex agglutination or enzyme immunoassay is a practical alternative to the throat swab. It has a sensitivity of 60% to 90% and a specificity of 95%.

Acute phase reactants

Both C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are widely available. Unlike ESR, CRP levels are not increased in presence of anaemia and not diminished in the presence of heart failure.

Electrocardiogram

Prolonged PR interval is accepted as a minor criterion and is not a sign of carditis. Accelerated junctional rhythm is well described in children. Higher grades of heart block (2nd degree or complete heart block) have also been described.

The WHO 2002-2003 criteria for the diagnosis of RF are shown in **Table 2**.

Role of Echocardiography for the Diagnosis of Rheumatic Fever

According to the WHO recommendations, clinical examination remains the basis of diagnosis of RF and carditis, and the role of echocardiography should be considered supportive. However, an echo-Doppler examination should be performed if the facilities are available. Echocardiography offers several clues to support the diagnosis of rheumatic fever (**Table 3**). Echocardiogram has several additional benefits in guiding appropriate therapy and in prognostication. However, strict echocardiographic criteria should be used to diagnose valve regurgitation. It is important not to label small colour Doppler jets of physiologic mitral regurgitation as significant. If mild mitral regurgitation is identified in absence of a murmur, the features suggestive of RF is a discrete posteriorly directed jet that often reaches the left atrial wall.

MANAGEMENT

The management algorithm for rheumatic fever is shown in **Figure 2**.

General Measures

Hospitalisation is recommended for confirmation of diagnosis, treatment initiation, patient and family education. A throat culture should be obtained; blood should be drawn for ASO, ESR, CRP and blood culture (if infective endocarditis needs to be ruled-out). A chest X-ray and an echocardiogram should also be done. Rest is recommended for 4 weeks for patients with carditis.

Eradication of Pharyngeal Streptococcal Infection

Eradication of the pharyngeal streptococcal infection is mandatory to limit repetitive exposure to streptococcal antigens. A single dose of benzathine penicillin (1.2 million units) is ideal. Alternatives include penicillin V (250 mg qid for 10 days) or erythromycin (250 mg qid for 10 days) for those with penicillin allergy.

Suppression of the Inflammation

Anti-inflammatory treatment with salicylates or steroids does not appear to influence the long-term outcome of RF or progression of heart valve lesions. Salicylates or steroids should be initiated only after a diagnosis of RF is confirmed. Aspirin, 100 mg/kg/day divided into 4 to 5 doses, is generally adequate for achieving a clinical response. The optimal aspirin dose should ensure an adequate response but avoid toxicity. After 2 weeks, the dose can be decreased to 60 to 70 mg/kg per day

Table 2: 2002-2003 WHO Criteria for the Diagnosis of Rheumatic Fever and Rheumatic Heart Disease (Based on the Revised Jones Criteria)

Major manifestations	Two major or one major and two minor manifestations plus evidence of a preceding group A streptococcal infection
Minor manifestations	Two major or one major and two minor manifestations plus evidence of a preceding group A streptococcal infection
Supporting evidence of a preceding streptococcal infection within the last 45 days	Two minor manifestations plus evidence of a preceding group A streptococcal infection
	Other major manifestations or evidence of group A streptococcal infection not required
	Patients do not require any other criteria to be present for the first time with patient diagnosed as having rheumatic heart mitral stenosis or mixed mitral valve disease and/or aortic valve disease
Primary episode of RF	Carditis Polyarthritis Chorea Erythema marginatum Subcutaneous nodules
Recurrent attack of RF in a patient without established rheumatic heart disease Recurrent attack of RF in a patient with established rheumatic heart disease	Clinical: fever, polyarthralgia Laboratory: elevated acute phase reactants (erythrocyte sedimentation rate or leucocyte count)
Rheumatic chorea, insidious onset rheumatic carditis	Electrocardiogram: prolonged P-R interval
Chronic valve lesions of RHD	Elevated or rising antistreptolysin-O or other streptococcal antibody, or a positive throat culture, or rapid antigen test for group A streptococci, or recent scarlet fever

1. *Patients may present with polyarthritis (or with only polyarthralgia or monoarthritis) and with several (3 or more) other minor manifestations, together with evidence of recent group A streptococcal infection. Some of these cases may later turn out to be rheumatic fever. It is prudent to consider them as cases of 'probable rheumatic fever' (once other diagnoses are excluded) and advise regular secondary prophylaxis. Such patients require close follow up and regular examination of the heart.*
2. *This cautious approach is particularly suitable for patients in vulnerable age groups in high incidence settings.*
3. *Infective endocarditis should be excluded.*
4. *Some patients with recurrent attacks may not fulfil these criteria.*
5. *Congenital heart disease should be excluded.*

Table 3: Echocardiographic Findings Suggestive of Rheumatic Fever

Structure	Modality	Findings
Mitral valve	Two-dimensional imaging	Thickened leaflets Limited mobility of posterior mitral leaflet Nodules on leaflet margins (25%) Flail anterior or posterior (rare) leaflet Evidence of chronic RHD Thickened chordal apparatus Varying degrees of stenosis Limited mobility of AML
	Colour Doppler	Posteriorly directed jet of mitral regurgitation
Aortic valve	2D colour Doppler	Thick leaflet margins Varying grades of aortic regurgitation Evidence of RHD Aortic stenosis Reduced leaflet mobility
Tricuspid valve	2D and colour Doppler	Rarely affected in the initial episode; chronic RHD is associated with organic tricuspid valve involvement in up to 30% with leaflet thickening, and varying degrees of TR; tricuspid stenosis is relatively uncommon but well-described
Atria	M-mode and 2D	Left atrial enlargement is an inevitable consequence of significant mitral regurgitation
Ventricles	M-mode and 2D	Left ventricle enlargement is a result of mitral regurgitation. LV function tends to be well-preserved except in the presence of acute severe MR. LV dysfunction is, therefore, rare in the absence of significant MR.

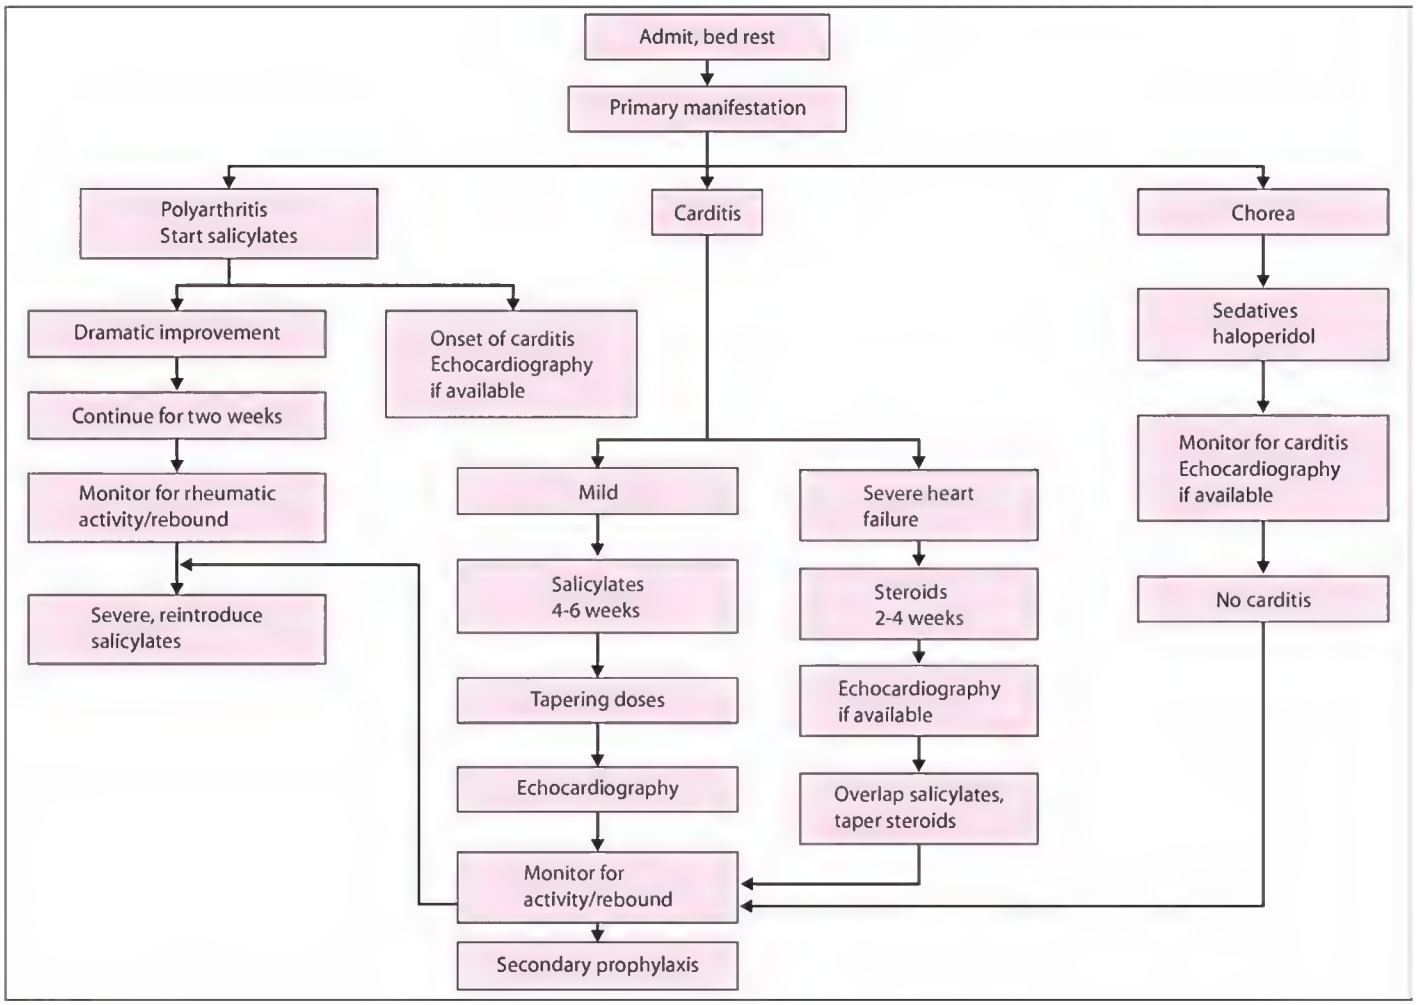


Figure 2: Algorithm for management of acute rheumatic fever.

for an additional 3 to 6 weeks. Any other non-steroidal anti-inflammatory drug (NSAID) can be used as an alternative for those allergic to aspirin.

Patients with carditis and heart failure should receive steroids to facilitate early recovery. Steroids rapidly relieve symptoms and shorten duration of hospitalisation. Steroids are also advisable in patients who do not respond to salicylates and who continue to worsen and develop heart failure despite anti-inflammatory therapy. Prednisone (1 to 2 mg/kg-day, to a maximum of 80 mg/day given once daily, or in divided doses) is usually the drug of choice. In life-threatening circumstances, therapy may be initiated with intravenous methylprednisolone. After 2 to 3 weeks of therapy, the dosage may be decreased by 25% each week. While reducing the steroid dosage, a period of overlap with aspirin is recommended to prevent rebound. Duration of treatment is dictated by the clinical recovery. Typically 4 to 6 weeks of total treatment is advisable. However, prolonged treatment is sometimes necessary for the small proportion of patients (5%).

Management of Heart Failure

Although heart failure in RF generally responds to bed rest and steroids, diuretics, angiotensin converting enzyme inhibitors and digoxin are often initiated early. This allows greater patient comfort and may help shorten the duration of hospitalisation. The role of ACE inhibitors in acute mitral or aortic valve regurgitation is controversial.

Management of Chorea

Chorea has traditionally been considered to be a self-limiting benign disease, requiring no therapy. However, there are recent reports that a protracted course can lead to disability and/or social isolation. The signs and symptoms of chorea do not respond well to anti-inflammatory agents or steroids. Supportive measures such as rest in a quiet room together with medications such as haloperidol, diazepam, and carbamazepine have all been reported to be effective. Pimozide is a new drug that is believed to be effective in rheumatic chorea.

Role of Surgery in Refractory Heart Failure

Under exceptional circumstances, valve replacement operation may be advised to help manage refractory heart failure from severe mitral (or rarely aortic) valve leakage. Typically, the valve leaflets are flail. Mitral valve repair can be considered for patients after the acute inflammation subsides because of the possibility of recurrence of mitral regurgitation from ongoing inflammation. Exceptionally, valve repair has been undertaken during the acute phase.

NATURAL HISTORY OF VALVE LESIONS

Mitral regurgitation associated with acute RF has a tendency to decline over the next several weeks or months once the acute inflammation subsides. Rarely, it may disappear altogether. There are also instances where stenosis develops with time.

PREVENTION

Primary Prevention

This refers to prevention of occurrence of RF for the first time following an episode of streptococcal sore throat infection. The antibiotic regimens are essentially identical listed for eliminating *Streptococci* from the throat during an acute episode of RF.

Secondary Prophylaxis (Prevention of Recurrences of RF)

One of the most important aspects of management of acute RF is the prevention of its recurrence through continuous antibiotic prophylaxis regimes. **Table 4** lists prophylactic regimes recommended by WHO.

Duration of secondary prophylaxis

The following WHO recommendations are widely accepted:

Patient without proven carditis

For 5 years after the last attack, or until 18 years of age (whichever is longer).

Patient with carditis mild mitral regurgitation or healed carditis

For 10 years after the last attack, or at least until 25 years of age (whichever is longer).

Patients with established rheumatic heart valve disease or following valve surgery or balloon mitral valvotomy

Life-long prophylaxis is usually recommended. However, some cardiologists do recommend discontinuation of prophylaxis after the age of 40 years because the likelihood of recurrence of RF beyond this age is considered minimal.

Table 4: Secondary Prophylaxis Following an Episode of Rheumatic Fever

Antibiotic	Mode of Administration	Dose
Benzathine penicillin	Single intramuscular injection every 3 to 4 weeks*	12,00,000 units for patients ≥30 kg; 600,000 units for patients <30 kg**
Penicillin V	Oral	250 mg twice daily
Sulphonamide (sulphadiazine, sulphadoxine, sulphisoxazole)	Oral	1 gm daily for patients ≥30 kg and 500 mg daily for patients <30 kg
Erythromycin (for those allergic to penicillin)	Oral	250 mg twice daily

** 3 weekly injections are recommended for RF prophylaxis in high prevalence regions.*
***For patients <30 kg in high prevalence regions, 600,000 units can be administered every 2 weeks.*

12.13 Valvular Heart Disease (I)

CN Manjunath

Rheumatic heart disease (RHD) constitutes the most common form of valvular heart disease in India. The reported prevalence of RHD is 1.0 to 5.4 per 1,000 school children in our country. Only 50% of patients with established RHD give a past history of rheumatic fever. This may be attributed to subclinical carditis or the difficulty encountered in diagnosis.

Rheumatic valvulitis most commonly affects the mitral valve (70% to 75%) followed by combined mitral and aortic involvement (20% to 25%), with isolated aortic disease being uncommon (5% to 8%). Though pathological involvement of tricuspid valve is seen in 30% to 50% of patients, clinical manifestations are rare. The mitral valve is most commonly affected in RHD because it withstands a high left ventricular (LV) pressure of about 120 mm Hg during systole (aortic valve is subjected to about 80 mm Hg during diastole).

MITRAL STENOSIS

Mitral stenosis (MS) is a condition characterised by structural abnormality of the mitral valve apparatus that results in obstruction to left ventricular inflow. The most common cause of MS is rheumatic carditis. Other causes are extremely uncommon and include congenital MS, mitral annular calcification (MAC), carcinoid syndrome, mucopolysaccharidosis, Fabry's disease, Whipple's disease, amyloidosis and methysergide therapy.

Isolated MS occurs in 25% of all RHD patients and about 40% have combined MS and mitral regurgitation (MR). The female to male ratio is 2:1.

Pathology

The mitral valve apparatus is composed of the annulus, anterior and posterior mitral leaflets which are attached to the anterolateral and posteromedial papillary muscles via the chordae tendinae (about 120 in number). The normal mitral valve orifice area is 4-6 cm^2. The mechanism by which the initial episode of rheumatic fever progresses onto MS, has been explained by two theories, namely the smoldering process of rheumatic carditis and 'Selzer and Cohn' hypothesis. According to this hypothesis, the initial mitral valvulitis leads to abnormal flow patterns across the mitral leaflets that promote thickening, fibrosis and calcification of leaflets. The thickened leaflets fuse along their edges, i.e. commissures, resulting in a stenosed mitral valve which has a 'Fish mouth' or 'Buttonhole' appearance. This commissural fusion may be associated with cuspal or chordal fusion or both. The severity of MS is determined by several parameters as enumerated in **Table 1**.

Pathophysiology

In normal individuals, the mean pressure in the left atrium (LA) is 2 to 12 mm Hg, whereas the LV end-diastolic pressure ranges from 5 to 12 mm Hg. During diastole, the mitral valve opens and blood flows from LA to LV and no pressure gradient exists across the mitral valve. When the mitral valve orifice area (MVOA) is reduced to < 2.0 cm^2, the LA pressure has to increase to propel the blood from LA to LV. In severe MS, the mean LA pressure may become as high as 25 mm Hg to maintain antegrade flow across the mitral valve. This diastolic transmitral pressure gradient is the haemodynamic hallmark of MS. During tachycardia, the diastolic phase shortens and the time available for blood flow from LA to LV is reduced. In such situations, the LA pressure raises abruptly and dramatically to maintain adequate transmitral blood flow. The elevated LA pressure is transmitted backwards into the pulmonary veins resulting in pulmonary venous hypertension which causes dyspnoea. When the mean LA pressure exceeds 25 mm Hg pulmonary oedema occurs. Hence conditions that cause tachycardia like exercise, anaemia, fever, pregnancy and atrial fibrillation worsen the symptoms of MS. On the other hand, treatment with beta-blocker lowers the heart rate and increases the diastolic filling period and produces symptomatic relief.

Table 1: Assessment of Severity of Mitral Stenosis

	MVOA (cm^2)	Mean Gradient (mm Hg)	PASP (mm Hg)
Mild MS	>1.5 to 2.0	<5	<30
Moderate MS	1.0 to 1.5	5 to 10	30 to 50
Severe MS	<1.0 to 0.5	10 to 20	>50
Critical MS	<0.5	>20	

MVOA = Mitral valve orifice area; PASP = Pulmonary artery systolic pressure.

Long standing MS eventually leads to pulmonary arterial hypertension (PH), the mechanism of which is explained by Jordan's hypothesis. According to this hypothesis, when the pulmonary venous pressure increases, fluid passes into alveolar walls and promotes thickening and fibrosis of the wall resulting in hypoxaemia. This hypoxaemia is sensed by chemoreceptors that lead to reflex pulmonary arterial vasoconstriction. This triad of passive pressure transmission, reflex vasoconstriction and obliterative changes in the vascular bed causes PH. When pulmonary artery pressure exceeds 60 mm Hg, right ventricular (RV) dysfunction with tricuspid regurgitation (TR) occurs. When PH is severe, the chance of developing pulmonary oedema decreases and symptoms of right heart failure dominates the clinical picture.

LA enlargement is a consequence of MS and fibrosis of atrial wall due to rheumatic carditis. The disorganisation of atrial muscle bundles coupled with in homogenous refractory periods culminates in atrial fibrillation (AF). Initially, AF tends to be paroxysmal and later on becomes permanent. Incidence of AF in symptomatic MS is 30% to 40%.

Clinical Features

The age of presentation of MS in Western countries is third or fourth decade. We, in India, often seen them in second decade.

Those presenting in teens are called as juvenile mitral stenosis. The most common symptom of MS is exertional dyspnoea. It is accompanied with history of orthopnoea and paroxysmal nocturnal dyspnoea (PND) which distinguish dyspnoea to be due to pulmonary venous hypertension (PVH). Patients have history of dyspnoea, orthopnoea, PND for a long duration. Second important symptom is haemoptysis. It can occur due to various causes as shown in **Table 2**.

Table 2: Causes of Haemoptysis in Mitral Stenosis

Pulmonary apoplexy (rupture of thin walled bronchial veins)
Acute pulmonary oedema
Pulmonary infarction
Winter bronchitis
Pulmonary haemosiderosis

History of palpitations is prominent in these patients specially when they develop atrial fibrillation (AF). Patients symptoms worsen after the onset of AF. They also complain of fatigue due to low cardiac output at this stage. Pedal oedema occurs later when right heart failure sets in and patients have pain in right hypochondrium due to hepatomegaly. Hoarseness of voice (Ortner's syndrome or cardiovocal syndrome) can occur due to compression of left recurrent laryngeal nerve by dilated LA or pulmonary artery. Chest pain is a rare symptom and can occur due to pulmonary hypertension, RV ischaemia or associated coronary artery disease.

The clinical findings in MS are characterised by mitral facies - pinkish purple patches on cheeks (due to low cardiac output and peripheral vasoconstriction). Patients are often weak and cachexic. The pulse is of normal volume and regular in sinus rhythm. It is irregular when AF occurs. Absent peripheral pulse denotes possible embolic occlusion. The blood pressure is normal. In AF, average of three values of BP should be taken. The JVP shows prominent 'a' wave in sinus rhythm. 'a' wave is absent in AF.

On cardiac examination, the apical impulse is normal in position and tapping (due to loud S1) in character. Apex displaced down and out (LV apex) denotes associated MR or AR. In gross, RV enlargement apex is shifted out but not downward. The left parasternal impulse heave his present due to RVH. In second space, P2 is palpable and PA pulsations can be felt denoting pulmonary artery hypertension. On auscultation, the first heart sound is loud S1 in sinus rhythm. LA pressure is high and this causes mitral leaflets to be well recessed into LV cavity. With onset of systole, the LV pressure rises rapidly and the valve closes with wide closing excursion causing loud S1. S1 is varying in intensity in AF. A soft S1 denotes calcific MS or associated MR or AR. The second heart sound is normally split and loud P2 denotes PH. An opening snap (OS) is snappy, high frequency sound heard 40 to 120 ms after S2. During early diastole, the high LA pressure causes rapid, excursion of anterior mitral leaflet to fully open position. The tensing of leaflets in this open position causes OS. Absent OS denotes calcific or fibrosed non pliable MS. The murmur due to diastolic flow cross stenosed mitral valve is a mid diastolic murmur (MDM). It is a rough, rumbling, low-pitched murmur best appreciated at apex in expiration, with bell of stethoscope with patient in left lateral position. The MDM is accentuated by exercise, coughing, squatting, amyl nitrite inhalation and decreased by strain phase of Valsalva manoeuvre.

A presystolic murmur (accentuation of MDM) occurs due to LA contraction which increases flow in presystolic phase augmenting MDM in sinus rhythm. It is absent in AF although it can occur in AF during beats with short cycle length (Crile's hypothesis). The other causes of MDM at apex are a Carey Comb murmur (acute rheumatic fever valvulitis), Austin Flint murmur in aortic regurgitation and MDM due to left atrial myxoma. The other murmur often heard is a pansystolic murmur of TR that increases in intensity with inspiration and is best heard in the lower left sternal border.

Two factors help in assessing severity of MS, clinically. The shorter the A2-OS interval more severe is the stenosis. The duration of MDM is directly proportional to severity of MS. A MDM that occupies the entire diastole denotes severe stenosis. The pliability of the valve is assessed by the intensity and sharpness of S1 and presence of OS.

Complications and Natural History

The complication unrelated to severity of stenosis includes AF, embolism and infective endocarditis. Incidence of systemic embolism is 20% and risk factors include age, size of LA and AF. Other complication includes pulmonary hypertension and heart failure.

The time interval from rheumatic fever to development of MS is 15 to 20 years. It further takes 5 to 10 years to progress from NYHA class II to III or IV. In India, the latent period is short and severe symptomatic stenosis occurs as early as 6 to 12 years of age. MS occurring before 18 years is termed as juvenile MS. The MVOA decreases by 0.09 cm^2/year. Five-year survival rate is 64% in NYHA class III patient and only 15% in class IV.

Investigations

ECG and radiographic findings are shown in **Tables 3 and 4**.

Table 3: ECG Findings

ECG shows evidence of LA enlargement in the form of bifid 'P' waves in lead II and 'P' terminal force in V1 >0.04 mms (Morris index)
Rhythm may be sinus or atrial fibrillation
An R/S ratio >1 in V1 denotes right ventricular hypertrophy (RVH)
When QRS axis is >60°, MVOA is usually <1.3 cm^2 and extreme right axis denotes severe PH

Table 4: Radiological Abnormalities

LA enlargement: Double density, splaying of carina, straightening of left heart border
Pulmonary venous hypertension
Grade 1 – Prominent upper lobe veins
Grade 2 – Kerley B, A and C lines
Grade 3 – Bat wing appearance of pulmonary oedema
Pulmonary arterial hypertension: Dilated PA (>17 mm in men, >16 mm in women)
Pulmonary haemosiderosis
Cardiomegaly suggests associated MR or AR or tricuspid disease

Echocardiography

Echocardiography is the investigation of choice to diagnose MS. The salient findings are described in **Table 5**. Out of 98,302 echocardiogram done between 1st January, 2009 and 31st December 2009 at Sri Jayadeva Institute of Cardiovascular

Sciences and Research, Bangalore, 8.6% (8,512) were diagnosed with RHD. Of these, 8,512 echocardiograms predominant MS constituted 55%, predominant MR 22% and combined MS and MR about 18%.

Table 5: Echocardiographic Findings in MS

Diastolic doming of mitral valve with thickened leaflets and commissural fusion, resulting in fish mouth appearance
Reduced EF slope
Determine severity of MS by:
MVOA by planimetry and pressure half time
Mean gradient by pulsed wave Doppler across mitral valve
Calculation of PA pressure by TR jet gradient
Calcification, submitral fusion
LA enlargement (Manjunath *et al*)
Site and size of LA clot can be assessed
Assess other valvular lesion and ventricular function
Assess suitability for balloon mitral valvotomy (BMV) using Wilkin's score or Cormier classification

Treatment

Medical

Penicillin prophylaxis is indicated in all rheumatic MS patients atleast up to 40 years. Asymptomatic patients with mild to moderate MS require only regular follow-up. But symptomatic patients require the following:

1. Diuretics to reduce pulmonary venous hypertension. Frusemide (20 to 40 mg) in combination with spironolactone (25 to 50 mg) is the preferred combination.
2. Beta-blocker in low dose is indicated even in sinus rhythm, as it prevents tachycardia and hence sudden surge in LA pressure and provides symptomatic relief. Digoxin has no role in MS in sinus rhythm.
3. Oral anticoagulation in presence of AF.
4. Patients should avoid sport activities and heavy exertion.

Restoration to sinus rhythm is possible in patients with AF, only when LA size is <5.5 cms. Patient should be optimally anticoagulated for a period of 4 weeks and clot should be ruled-out before cardioversion. All AF patients require rate control with beta-blockers, calcium channel blockers and digoxin. The target heart rate is 60 to 80 beats/min at rest and <100 beats/min with mild exercise. Anticoagulation to achieve an INR of 2.0 to 3.0 is warranted.

Balloon mitral valvotomy

Balloon mitral valvotomy (BMV) in the procedure of choice when indicated. The indications are as under. BMV is indicated in patients with suitable valve morphology, when they are: (i) symptomatic (NYHA class II, III or IV) with moderate to severe MS; (ii) asymptomatic with severe MS with PA pressure > 50 mmHg at rest or > 60 mm Hg on exercise or new onset AF; (iii) MR less than moderate; and (iv) absence of LA thrombus

Mitral stenosis in pregnancy shows worsening of symptoms specially in second trimester due to fluid overload. These patients may need semi-urgent corrective BMV during pregnancy. Mitral restenosis occurs often (~60% to 70%) after 8 to 12 years. These patients require repeat procedures like BMV, CMV or valve replacement.

BMV is contraindicated in patients with (i) bicommisural calcification; (ii) densely calcified valve; (iii) more than moderate MR; (iv) specific types of LA clot; and (v) lack of expertise.

Complications of BMV include MR (15%, of which 2% require emergency surgery), cardiac tamponade (1% to 3%), stroke (1%) and residual ASD (5%). The overall mortality is about (0.5% to 1%). Data from national interventional council registry shows that in the year 2006; total of 7,221 BMVs were performed in India with a procedural success of 96%.

Mitral valve replacement

Mitral valve replacement is indicated in:

1. Symptomatic (NYHA class III or IV) patients with moderate to severe MS when BMV is contraindicated
2. Symptomatic (NYHA class I or II) with severe MS when PA pressure is > 60 mmHg if BMV is contraindicated
3. Other value requiring surgery.

Open mitral valvotomy is currently done only when the chest is opened for some other surgery, presence of left atrial clot or in Lutembacher's syndrome. Closed mitral valvotomy (CMV) was performed earlier. This has been replaced now with BMV.

MITRAL REGURGITATION

RHD is the commonest cause of mitral regurgitation (MR). Incidence of isolated rheumatic MR is 10%. MR may be acute or chronic based on the mode of onset.

Chronic Mitral Regurgitation

The aetiopathogenesis of chronic MR is listed in **Table 6**.

Table 6: Aetiopathogenesis of Chronic MR

RHD: Fibrosis, shortening and retraction of leaflets and subvalvular structures leads to non-coaptaton of leaflets
MVP: Redundant leaflets with interchordal hooding
Degenerative: Calcification causes loss of sphincteric action of annulus
DCM: Annular dilation
HCM: SAM of mitral valve and intrinsic abnormalities of valve
Connective tissue disorders: Valvulitis and vegetation
Congenital: Cleft AML in AV canal defect

DCM = Diloted cordiomyopathy; HCM = Hypertrophic cordiomyopothy; SAM = Systolic onterior motion.

Mitral regurgitation may be primary (valve disease) or secondary (functional). Secondary MR occurs in dilated cardiomyopathy or ischaemic heart disease.

Mitral valve prolapse (floppy mitral valve) is one of the more common causes of mild mitral regurgitation often seen in young women. It may be associated with Marfan's syndrome or connective tissue disorders. It may present with some benign arrhythmias (VPC's), atypical chest pain or small increased risk of stroke. It is characterised by mid systolic click and late systolic murmur. In some patients, chordal rupture can occur resulting in severe MR. These patients benefit from β-blockers.

Pathophysiology

During systole, the LV end-diastolic volume is ejected into aorta and LA. In chronic MR, LA is compliant; hence it accommodates the regurgitant volume without increase in LA pressure. As the

LA receives blood from both pulmonary veins and LV during systole, there is volume overload of LA. This increased volume of blood in LA is emptied into LV resulting in LV volume overload. As LV volume increases, LV dilation occurs. This, in turn, leads to mitral annular dilation and worsening of MR. Thus, a vicious cycle is established wherein 'MR begets MR'.

The increased LV preload (increased volume of blood from LA) and reduced afterload (decreased forward flow into aorta) coupled with eccentric hypertrophy of LV leads to supranormal ejection fraction (EF) (>60%) and normal cardiac output is maintained. This constitutes the compensated phase and patient may be asymptomatic for many years despite severe MR. Even a fall in EF to low normal levels (50% to 60%) denotes onset of LV dysfunction. This constitutes the decompensated phase and leads to progressive LV dysfunction and heart failure.

Giant LA (>65 mm) is a feature of chronic MR and it predisposes to AF. LA thrombus is less likely as compared to MS. Other complications of MR include infective endocarditis (IE), pulmonary arterial hypertension and heart failure.

Clinical Features

The predominant symptom of MR is chronic fatigue due to low cardiac output. Palpitations may be due to LV volume overload or AF. Unlike MS, dyspnoea is a late symptom of MR and denotes LV dysfunction, pulmonary hypertension or noncompliant LA.

The clinical findings are: the pulse is usually normal but may show a pseudo collapsing character (due to LV volume overload, increased volume of blood is pumped rapidly into aorta, giving a rapid upstroke to the pulse). It is generally regular since AF is less common in MR than in MS although these patients have larger LA. The blood pressure is usually normal. The JVP is unremarkable. On cardiac examination, the apical impulse is hyperdynamic and is shifted downwards and laterally. The parasternal impulse shows rocking motion of the precordium (LA enlargement causes late systolic pulsation in lower left sternal border). On palpation, LV apex and S3 may be there. Features of PAH are late and less prominent than in MS. On auscultation, S1 is soft (reduced leaflet excursion due to abnormal leaflets) and S2 widely split (due to early occurrence of A2, as LV systole is completed earlier). S3 is audible due to increased flow rate across mitral valve (denotes severe MR). A pansystolic, blowing, high-pitched murmur of uniform intensity is best heard at the apex and radiates to axilla (radiates to sternum if MR is due to posterior leaflet abnormality). The murmur does not vary in intensity following an ectopic beat because regurgitant volume is unchanged due to reduced regurgitant orifice area and increased regurgitant fraction. This helps in differentiating from aortic stenosis (AS) murmur. In dynamic auscultation, squatting and handgrip increase intensity of murmur and standing, Valsalva, exercise and amyl nitrite decrease the intensity of murmur. In some cases with severe MR, a soft MDM may be heard due to early rapid filling.

Clinically MR is considered severe, when:

1. Apex is hyperdynamic and shifted down and out
2. Presence of S3
3. Flow MDM at apex
4. Wide split S2

Intensity of PSM is not related to severity of MR.

Natural History

Mild-to-moderate MR remain asymptomatic for several years. Asymptomatic severe MR invariably progresses to symptoms or LV dysfunction within 10 years. The 5 and 10 year survival of symptomatic, severe MR is 30% and 10% respectively, without intervention. Annual mortality is about 6.3%.

Investigations

Electrocardiography and radiographic findings of MR are indicated in **Tables 7 and 8**.

Table 7: ECG Findings of MR

Normal
LA enlargement
Atrial fibrillation (AF)
LV hypertrophy (LVH) with volume overload pattern
Q waves in V5, V6

Table 8: CXR in MR

Cardiomegaly of LV type
LA enlargement (can be aneurysmal)
Evidence of pulmonary venous hypertension is rare. However, with onset of LV dysfunction, it is evident.

Echocardiography

Echocardiography is the investigation of choice to diagnose, assess severity and determine treatment options. Findings in MR are described in **Table 9**.

Table 9: Echocardiography in MR

Dilated LA and LV
Assess mitral apparatus for cause of MR
MR is severe when:
MR jet area to LA area >50%
Dense spectral pattern on Doppler
Vena contracta >6 mm
Large PISA (Proximal isovelocity surface area)
Systolic flow reversal in pulmonary vein
Assess PA pressure and ventricular function
EF <60% denotes LV dysfunction

Treatment

Medical

Penicillin prophylaxis is indicated up to 40 years of age. Infective endocarditis prophylaxis is not required. Asymptomatic patient with MR requires only regular follow-up. But symptomatic patient requires the following:

1. Diuretics, if pulmonary venous hypertension is present.
2. ACE-inhibitors are indicated, when EF is <60%.
3. AF requires cardioversion or rate control and anticoagulation.

Medical management has very little to offer for MR patients and surgery is the treatment of choice when warranted.

Surgery

Mitral valve repair is preferred over mitral valve replacement (MVR) when feasible. MVR is possible in: MVP MR, ischaemic MR, annular dilation, chordal rupture, leaflet perforation, and children with pliable valves. Rheumatic MR usually requires MVR rather than repair.

Indications of MVR/repair

1. NYHA class II, III or IV symptoms with severe MR
2. Asymptomatic patient with severe MR, when:
   - EF <60%
   - LV end systolic dimension >40 mm
   - PASP >50 at rest or >60 mm Hg on exercise
   - New onset AF

Two types of valves are used for replacement. Metallic valves and bioprosthetic valves. Metallic valves (bi-leaflet, e.g. St. Jude valve) require anticoagulation for lifelong, to keep INR between 2.5 and 3.0. These have longer life. The bioprosthetic valve do not require anticoagulation, however, these valves show dehiscence after 8 to 10 years. Choice of valve depends on age, education level and choice of patient.

MVR is not indicated in severe symptomatic MR when EF <30%, as the perioperative mortality exceeds conservative management.

Percutaneous mitral valve repair (PMVR) using MitraClip is a promising therapy for select subset of MR.

Acute Mitral Regurgitation

Acute MR is a cardiac emergency. The causes of acute MR are listed in **Table 10**.

Table 10: Aetiology of Acute MR

Acute coronary syndrome (papillary muscle dysfunction/rupture)
Infective endocarditis
Acute rheumatic carditis
Post-BMV
Trauma
Prosthetic valve dysfunction
Chordal rupture

Ischaemia of papillary muscles can cause acute MR. The anterolateral papillary muscle has dual blood supply from diagonal and obtuse marginal coronary branches and is less prone for ischaemia. The posteromedial papillary muscle is supplied only by PDA branch and is prone for ischaemia.

In acute MR, the LA is small, noncompliant and is unable to accommodate the regurgitant blood. So the LA pressure rises sharply and abruptly, resulting in acute pulmonary oedema and even cardiogenic shock. Most common symptom of acute MR is sudden onset of breathlessness. Unlike chronic MR, apical impulse is normal in character and the systolic MR murmur is shorter and ends well before A2. Normal LA and LV dimensions with severe MR on Doppler echocardiography suggest the diagnosis of acute MR.

Haemodynamic stabilisation is achieved with nitroprusside, inotropic support and intra-aortic balloon pump. Emergency mitral valve repair or replacement is the treatment of choice.

TRICUSPID STENOSIS

Tricuspid stenosis (TS) always occurs along with rheumatic MS. Rare cause of TS includes carcinod syndrome, IE, tumour and endomyocardial fibrosis. Clinically significant TS occur only in 5% of patients. Pathology of the valve is similar to MS except that calcification is uncommon. Presence of transtricuspid mean diastolic pressure gradient is the haemodynamic hallmark of TS.

Organic tricuspid valve disease should be suspected when right heart symptoms and signs dominate the clinical picture. Most common symptom of TS is fatigue due to reduced cardiac output. Symptoms of MS like dyspnoea and orthopnoea are characteristically absent. Gross ascites and pedal oedema are invariably present. JVP reveals prominent 'a' waves and slow 'y' descent. Absent parasternal heave with presystolic pulsatile, tender hepatomegaly suggests RV inflow obstruction. In addition to the auscultatory findings of mitral valve disease, an opening snap and a crescendo-decrescendo mid-diastolic murmur at lower left sternal border, which increases on inspiration, are present.

ECG and radiograph reveal RA enlargement. Radiographic findings of pulmonary venous hypertension are rare. The echocardiograph shows diastolic doming of tricuspid valve. A mean tricuspid gradient of >2 mm Hg confirms the diagnosis of TS and a gradient >5 mm Hg denotes severe TS.

Judicious use of two or more diuretics that have different mechanism of action with intensive salt restriction is required to treat the pedal oedema and ascites. Percutaneous transvenous tricuspid commisurotomy can be done where feasible. Alternatively, open valvotomy can be done at the time of surgery for the other valvular lesions. Rarely, valve replacement with bioprosthetic valve may be required for optimal outcomes.

TRICUSPID REGURGITATION

Tricuspid regurgitation (TR) may be classified as: primary TR – intrinsic abnormality of valve, and secondary TR – dilation of RV and tricuspid annulus causes TR.

Secondary or functional TR is the most common type and is usually due to left heart disease. Most common cause of primary TR is RHD. Other causes include IE, carcinoid syndrome, Ebstein's anomaly, tricuspid valve prolapse or drugs. *Staphylococcus aureus* endocarditis and IE in intravenous drug abusers are notorious for developing TR.

Clinically, patients present with fatigue, ascites and pedal oedema. JVP is elevated with prominent 'C-V' waves. Tender systolic pulsations of liver may be appreciated. In secondary TR, a PSM that increases in intensity with inspiration is heard in lower left sternal border, whereas, in organic TR, the murmur is low in intensity and occupies only first half of systole. Other corroborative evidence of pulmonary hypertension like parasternal heave, loud P2, pulmonary ejection systolic murmur, ejection click or Graham Steell murmur may be present in secondary TR.

ECG shows RA enlargement. Radiograph shows RV type of cardiomegaly with gross RA enlargement. Echocardiography is useful to assess the severity and aetiology of TR. If the pulmonary artery systolic pressure exceeds 55 mm Hg, then TR is likely to be secondary.

Aggressive diuretic therapy is needed to reduce oedema. Secondary TR requires appropriate treatment for underlying disease. If the tricuspid annulus exceeds 21 mm/m^2, then tricuspid annuloplasty (Ring or De Vegas annuloplasty) is a must

to relieve symptoms and this can be done during surgery for other valves.

12.14 Valvular Heart Disease (II)

VK Bahl, Ishwar Chandra Malav

AORTIC STENOSIS

Aetiology

The three common causes of aortic stenosis (AS) are congenital, rheumatic and degenerative. It is seen in patients who are 35 years or older and results from calcification of a congenital or rheumatic valve or of a normal valve that has undergone 'degenerative' changes. Rare causes of AS include obstructive infective vegetations, homozygous type II hyperlipoproteinaemia, Paget's disease of bone, rheumatoid disease, ochronosis, and irradiation.

Pathophysiology

AS can be mild, moderate or severe depending on the constriction and calcification of aortic valve. This causes pressure overload on the left ventricle leading to concentric LV hypertrophy, keeping the cardiac output in the normal range (**Table 1**).

Table 1: Severity of Aortic Stenosis According to Valve Area and Consequent Gradient Across Valve and Echo Doppler Jet Velocity

	Valve Area (cm^2)	Gradient (mm Hg)	Doppler Jet Velocity (m/sec)
Mild	>1.5	<25	<3
Moderate	1 to 1.5	25 to 40	3 to 4
Severe	<1.0	>40	>4

As the severity of AS increases, cardiac output remains within the normal range at rest but fails to increase in proportion to the amount of exercise performed or does not increase at all. Eventually left ventricular failure occurs giving rise to pulmonary hypertension and right-sided heart failure (**Figure 1**).

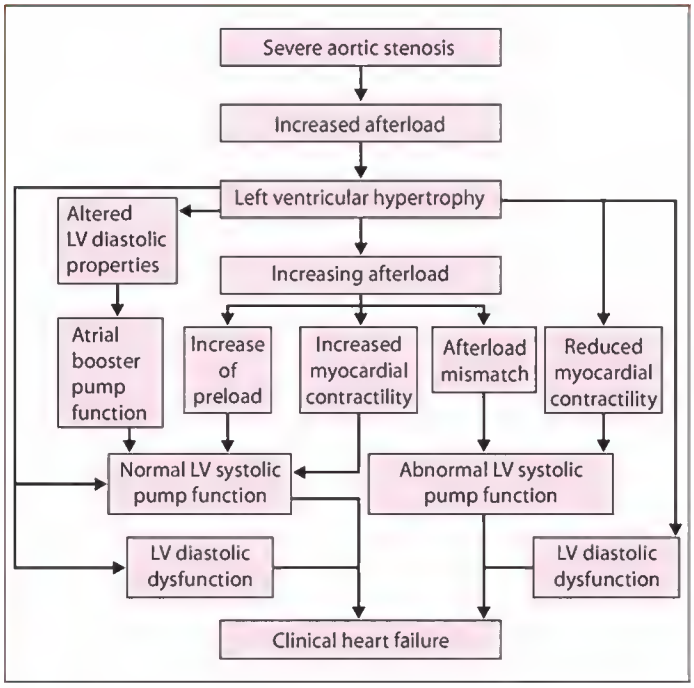

Figure 1: Pathophysiology of aortic stenosis.

Clinical Features

History

Most patients with valvular AS are asymptomatic. The symptoms of AS are angina pectoris, syncope, exertional presyncope, dyspnoea (on exertion, orthopnoea, paroxysmal nocturnal dyspnoea, pulmonary oedema), and the symptoms of heart failure. Sudden cardiac death is stated to occur in 5% of patients with AS. It occurs only in those with severe valve stenosis. Typical angina pectoris occurs with or without associated CAD. Exertional syncope occurring on effort is caused by either systemic vasodilatation in the presence of a fixed or inadequate cardiac output, an arrhythmia, or both. Dyspnoea on exertion, orthopnoea, paroxysmal nocturnal dyspnoea, and pulmonary oedema result from varying degrees of pulmonary venous hypertension. Systemic venous congestion is rather a late phenomenon with enlargement of the liver and peripheral oedema results from increased systemic venous pressure and salt and water retention. There is an increased incidence of gastrointestinal arteriovenous malformations, also known as Heyde syndrome. As a result, these patients are susceptible to gastrointestinal haemorrhage and anaemia. Bleeding can be caused by an acquired defect in the structure of von Willebrand factor. Calcific systemic embolism may occur.

Physical examination

The arterial pulse is slow rising and late peaking (parvus et tardus). A systolic thrill may be felt in the carotid arteries. The jugular venous pulse and the heart size are normal in absence of heart failure. The cardiac impulse is heaving and sustained in character with the presence of palpable S4. The S2 may be single since A2 and P2 are superimposed or A2 is absent or soft. It may be paradoxically split because of late A2. A systolic ejection sound is often present in young patients with valvular AS and patients with bicuspid AV.

An aortic systolic thrill is often present at the base of the heart. The turbulent flow across stenotic aortic valve causes a mid-systolic ejection murmur that peaks late in systole. In older patients, the systolic ejection murmur may be heard only at the apex of the heart (Gallavardin phenomenon). The intensity of the systolic murmur varies from beat to beat. This characteristic is helpful in differentiating AS from MR, in which the murmur is usually unaffected. The murmur of valvular AS is augmented by squatting, which increases stroke volume. It is reduced in intensity during the strain of the Valsalva manoeuvre and when standing.

Severe AS is indicated by slow rising pulse, presence of S4, paradoxical splitting of S2 and late peaking systolic ejection murmur. In the presence of heart failure, the jugular venous

pressure is often increased, the LV is dilated, a third heart sound is present, and the systolic murmur may be very soft or absent. Physical findings are summarised according to severity in **Table 2**.

Table 2: Physical Findings with Varying Severity of Aortic Valve Stenosis

	Mild AS	Moderate AS	Severe AS + Normal LV Function	Severe AS + LV Dysfunction	Severe AS + Heart Failure[a]
Arterial pulse	Normal	Slowly rising	*Parvus et tardus*	*Parvus et tardus*	Small volume
Jugular venous pulse	Normal	Normal	Normal	Normal	±
Carotid thrill	±	±	±	±	±
Cardiac impulse	Normal	Heaving	Heaving, sustained palpable 'a' wave	Heaving	Heaving or reduced
Precordial thrill	±	±	Usually ++	±	–
Auscultation					
S4	–	±	+	+	–
S3	–	–	–	±	+
ESS	+	±	–	–	–
Peak of ESM	Early systole	Mid systole	Late systole	Late to midsystole, soft	Mid systole, soft or absent
S2	Normal	Normal or single	Single or paradoxical	Single	Single

Investigations

The ECG, chest radiograph and echocardiography are baseline investigations required before these patients management plan can be made. The salient features of these investigations in aortic stenosis are shown in **Tables 3 to 5**.

Table 3: ECG Findings

Left ventricular hypertrophy with or without secondary ST-T wave changes. (Pressure overload pattern – ST depression and T wave inversion in lateral leads)

LA enlargement/hypertrophy

Sometimes shows conduction delay, left bundle branch block.

Heart blocks (calcification) can occur rarely

Atrial fibrillation indicates associated mitral disease or heart failure

Table 4: Radiological Abnormalities

Normal sized heart

Dilated proximal ascending aorta (post-stenotic dilation)

Calcification of aortic valve (better seen on fluoroscopy). Calcification does not mean severe AS

Late stages heart size large with pulmonary venous hypertension

Table 5: Echocardiography

Valve thickening and doming on 2D and gradient across valve on CW Doppler

All severe AS in adults will be calcified

Allows definition of valve anatomy, cause of AS, calcification and assessment of severity of AS

Left ventricular hypertrophy, systolic functions (ejection fraction) can be evaluated

Assessment of aortic root dilatation and associated mitral valve disease

Chest X-ray

Cardiac catheterisation and angiography

The main indication for cardiac catheterisation and angiography is to look for associated CAD in these patients before surgery. Otherwise, the lesion can be assessed and followed-up with echocardiography. The gradient on cardiac catheterisation is seen by measuring simultaneous LV and ascending aortic pressures. Cardiac output can be measured by either the Fick principle or the indicator dilution technique.

Natural History

The natural history of AS in the adult consists of a prolonged latent period. Once moderate stenosis is present (jet velocity >3 m/s), the average rate of progression is an increase in jet velocity of 0.3 m/s per year, an increase in mean pressure gradient of 7 mm Hg per year, and a decrease in valve area of 0.1 cm^2 per year. Eventually, symptoms of angina, syncope, or heart failure develop and the outlook changes dramatically. After the onset of symptoms, average survival is 2 to 3 years, with a high-risk of sudden death.

Management

Medical treatment

Patients with severe AS should be cautioned to avoid vigorous athletic and physical activity. Exercise stress testing should be absolutely avoided in symptomatic patients. Symptomatic patients with severe AS are usually operative candidates because medical therapy has little to offer. However, medical therapy may be necessary in patients who are considered to be inoperable (usually because of comorbid conditions that preclude surgery). Diuretics must be used with caution because hypovolaemia may reduce the elevated LV end-diastolic pressure, lower cardiac output, and produce orthostatic hypotension. ACE inhibitors should be used with caution but are beneficial in treating patients with symptomatic LV systolic dysfunction who are not candidates for surgery. Beta-adrenergic blockers can depress myocardial function and induce LV failure and should be avoided in patients with AS. AF should be treated promptly (**Table 6**).

Surgical treatment

Children: In the adolescent or young adult with severe congenital AS, balloon aortic valvotomy is recommended in all symptomatic patients and in asymptomatic patients with a transvalvular gradient greater than 60 mm Hg or in those with ECG showing ST changes at rest or with exercise. The same indications are appropriate for surgical intervention, although balloon valvotomy is probably preferable at experienced centres.

Adults: Aortic valve replacement (AVR) is the treatment of choice for patients of severe AS. AVR is indicated for symptomatic patients with severe AS, patients with severe AS undergoing coronary artery bypass graft surgery (CABG), patients with severe AS undergoing surgery on the aorta or other heart valves, and patients with severe AS and LV systolic dysfunction (ejection fraction less than 0.50).

Table 6: Medical Treatment of Patients with Aortic Valve Stenosis

Antibiotic prophylaxis
Infective endocarditis
Recurrent rheumatic carditis
Restriction of activities
Severe exercise
Competitive sports
Arrhythmias
Prevent and/or control
Restore sinus rhythm, if possible
Cardiac medications (only if essential)
Avoid negative inotropic and proarrhythmic agents if possible
Diuretics – use cautiously
Arteriolar and venodilators – use cautiously
Follow-up of asymptomatic patients
Mild aortic stenosis: every 2 to 5 years
Moderate aortic stenosis: every 6 to 12 months
Develop symptoms: immediate

AORTIC REGURGITATION

Aetiology

Aortic regurgitation (AR) can result from disease of the aortic valve (aortic cusp) and due to dilatation of aortic root. Physical findings can help differentiate between these although echocardiography is required for this. Generally, AR is chronic in most conditions. However, acute AR can be seen in infective endocarditis, aortic dissection and during acute rheumatic fever (Table 7).

Table 7: Aetiology of Chronic Aortic Valve Regurgitation

Aortic root dilatation
Hypertension with aortic root dilatation, atherosclerosis
Various forms of aortitis and arteritis, e.g. giant cell arteritis and Takayasu disease, syphilis
Connective tissue disease, e.g. Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome
Autoimmune diseases, e.g. ankylosing spondylitis, rheumatoid arthritis, and systemic lupus erythematosus
Congenital lesions, e.g. supravalvular or discrete subvalvular aortic stenosis, ventricular septal defect, and aneurysm of the sinus of Valsalva
Aortic valve diseases
Congenital bicuspid valve
Rheumatic heart disease
Previous infective endocarditis

Pathophysiology

Acute AR results in severe volume overload of left ventricle with resultant pulmonary congestion as LV chamber is small and LV and LA pressures are increased markedly. There is a fall in cardiac output due to decrease in stroke volume.

In contrast, in cases of chronic aortic regurgitation eccentric cardiac hypertrophy with the increased preload allows a large increase in LV end-diastolic volume. The large total stroke volume allows forward stroke volume to be normal despite a large regurgitant volume. The large total stroke volume along with the wide pulse pressure produces most of the physical signs of aortic regurgitation. The combined pressure and volume overload stimulates the development of both concentric and eccentric hypertrophy. After many years, LV dysfunction eventually develops, with further LV dilation, elevation of LV filling pressure, decreased EF, and reduced total and forward stroke volume.

Natural History

The rate of progression to symptoms and/or LV systolic dysfunction is about 4.3% per year in asymptomatic patients of severe AR. Sudden death occurs at the rate of less than 0.2% per year in this subgroup of patients. The average rate of symptom onset in patients with depressed LV function is greater than 25% per year. Mortality rates of greater than 10% per year have been reported in patients with angina pectoris and greater than 20% per year in those with heart failure.

Clinical Features

History

Patients with aortic regurgitation in the chronic compensated phase are often entirely asymptomatic. As LV decompensation proceeds, symptoms of dyspnoea, palpitations, orthopnoea, and in advanced cases, paroxysmal nocturnal dyspnoea and peripheral oedema occur. Nocturnal angina occurs due to bradycardia and increased AR with reduced aortic diastolic pressure leading to diminished coronary perfusion.

Physical examination

In patients with chronic, severe AR, the head frequently bobs with each heartbeat (de Musset sign), and the pulses are of the 'water-hammer' or collapsing type with abrupt distention and quick collapse (Corrigan pulse). A bisferiens pulse may be present and is more readily recognised in the brachial and femoral arteries than in the carotid arteries. Traube sign (also known as 'pistol shot sounds') refers to booming systolic and diastolic sounds heard over the femoral artery; Müller sign consists of systolic pulsations of the uvula; and Duroziez sign consists of a systolic murmur heard over the femoral artery when it is compressed proximally and a diastolic murmur when it is compressed distally. Capillary pulsations (i.e. Quincke sign) can be detected by pressing a glass slide on the patient's lip, by transmitting a light through the patient's fingertips, or by exerting gentle pressure on the tip of a fingernail.

Systolic arterial pressure is elevated, and diastolic pressure is abnormally low. Hill sign refers to popliteal cuff systolic pressure exceeding brachial cuff pressure by more than 60 mm Hg. Korotkoff sounds often persist to zero even though intraarterial pressure rarely falls below 30 mm Hg. The point of change in Korotkoff sounds (i.e. the muffling of these sounds in phase IV) correlates with the diastolic pressure.

The apical impulse is diffuse and hyperdynamic and is displaced laterally and inferiorly. The augmented stroke volume may create a systolic thrill at the base of the heart or suprasternal notch, and over the carotid arteries. The PR interval may be prolonged, causing a soft S1. A2 may be normal or accentuated when AR is due to disease of the aortic root but is soft or absent when the valve is causing AR. P2 may be obscured by the early diastolic murmur. Thus, S2 may be absent or single or exhibit narrow or paradoxical splitting. A systolic ejection sound, presumably related to abrupt distention of the aorta by the augmented stroke volume, is frequently audible. S3 gallop correlates with an increased LV end-diastolic volume. Its development may be a sign of impaired LV function, which is useful in identifying patients with severe AR who are candidates for surgical treatment.

The aortic regurgitant murmur, the principal physical finding of AR, is one of high frequency that begins immediately after A2. The murmur is heard best with the diaphragm of the stethoscope while the patient is sitting up and leaning forward, with the breath held in deep exhalation. The severity of AR correlates better with the duration than with the intensity of the murmur. When the murmur is musical ('cooing dove' murmur), it usually signifies eversion or perforation of an aortic cusp. In patients with severe AR and LV decompensation, equilibration of aortic and LV pressures in late diastole abolishes the late diastolic component of the regurgitant murmur. When regurgitation is caused by primary valvular disease, the diastolic murmur is heard best along the left sternal border in the 3rd and 4th intercostal spaces. However, when it is caused mainly by dilation of the ascending aorta, the murmur is often more readily audible along the right sternal border. Many patients with chronic AR have a harsh systolic outflow murmur caused by the increased total LV stroke volume and ejection rate. A mid-diastolic and late diastolic apical rumble, the Austin Flint murmur, is common in severe AR and may occur in the presence of a normal mitral valve. This murmur appears to be created by rapid antegrade flow across a mitral orifice that is narrowed by the rapidly rising LV diastolic pressure caused by severe aortic reflux impinging on the anterior leaflet of the mitral valve. The Austin Flint murmur may be difficult to differentiate from that caused by mitral stenosis (MS), but the presence of an opening snap and a loud S1 in MS and the absence of these findings in AR are helpful clues. As the LV end-diastolic pressure rises, the Austin Flint murmur commences and terminates earlier.

The diastolic murmur of AR may be accentuated when the patient sits up and leans forward or by interventions that raise the arterial pressure, such as squatting or isometric exercise. The intensity of the murmur is reduced by interventions that lower the systolic pressure, such as inhalation of amyl nitrite or the strain of the Valsalva manoeuvre. The Austin Flint murmur, like the murmur of AR, is augmented by isometric exercise and administration of vasopressors and is reduced by amyl nitrite inhalation.

In sharp contrast to the patients with chronic AR patients with acute, severe AR appear gravely ill, with tachycardia, severe peripheral vasoconstriction and cyanosis, and sometimes with pulmonary congestion and oedema. The peripheral signs of AR are often not impressive and certainly not as dramatic as in patients with chronic AR. The normal or only slightly widened pulse pressure may lead to serious underestimation of the severity of the valvular lesion. The LV impulse is normal. S1 may be soft or absent because of premature closure of the mitral valve. Closure of the mitral valve may be incomplete, and diastolic MR may occur. Evidence of pulmonary hypertension, with an accentuated P2, S3, and S4, is frequently present.

The early diastolic murmur of acute AR is lower pitched and shorter than that of chronic AR. The Austin Flint murmur is often present, but is brief and ceases when LV pressure exceeds left atrial pressure in diastole. With premature diastolic closure of the mitral valve, the presystolic portion of the Austin Flint murmur is eliminated (**Table 8**).

Table 8: Physical Findings with Varying Severity of Chronic Aortic Valve Regurgitation

	Mild AR	Moderate AR	Severe AR	Severe AR + Left Ventricular Systolic Dysfunction	Severe AR + Heart Failure + Left Ventricular Systolic Dysfunction
Arterial pulse	Normal	Corrigan + to ++	Corrigan +++	Corrigan ++	Corrigan +
Arterial pressure					
Systolic	Normal	Increased + to ++	Increased +++	Increased ++	Normal +
Diastolic	Normal	Decreased + to ++	Decreased +++ to ++++	Decreased ++ to +++	Decreased +
Pulse pressure	Often normal	Increased + to ++	Increased +++ to ++++	Increased ++ to +++	Increased +
Cardiac impulse	Often normal	Hyperdynamic	Very hyperdynamic visible ± chest may rock	Hyperdynamic	May be hypodynamic
Precordial thrill

Investigations

ECG, chest radiograph and echocardiography are baseline investigations (**Tables 9 to 11**). These reveal features of LV dilatation and volume overload which are the hallmark of chronic aortic regurgitation.

Table 9: ECG Findings

Left axis deviation with left ventricular hypertrophy of volume overload, pattern (prominent Q waves in leads I, aVL, and V3 through V6)

Tall and upright T-waves. Later on inverted T-wave, with ST-segment depressions

Intraventricular conduction defects occur late in the course and are usually associated with LV dysfunction

Table 10: Radiological Abnormalities

Marked enlargement of cardiac shadow

Calcification of the aortic valve uncommon

Dilation of the ascending aorta (more than in AS)

Severe aneurysmal dilation of the aorta suggests aortic root disease (Marfan syndrome, cystic medial necrosis, or annuloaortic ectasia)

Linear calcifications in the wall of the ascending aorta – syphilitic aortitis

Acute AR: less cardiac dilatation and more pulmonary venous hypertension

Table 11: Echocardiography

Transthoracic echocardiography: measurement of LV end-diastolic and end-systolic dimensions and volumes, ejection fraction, and mass. Serial measurements for follow-up

High-frequency fluttering of the anterior leaflet of the mitral valve during diastole

Doppler echocardiography and colour flow Doppler imaging are the most sensitive and accurate non-invasive techniques in the diagnosis and evaluation of AR

AR can be quantified into mild, moderate, and severe AR on above basis

LV size and ejection fraction are normal

Cardiac catheterisation and angiography

Cardiac catheterisation is undertaken when the severity of AR is not clear on non-invasive evaluation. The indications for selective coronary angiography are the same as for aortic stenosis.

Management

Medical treatment

Majority of patients with AR are not candidates for prophylaxis. Patients with mild or moderate AR should be followed clinically and by echocardiography. Asymptomatic patients with chronic, severe AR and normal LV function should be examined at intervals of approximately 6 months. Patients with AR who have limitations of cardiac reserve and/or evidence of declining LV function should avoid heavy exertion. Systemic arterial diastolic hypertension should be treated because it increases the regurgitant flow; vasodilating agents such as nifedipine or ACE-inhibitors are preferred and beta-blocking agents should be used with great caution. AF and bradyarrhythmias are poorly tolerated and should be prevented, if possible.

Vasodilator therapy

There is considerable uncertainty regarding vasodilator therapy. Short-term studies spanning 6 months to 2 years have demonstrated beneficial haemodynamic effects of oral hydralazine, nifedipine, felodipine, and ACE-inhibitors. But, in view of conflicting data, definitive recommendations regarding the indications for long-acting nifedipine or ACE-inhibitors are not possible.

Surgery: Indications

AVR is the treatment of choice in symptomatic patients. Chronic medical therapy may be necessary in some patients who refuse surgery or are considered to be inoperable because of co-morbid conditions. These patients should receive an aggressive heart failure regimen with ACE-inhibitors (and perhaps nitrates), digoxin, diuretics, and salt restriction, but beta-blockers should be avoided. In patients who are candidates for surgery but who have severely decompensated LV function, vasodilator therapy may be particularly helpful in stabilising patients while preparing for operation. Such patients also respond, at least temporarily, to treatment with digitalis glycosides, salt restriction, and diuretics.

AVR is indicated for following patients with AR:

1. Symptomatic patients with severe AR.
2. Asymptomatic patients with chronic severe AR and LV systolic dysfunction (ejection fraction 0.50 or less) at rest.
3. Patients with chronic severe AR while undergoing CABG or surgery on the aorta or other heart valves.
4. Asymptomatic patients with severe AR with normal LV systolic function (ejection fraction greater than 0.50) but with severe LV dilatation (end-diastolic dimension greater than 75 mm Hg or end-systolic dimension greater than 55 mm Hg).

PULMONARY VALVE DISEASE: VALVULAR PULMONIC STENOSIS

Aetiology

Diseases of pulmonary valve (PV) are more often congenital in origin. There are 3 morphological types of congenital pulmonary stenosis (PS): (i) typical dome-shaped PV; (ii) dysplastic PV; and (iii) unicuspid or bicuspid PV.

Pulmonary valve disease as an acquired condition in the adult is extremely rare and may be seen in rheumatic fever, bacterial endocarditis, carcinoid heart disease, etc.

Pathophysiology

PS increases RV afterload and causes right ventricular hypertrophy. Right ventricular hypertrophy under usual circumstances maintains normal pulmonary blood flow. When the normal output is not maintained, right ventricular failure ensues. This occurs in two instances: in neonates with critical PS and in patients with severe PS later in childhood or adulthood. With increased right ventricular systolic pressure, RV compliance decreases and resulting increased right atrial pressure may cause right to left shunt through patent foramen ovale.

Natural History

Adult patients with mild valvular PS do not progress. Moderate PS can progress in 20% of unoperated patients and may require intervention. Patients with severe PS will have had balloon or surgical valvotomy to survive to adult life. Long-term survival in patients with repaired pulmonary valve stenosis is similar to that of the general population, with excellent to good functional class at long-term follow-up in most patients.

Clinical Features

History

Many patients with PS are asymptomatic when first seen. With severe PS, RV hypertrophy develops, and symptoms of dyspnoea, fatigue, chest pain, palpitations, presyncope, and decreased exercise tolerance may occur. If the right atrial (RA) pressure increases, features of right heart failure are present and the opening of a patent foramen ovale may occur along with cyanosis.

Physical examination

Most adult patients with PV or other RVOT obstructive lesions are normal in appearance, although certain phenotypical syndromes occur that include valvular, branch, or peripheral PS. These include the rubella syndrome, Noonan syndrome (60% have a dysplastic valve), Alagille syndrome, Williams syndrome and Keutel syndrome.

Physical examination may reveal a prominent jugular A wave, a right ventricular lift, and possibly a thrill in the 2nd left intercostal space. Auscultation reveals a normal S1, a single or split S2 with a diminished P2 (unless the obstruction is supravalvular, in which case the intensity of the P2 is normal or increased), and a systolic ejection murmur best heard in the 2nd left intercostal space. When the pulmonary valve is thin and pliable, a systolic ejection click will be heard which decreases on inspiration. As the severity of the pulmonary stenosis progresses, the interval between S1 and the systolic ejection click becomes shorter, S2 becomes widely split, P2 diminishes or disappears, and the systolic ejection murmur lengthens and peaks later in systole, often extending beyond A2. An ejection click seldom occurs with dysplastic pulmonary stenosis. Signs of right heart failure are present in advanced stages (**Table 12**).

Investigations

Electrocardiogram

With pulmonary valve stenosis, the electrocardiogram reflects the haemodynamic severity of the lesion. With severe pulmonary stenosis, the electrocardiogram shows right axis deviation and right ventricular hypertrophy with a qR wave in the V_1 lead. With moderately severe pulmonary stenosis, there is an rSR' in the V_1 lead. With severe right ventricular hypertrophy, peaked P waves in the II, III, and aVF leads reflect right atrial abnormality.

Chest radiograph

With severe pulmonary stenosis, right ventricular hypertrophy is manifested by lifting of the apex off the left hemidiaphragm and filling in of the retrosternal space in the lateral chest radiograph. The heart size on chest radiograph is usually normal unless there is RV failure or an associated cardiac lesion. Dilatation of the main and left pulmonary artery is common in doming but not in dysplastic PS or in subpulmonic stenosis. Calcification may be seen in older patients. The RA and RV may be enlarged if there is RV decompensation.

Echocardiography

The echocardiogram is generally definitive. A Doppler gradient is evident, the valve mobility can be assessed along with subpulmonic or supravalvular stenosis, the size and function of the RV can be determined and any vegetation on pulmonary valve can be assessed. Continuous, pulsed, and colour-flow Doppler confirm any pulmonary regurgitation, tricuspid regurgitation, or right-to-left shunting. Saline microcavitations can also confirm a right-to-left shunt. When the PS is severe, interventricular septal flattening may occur. In patients with a dysplastic valve, the valve is thickened and immobile, and there is lack of a dilated pulmonary main trunk. With carcinoid involvement of the pulmonary valve, thickening and lack of flexibility can be seen.

Table 12: Parameters for Severity of Pulmonary Stenosis

Haemodynamic Evaluation: Degree of Obstruction	Haemodynamic Evaluation: Peak Systolic Doppler Gradient (mm Hg)	Haemodynamic Evaluation: RV Systolic Pressure (mm Hg)	Physical Examination
Trivial	<25	<50	—
Mild	25 to 49	50 to 74	**Jugular venous pressure:** Normal except mildly increased 'a' wave **RV palpation:** No RV lift **Auscultation:** Ejection sound present (decreases with inspiration: systolic ejection murmur increases with inspiration and ends in midsystole) generally grade 3/6 or less
Moderate	50 to 79	75 to 100	**Jugular venous pressure:** Elevated; 'c-v' wave if present
Severe	>80	>100	Increased 'a' wave **RV palpation:** RV lift; generally no impulse over PA; thrill may be present **Auscultation:** No ejection sound; prolonged RV outflow tract systolic ejection murmur with no P2 or wide split of second sound if P2 present; murmur often 3-6/6 in intensity; right-sided S4

Cardiac catheterisation and angiography

Cardiac catheterisation is rarely necessary for diagnosis. Gradients above, at, and below the PV should be obtained. A peak RV systolic value of <35 mm Hg and a systolic PV gradient of <10 mm Hg are the upper limits of normal. RV function can be assessed, and shunting through any patent foramen ovale can be defined. RV angiography helps to define contractile function, the presence of infundibular obstruction, and the mobility of the PV. Pulmonary angiography assesses the degree of PR and any stenotic lesions in the main, branch, or peripheral pulmonary arteries.

Management

No intervention is required in mild PS. With severe PS, right ventricular failure most commonly occurs after the fourth decade of life. With severe pulmonary valve stenosis, surgical repair in the past has given good long-term results. At present, balloon valvotomy is the treatment of choice, even in the adult with congenital pulmonary valve stenosis. Immediate and intermediate results are similar to those of surgery. Following are the recommendations regarding percutaneous or surgical intervention in patients with valvular pulmonary stenosis:

1. Balloon valvotomy is recommended for asymptomatic patients with a domed pulmonary valve and a peak gradient greater than 60 mm Hg or a mean gradient greater than 40 mm Hg (in association with less than moderate pulmonic valve regurgitation).
2. Balloon valvotomy is recommended for symptomatic patients with a domed pulmonary valve and a peak gradient greater than 50 mm Hg or a mean gradient greater than 30 mm Hg (in association with less than moderate pulmonic regurgitation).
3. Surgical therapy is recommended for patients with severe PS and an associated hypoplastic pulmonary annulus, severe pulmonary regurgitation, subvalvular PS, or supravalvular PS.

PULMONARY REGURGITATION

Aetiology

By far, the most common cause of pulmonic regurgitation (PR) is dilation of the valve ring secondary to pulmonary hypertension (of any aetiology) or to dilation of the pulmonary artery, either idiopathic or consequent to a connective tissue disorder such as the Marfan's syndrome. The second most common cause of PR is infective endocarditis. Less frequently, PR is iatrogenic and is induced at the time of surgical treatment of congenital PS or tetralogy of Fallot. Less common causes include trauma, carcinoid syndrome, rheumatic involvement, injury produced by a pulmonary artery flow-directed catheter, syphilis, and chest trauma.

Pathophysiology

In pulmonary valve regurgitation, there is a volume overload of the right ventricle, resulting in dilatation of the right ventricle and, eventually, eccentric right ventricular hypertrophy. With the increased right ventricular stroke volume, there is dilatation of the proximal pulmonary arteries. In the absence of pulmonary hypertension, even severe volume overload of the right ventricle is well-tolerated for many years; however, the prognosis is not entirely benign, because right ventricular dysfunction and right heart failure can occur.

With pulmonary hypertension, the patient has right ventricular hypertrophy, and pulmonary regurgitation occurs with dilatation of the pulmonary valve annulus. The degree of pulmonary regurgitation is usually not severe and is rarely haemodynamically significant. Right ventricular dilatation and dysfunction leading to right ventricular failure are more frequent in these patients as a result of the right ventricular systolic overload rather than as a result of the pulmonary regurgitation.

Clinical Features

History

Patients with pulmonary hypertension have symptoms related to the cause of the pulmonary hypertension. Patients with PR owing to endocarditis have symptoms related to the infection such as fever, left heart failure if the mitral or aortic valve is infected, or septic pulmonary emboli with an infected tricuspid valve. When the patient has PR due to carcinoid tumour, the symptoms are dominated by those seen with metastatic carcinoid tumour.

Isolated PR causes RV volume overload and may be tolerated for many years without difficulty unless it complicates, or is complicated by, pulmonary hypertension.

Physical examination

The physical findings in isolated PR are those of a prominent right ventricular anterior precordial lift, frequently with a lift in the second left interspace that is caused by the dilated pulmonary artery. There is also a diastolic murmur along the left sternal border in the second and third interspaces. With isolated pulmonary valve regurgitation, this murmur starts 0.04 to 0.06 seconds after the aortic second sound and is characteristically short and low-pitched.

If pulmonary hypertension is present, the second heart sound is single and accentuated, and the diastolic murmur starts with P2 and is high-pitched and decrescendo in character. This is called the Graham-Steell murmur.

If the pulmonary regurgitant volume is large, an early peaking systolic ejection murmur ending before the second heart sound may be heard and can be grade 3 to 4/6 in loudness.

Investigation

Electrocardiogram

In the absence of pulmonary hypertension, PR often results in an ECG that reflects RV diastolic overload, i.e. an rSr (or rsR) configuration in the right precordial leads. PR secondary to pulmonary hypertension is usually associated with ECG evidence of RV hypertrophy.

Chest radiograph

Both the pulmonary artery and the right ventricle are usually enlarged, but these signs are nonspecific.

Echocardiography

Two-dimensional echocardiography shows RV dilation and in patients with pulmonary hypertension, RV hypertrophy as well. RV function can be evaluated. Abnormal motion of the septum

characteristic of volume overload of the right ventricle in diastole and/or septal flutter may be evident. The motion of the pulmonic valve may point to the cause of the PR. Doppler echocardiography is extremely accurate in detecting PR and in helping to estimate its severity.

Management

PR alone is seldom severe enough to require specific treatment. Treatment of the primary condition, such as infective endocarditis, or the lesion responsible for the pulmonary hypertension, such as surgery for mitral valvular disease, often ameliorates the PR. Surgical treatment directed specifically at the pulmonic valve, such as patients with severe PR caused by surgical correction of tetralogy of Fallot, is required only occasionally because of intractable right heart failure. Under such circumstances, valve replacement may be carried out, preferably with a porcine bioprosthesis or a pulmonary allograft.

MULTIVALVULAR DISEASE

Multivalvular involvement is caused frequently by rheumatic fever, myxomatous heart disease, Marfan's syndrome and other connective tissue disorders. Degenerative calcification of the aortic valve may be associated with degenerative mitral annular calcification and cause AS and MR. Different pathological conditions may affect two valves in the same patient, such as infective endocarditis on the aortic valve causing AR and ischaemia causing MR.

In patients with multivalvular disease, the clinical manifestations depend on the relative severities of each of the lesions. Usually, the proximal lesion tends to mask the distal lesion.

It is important to recognise multivalvular involvement preoperatively because failure to correct all significant valvular disease at the time of operation increases mortality considerably. In patients with multivalvular disease, the relative severity of each lesion may be difficult to estimate by clinical examination and noninvasive techniques because one lesion may mask the manifestations of the other. For this reason, patients suspected of having multivalvular involvement and who are being considered for surgical treatment should undergo careful clinical evaluation and both full Doppler echocardiographic evaluation and right- and left-cardiac catheterisation and angiography.

Mitral Stenosis and Aortic Regurgitation

Approximately 10% of patients with mitral stenosis (MS) have severe rheumatic AR. In keeping with the general observation that a proximal lesion may mask a distal lesion, significant AR may be missed in patients with severe MS. On the other hand, MS may be missed or, conversely, may be falsely diagnosed on clinical examination of patients with obvious AR. An accentuated S1 and an opening snap in a patient with AR should suggest the possibility of mitral valvular disease. However, an Austin Flint murmur is often inappropriately considered to be the diastolic rumbling murmur of MS. These two murmurs may be distinguished at the bedside by means of amyl nitrite inhalation, which diminishes the Austin Flint murmur but augments the murmur of MS; isometric handgrip and squatting augment both the diastolic murmur of AR and the Austin Flint murmur. Echocardiography, particularly pulsed Doppler echocardiography, is of decisive value in detecting MS and MR.

Since double-valve replacement is associated with increased short-term and long-term risk, balloon mitral valvotomy can be the first procedure. If this causes LV dilation, AVR can follow. Alternatively, open mitral valvotomy and AVR can be performed at the same time.

Aortic Stenosis and Mitral Stenosis

This combination is most commonly caused by rheumatic heart disease. The murmur of MS may not be easily discerned in presence of severe aortic valve stenosis. The loud systolic murmur of AS is also heard at the apex and hypertrophied left ventricle may mask the diastolic rumble of MS. Similarly, the low cardiac output resulting from severe MS may result in underestimation of the severity of AS as the resulting gradient is low. The echocardiogram exhibits pathology in both valves, and the severity of MS based on pressure half time is unaffected by AS. The peak and mean gradients are underestimated because of reduced cardiac output.

Percutaneous balloon valvotomy for MS may result in increased cardiac output and acute LV failure may develop when the severity of AS has not been recognised. The appropriate treatment consists of aortic valve replacement and mitral valve repair or replacement.

Aortic Stenosis and Mitral Regurgitation

This combination of lesions is usually caused by rheumatic heart disease. The combination of severe AS and mitral regurgitation (MR) is a hazardous one. AS augments the volume of MR flow, whereas the presence of MR diminishes the ventricular pre-load necessary for maintenance of the LV stroke volume in patients with AS. The result is a reduced forward cardiac output and marked left atrial and pulmonary venous hypertension. The development of AF (due to left atrial enlargement) has an adverse haemodynamic effect in the presence of AS. The physical findings may be confusing. In patients with severe AS and MR, both valves must usually be treated surgically by AVR and, if possible, by MV repair or MVR.

Aortic Regurgitation and Mitral Regurgitation

This relatively frequent combination of lesions may be caused by rheumatic heart disease, myxomatous degeneration, or by dilation of both annuli in patients with connective tissue disorders. The left ventricle is usually greatly dilated. The clinical features of AR usually predominate. When both valvular leaks are severe, this combination of lesions is poorly tolerated. The normal mitral valve ordinarily serves as a 'backup' to the aortic valve, and premature (diastolic) closure of the mitral valve limits the volume of reflux that occurs in patients with acute AR. With severe combined regurgitant lesions, regardless of the cause of the mitral lesion, blood may reflux from the aorta through both chambers of the left-side of the heart into the pulmonary veins. Physical and laboratory examinations usually show evidence of both lesions. An S3 and a brisk arterial pulse are frequently present. The relative severity of each lesion can be assessed best by Doppler echocardiography and contrast angiography. This combination of lesions leads to severe LV dilation.

MR that occurs in patients with AR secondary to LV dilation often regresses following AVR alone. If severe, the MR may be

corrected by annuloplasty at the time of AVR. An intrinsically normal mitral valve that is regurgitant because of a dilated annulus should not be replaced.

Mitral Stenosis and Tricuspid Regurgitation

If pulmonary hypertension is severe and the tricuspid valve anatomy is not grossly distorted, improvement in tricuspid regurgitation (TR) can be expected after correction of MS. On the other hand, if there is severe rheumatic deformity of the tricuspid valve, dilatation of the tricuspid annulus, or severe TR, competence is likely to be restored only by surgery.

If the mitral valve anatomy is favourable for percutaneous balloon valvotomy and there is concomitant pulmonary hypertension, valvotomy should be performed regardless of symptom status. After successful mitral valvotomy, pulmonary hypertension and TR almost always diminish.

If mitral valve surgery is performed, concomitant tricuspid annuloplasty should be considered, especially if there are preoperative signs or symptoms of right-sided heart failure, rather than risking severe persistent TR, which may necessitate a second operation. Annuloplasty of the tricuspid valve based on tricuspid dilatation (tricuspid annulus diameter >35 mm) improves functional status independent of degree of TR.

Triple-Valve Disease

Haemodynamically significant disease involving the mitral, aortic and tricuspid valves is uncommon. Patients with trivalvular disease may present in advanced heart failure with marked cardiomegaly, and surgical correction of all three valvular lesions is imperative. However, triple-valve replacement is a long and complex operation. It should be avoided, if possible. In many patients with trivalvular disease, it is possible to replace the aortic valve, repair the mitral valve, and perform a tricuspid annuloplasty or valvuloplasty.

When multiple prosthetic valves must be inserted, it is logical to select either two bioprostheses or two mechanical prostheses for the left side of the heart. If the patient is to be exposed to the hazards of anticoagulants for one mechanical prosthesis, it seems unreasonable to add the potential risks of early failure of a bioprosthesis. However, if two mechanical prostheses are selected for the left side of the heart, the use of a bioprosthesis in the tricuspid position is suggested.

12.15 Infective Endocarditis

Shyam S Kothari

Infective endocarditis (IE), an endovascular microbiological infection of cardiovascular structures, remains a serious illness. The various considerations in the diagnosis and management of IE provide such a challenge that it can be said that 'know IE and you know medicine.' In this chapter, salient aspects of IE are recapitulated with an emphasis on Indian experience.

EPIDEMIOLOGY

Despite several advances in the field of medicine, the incidence of IE has not reduced significantly over last 50 years, but the pattern of the disease has changed. IE occurs in 1-6/100,000 patient years in the Western world. There are no systematic population based data from India, but the incidence may be higher due to large number of rheumatic heart disease (RHD) and untreated congenital heart disease (CHD) patients in India. Hospital-based studies show a higher, prevalence of underlying RHD, lower pick up of vegetations and blood cultures and greater mortality in the Indian series as compared to the western data. These trends are shown in **Table 1**.

IE is uncommon in infants and children and the incidence increases with age. Males outnumber females (M:F = 1.7:1 in general, but up to 7:1 in patients above 70 years of age in some series). About 75% of episodes occur in diseased native valves, whereas infection on a normal native valve is increasingly seen as nosocomial infection in immunocompromised, elderly, diabetics, and in intravenous drug users. The relative proportions of valves involved in IE is interesting and possibly result from the difference in the pressure gradients across the valves. In an autopsy series of 1,024 patients in the pre-antibiotic era, the proportions of involved valves were mitral valve in 86 %, aortic 55%, tricuspid valve 19% and pulmonary valve in 1.1%. Nowadays higher proportion of aortic valve involvement may be seen in elderly and tricuspid valve in drug addicts. The different underlying lesions have different risks of being affected by IE, perhaps depending on the strength of the abnormal haemodynamic jets. For example, IE is very uncommon in atrial septal defect where the blood flows from left to right atrium with low pressure difference compared to ventricular septal defects with high pressure gradients between the ventricles. It is also uncommon in patients with Eisenmenger's syndrome where the difference in pressures between the chambers is abolished and there are no high velocity jets. Further, in mitral valve lesions also, IE is uncommon in patients of mitral stenosis compared to patients with mitral regurgitations. The general risks are shown in **Table 2**.

It is clinically useful to consider IE (1) in terms of the tempo of the disease (acute or subacute); (2) in terms of the valve involved (diseased native, normal native or prosthetic valve); and (3) in terms of the causative organism (common organism like *Streptococcus viridans*, or virulent like methicilin resistant *Staphylococcus aureus* or fungi, or unknown organisms). The major differences between acute and sub acute bacterial

Table 2: Risk of IE in Various Cardiac Lesions

High Risk	Moderate Risk	Low Risk
Prosthetic heart valves	Mitral valve prolapse with MR	Mitral valve prolapse without MR
Previous IE	Degenerative valvular disease in elderly patients	Isolated ASD
Tetralogy of Fallot	Tricuspid regurgitation	Cardiac pacemaker
Especially with BT shunt	Pure mitral stenosis	Prior CABG
PDA	Tricuspid stenosis	Prior Kawasaki's disease
Aortic regurgitation	Pulmonary stenosis	Rheumatic fever without valvular dysfunction
Mitral regurgitation	Hypertrophic obstructive cardiomyopathy	
Mitral stenosis with regurgitation		
VSD		
Coarctation of aorta		

endocarditis are shown in **Table 3**. These considerations influence the treatment and prognosis. Thus, subacute IE caused by *Streptococcus viridans* in a RHD patient is viewed differently from staphylococcal endocarditis on a native mitral valve in a patient on maintenance haemodialysis.

Table 3: Salient Features of Acute and Sub-acute Bacterial Endocarditis (Significant Overlap is Seen)

	Acute	Sub-acute
Onset (from bacteraemia)	Within 2 weeks	Within 2 months
Progression	Days to weeks	Weeks to months
Organism	Virulent (i.e. *Staphylococcus aureus*)	Less virulent (i.e. *Streptococcus viridans*)
Structural heart disease	Absent	Present

PATHOGENESIS

The hallmark of IE is the presence of vegetation in the endocardium of the heart. Normal endocardium is resistant to infection, but a traumatised endocardial surface is exposed to platelets and fibrin. Local trauma from an abnormal blood jet or systemic factors may result in unhealthy endocardium. A coagulum of platelet and fibrin is formed on the endocardial surface resulting in non-bacterial thrombotic endocarditis (NBTE). Any subsequent bacteraemia may colonise such vegetation. The vegetation are avascular and the fibrin layer possibly provide a barrier from leucocytes, thus bacteria rapidly grow within these vegetations. Early treatment may eradicate infection from vegetation but after 3 days it is not possible to get rid of the bacteria from vegetations due to high density and other dynamics of bacterial growth, thus underlying the need for long-term bactericidal antibiotics therapy for IE. The micro-organisms grow within vegetation and shed bacteria in circulation frequently; some of the colonies become metabolically inactive and hence difficult to eradicate. The infection can spread locally, or systemically.

The vegetation may occur at the valves, on mural endocardium (e.g. in front of the VSD jet), in aorta (beyond coarctation site), in pulmonary arteries (at the ductus arteriosus insertion site) or in aneurysms. In the valves typically, vegetation occur on the atrial surface in mitral valve in a patient with mitral regurgitation and ventricular surface of aortic valves in patients with aortic regurgitation respectively. These observations are consistent with Rod Board's hypothesis of bacterial colonisation resulting from venturi effects of jet lesions. In Libman-Sacks endocarditis, and in marantic IE, the vegetation occur at the ventricular surface of MR, on chordae tendineae, etc. In a patient of aortic regurgitation due to IE, mitral valve may become infected and the vegetation are seen at the chordae where the jet of aortic regurgitation strikes the mitral valve (**Figure 1**). The vegetation of IE may grow from few millimetres to as large as few centimetres and may obstruct the valve. These may regress with treatment or may disappear due to embolisation. Increasing size of vegetation during treatment usually, but not always, indicate persistent infection and treatment failure. Large vegetations are seen in fungal endocarditis, and also with Gram-negative IE but size of vegetation is not a reliable criterion for the diagnosis of the organism. The clinical features of the disease result from infection, local destruction in the heart, embolism, and immune activation.

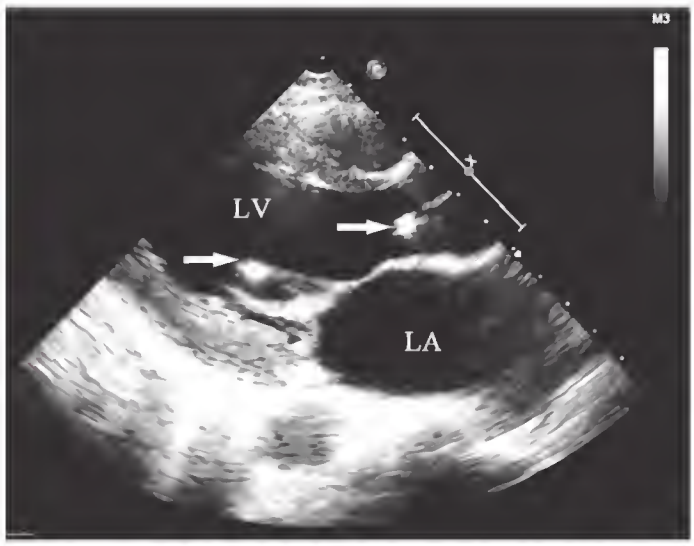

Figure 1: Echocardiogram (parasternal long axis view) showing vegetations on aortic and mitral valves (arrows).

LA = Left atrium; LV = Left ventricle.

THE ORGANISMS

It is good to remember that while many micro-organisms may cause IE, most episodes are caused by only a few bacterial species of streptococci and staphylococci. The organism causing IE have certain peculiarities, viz. ability to adhere to the endothelial surface, or the ability to penetrate normal endothelial barrier. It is hypothesised that factors such as fibronectin binding proteins on *S. aureus*, clumping factors or glucans on *S. viridans* are important in this regard. Despite frequent occurrence of Gram-negative bacteraemia, organisms such as Klebsiella, or Salmonella rarely cause IE. Generally speaking, nearly 75% to 80% of the episodes are caused by streptococcal and staphylococcus sp., 5% Gram-negative bacilli (of HACEK groups mainly, and Pseudomonas), 5% fungi, and rest by other uncommon organisms including coxiella, legionella, anaerobes (<1%), and others. The other organism must be considered in the clinical context. For example, fungal IE in patients who have received broad spectrum antibiotics for long time for some systemic infection, Brucella or Q fever in a dairy worker or a veterinarian who has chronic IE with large vegetations and negative blood cultures. Bartonella in a HIV positive homeless destitute, but such association or background is not enough to establish the diagnosis. A brief discussion about the common organisms is in order.

Streptococci

Streptococcus viridans species (*S. mitis*, *S. salivarius*, *S. sanguinis*) is a normal commensal organism of the oropharynx and still remains the commonest cause of native valve IE in the average community setting. Most *Streptococcus viridans* are penicillin sensitive although some strains may require higher minimum inhibitory concentration (MIC). Some strains of streptococci (e.g. abiotrophia) are fastidious and require special culture medium and also higher MIC for cure.

Streptococcus bovis has emerged as a common cause of IE in elderly. Isolation of this organism in blood culture in a patient mandates the evaluation of gastrointestinal tract for colonic cancer or polyps.

Streptococcus faecalis (enterococci) is a commensal of genitourinary tract and is an uncommon cause of community acquired IE. The microbe has a high order of resistance to antibiotics. It causes a recalcitrant form of IE needs special considerations for treatment. Occasionally, it can cause acute form of IE.

B streptococcus may cause IE in neonates or in the post-partum setting. β haemolytic streptococci, the cause of acute rheumatic fever, causes a destructive IE but is a very rare occurrence.

Staphylococci

Staphylococcus aureus has been increasingly seen now and has become the commonest cause of IE in some series. Typically, it causes acute IE with local destruction, CNS embolism and metastatic septic foci. *S. epidermidis*, a coagulase negative *Staphylococcus* is a normal commensal of skin flora and is the commonest cause of early prosthetic valve IE . It may also cause destructive IE. *S. lugdunensis*, another coagulase negative *Staphylococcus* has emerged as cause of destructive IE. *S. aureus* can also cause subacute IE.

Other Organisms

Gram-negative organism of HACEK group cause IE in <5% cases. (HACEK include *Haemophilus, Actinobacter, Cardiobacter, Eikenella, Kingella). Pseudomonas aeruginosa* rarely cause IE, but may be an important cause in drug addicts, in HIV positives, and in nosocomially acquired IE. Fungi are dreaded cause of IE (*candida* or aspergillosis) and typically occur in a settings for fungal sepsis like post-operative prosthetic valve IE. Anaerobes cause <1% IE. Other interesting causes of IE include brucella, chlamydia, psittacosis, legionella, mycobacterium, tropheryma whippelei, bartonella, etc.

CLINICAL FEATURES

IE has protean manifestations and is not uncommon for patients to remain undiagnosed for months as PUO. With the advent of echocardiography, the diagnosis is facilitated very significantly, still patients may present to neurology, nephrology or haematology departments with different complaints. The clinical manifestation of IE can be grouped into four headings:

1. **Constitutional Features**

   Anorexia, fatigue, night sweats and feeling unwell are universal. Weight loss can be quite significant and is attributed to cytokine activation. Aches, pains, arthralgia and backache are common and may be the presenting features confusing the primary diagnosis.

   Fever is almost always present in IE, and has no typical pattern. Recurrent chills at onset favours a bacteraemic illness, though frank rigors are uncommon. The usual temperature varies from 100 °F to 103 °F, but hectic fever with rigors may be seen in acute IE. Fever is sometimes not reported by the patient and may not be conspicuous in nearly 5% of patients such as frail elderly, renal failure, due to prior antibiotic use or in immunosuppressed patients.

2. **Cardiac Involvement**

   A heart murmur is present in the majority of patients, but may be faint or absent in right-sided endocarditis. The patient may have a murmur from a previous lesion and change in murmur may not be appreciable. Changing murmurs or new murmur may occur with valve destruction, chordal rupture, paravalvular leaks or fistulae formation. Local invasion and destruction occur rapidly in acute IE but may occur with all IE, albeit, slowly and uncommonly with usual *Streptococcus viridans* IE. *Staphylococcus aureus, S. lugdunensis*, beta-haemolytic streptococci and pseudomonas cause rapidly destructive IE. Extension beyond valve ring resulting in annular abscess, myocardial abscesses, pericardial extension and tamponade or coronary artery embolism may all lead to worsening cardiac status, but the valve lesions are the most significant amongst all of these as the cause of heart failure. Mechanical complication may occur even after bacteriological cure of IE. Congestive heart failure is the commonest cause of death from IE.

3. **Embolism**

   Embolisms to organs is often clinically silent, although detected in autopsy in 60%. Any organ may be involved by embolism of the vegetations from IE, but brain, spleen, kidneys, bowels, limbs, or lungs (in right-side IE) predominate. Embolism occurs in nearly 50% of patients with IE and is the presenting feature in many patients because it often occurs early in the disease. The incidence of embolism is high in the first 2 weeks of illness and falls rapidly with treatment even though it may occur after full treatment in some patients. It occurs at a rate of 12 per 1,000 patient days in the initial 2 weeks, but decrease to 1.2 per 1,000 patient days after 2 weeks of treatment. It is difficult to predict embolism. Various features such as size, shape, mobility, location of vegetations, causative organism and other characteristics of patients have been studied to predict embolisation. Vegetations more than 10 mm, vegetations on anterior mitral leaflet (which moves twice during diastole), and that caused by *S. aureus*, fungi, or Gram-negative bacilli are more likely to embolise. Mobility of vegetation is difficult to quantify and some studies suggest that mobility is only a matter of size of vegetation and not independent predictor of embolism. Increasing size of vegetation during treatment is associated with higher risks of embolism. In one study, presence of anti-phospholipid antibodies predicted embolism, but in general, predicting embolisation in an individual patient is not possible.

   Embolism occurs at branch point of arteries. In CNS, 90% of embolism occurs in middle cerebral artery territory leading to serious neurological deficits. Embolism to splenic artery is common but clinically may not be apparent or may cause splenic infarct. Pain in left hypochondrium referred to left shoulder in a patient of IE is suggestive of splenic infarct. Similarly, renal infarct may cause loin pain, hypertension, and haematuria. Mesenteric ischaemia, and limb threatening ischaemia may also occur with embolism. Bacteria or fungi can be grown from materials recovered at surgery. Embolism of IE is not influenced by anticoagulant or antiplatelet treatment. Right-sided IE is regularly accompanied by pulmonary embolism leading to lung infiltrate, consolidation, infarct, abscess or pulmonary artery pseudoaneurysms. Mycotic aneurysms result from embolisation to vasa vasorum of the vessels and subsequent weakness of the wall or from direct arterial wall

infection. These are most commonly seen in the brain and may result in catastrophic haemorrhage. Mycotic aneurysm are more common with *S. viridans* than staphylococcal IE.

4. **Immunological Manifestation**

IE results in intense humoral and cellular immune stimulation. Peripheral stigmata of IE are supposed to result from immune complex deposition although septic embolism may account for some of these.

Osler's Nodes

Typically, 2 to 15 mm pea-shaped, painful reddish nodules in the pulp of fingers and toes are seen in classical IE. These are uncommonly seen in acute IE, and possibly result from vasculitis. Sometimes, bacteria have been recovered from these lesions. Similar lesions may occur in gonococcal infection, haemolytic anaemia, SLE, marantic endocarditis, and in extremities with cannulated infected arterial lines. Lesions are transient, multiple and do not ulcerate.

Janeway's Lesion

Flat macular erythematous non-painful lesion in palms and soles, often seen in acute *Staphylococcus* IE. Bacteria may be isolated from these.

Petechiae and Purpura

Petechiae are common, may occur in crops, seen after few weeks of infection and usually identified in sublingual, subconjunctival areas, but can occur anywhere in the skin. They represent vasculitis, thrombocytopaenia, or sepsis. Streaky lines in nails are not characteristic of IE and may occur from trauma or other causes in many hospitalised patients.

Roth's Spots

Retinal haemorrhages with white centres are Roth's spots. These lesions are seen in number of conditions and represent capillary haemorrhages, not bacterial infection. These are also seen in anaemia, leukaemia, vasculitis, diabetes, carbon monoxide poisoning and rarely in HIV. These lesions undergo changes quickly.

INVESTIGATIONS

Haematological

Normocytic normochromic anaemia of chronic disease is the rule in IE. Leucocytosis is not common and normal counts are seen in 70% to 80%. Acute IE (staphylococcal and others), and fungal infection cause leucocytosis. Shift to left and toxic granulations may occur. ESR is very useful, though non-specific test, and should not be omitted. Mean ESR in IE is in the range of 50 to 60 mm in first hour. (High ESR as minor criteria is >30 mm in patients less than 60 years, and >50 for older patients). CRP (>100 mg/L) is faster to resolve than ESR. A very high ESR helps in narrowing differential diagnosis in patient of PUO.

Other haematological tests are sometimes useful. Rheumatoid factor is positive in half of the cases, specially with longer clinical course. Circulating immune complex are seen in majority of patients but have no major additional value. Cryoglobulinaemia may occur. Non-specific elevation of gamma globulin is common. Serum complement is reduced in patients with glomerulonephritis and IE. Anti-streptolysin O (ASLO) is not elevated (except in the rare β haemolytic streptococcal IE). Elevated procalcitonin is seen with sepsis, more so in staphylococcal sepsis. Serum ferritin, acute phase reactant may be elevated early in the course, but in chronic phase it is more often elevated in malignancy and Still's disease.

Urine

Microscopic haematuria is common. Gross haematuria suggests renal infarct. Proteinuria, casts may occur in patients with glomerulonephritis. Rapidly progressive crescentic glomerulonephritis sometimes occurs in IE and it resolves with antibiotics treatment, and/or with plasmapheresis.

Blood Culture

Blood culture must be carefully obtained with antiseptic precautions. It is recommended to take three sets of cultures (at least 1 hour apart), and from two separate venipunctures, (10 mL blood in adults) in each bottle is required, in sicker patients, empirical treatment may be started after taking culture; but in stable patients who have received prior antibiotics waiting for 48 hours before taking cultures should be practised. Addition of polysulphonates or resins to culture bottles may be helpful. Better culture medium like BACTEC improve the positivity rates and yield results early but are not widely available. If there is no growth after 5 to 7 days and IE is suspected, subcultures on special media should be done. But chances of contaminant growth also increase after 5 to 6 days. Fastidious organisms like nutritional variant *S. viridans*, or HACEK organisms need special culture media techniques.

Help of microbiologist should be sought early in the disease and since each laboratory may have local protocols, this should be discussed. Acridine dye test is sometimes useful in identifying organism even with obviously negative cultures.

Isolation of a microbe typically known to cause IE is highly likely to be the significant, but sometimes it is difficult to distinguish contaminant from the culprit, or simple bacteraemia from IE. Staphylococcal bacteraemia is associated with IE in nearly a quarter but enterococcal bacteraemia have IE in only 10% of patients. Community acquired bacteraemia, persistent bacteraemia in the absence of obvious focus favour the diagnosis of IE. Diphtheroids, acinetobacter are common commensals and contaminants but isolation from multiple cultures may be significant. Polymicrobial IE is uncommon except in drug addicts.

Several bacteria do not grow in the culture medium and serological tests or histological confirmation is required for the diagnosis. Example includes Brucella, Q fever, bartonella, legionella. More recently PCR techniques are utilised for the diagnosis of some of these, and in future wider availability of PCR probes for usual IE will make the diagnosis quick for routine cases as well. Identification of bacterial 16SrRNA and specific DNA after amplification can identify responsible agent from tissues obtained at operation in culture negative cases. However, PCR may remain positive in treated old IE as well. Similarly, histological demonstration of micro-organism from valves, sometimes, may represent dead bacteria.

Antibiotic sensitivity of the organism is a vital information for selection of antibiotics, though sometimes *in vivo* sensitivity may be different. Finding the minimum inhibitory concentration (MIC) to antibiotic like penicillin is useful in the treatment of IE, but is not widely practised.

ECHOCARDIOGRAPHY

Echocardiography is the cornerstone of the diagnosis of IE and has revolutionised the management of IE. Presence of vegetations, new onset valve regurgitation, annular abscess or valve dehiscence are diagnostic of IE. Of these, vegetations are most important. Typical vegetation of IE is seen as oscillating mass few mm to cm(s) in size attached to valve or mural endocardium having an independent mobility. Vegetations more than 2 mm are identifiable by echo-cardiogram, but the identification of vegetation is dependent on the experience of operator. Vegetations may be confused with some normal tissues like Chiari malformations in right atrium, parts of normal chordae, surgical stitch. Vegetations may also occur in other disease like marantic and Libman-Sacks endocarditis or anti-phospholipid antibody syndrome and in acute rheumatic fever. Sometimes, the vegetations may be too small or sessile, or represent previous treated IE. Further, up to 20% patients may have limited echocardiographic windows. Thus, possibilities of misdiagnosis and missed diagnosis of IE remain even with echocardiography. In general, transthoracic echocardiography has a sensitivity of 65% to 70% for the diagnosis of IE. Transoesophageal echo-cardiography (TEE) is preferred in doubtful cases, in poor echo-cardiographic window, or prosthetic valve IE, and for monitoring the complications of IE.

Echocardiography is required to monitor the course of the illness and is extremely useful for therapeutic decisions as it also gives haemodynamic information and idea about therapeutic response. Severity of regurgitation, ventricular function, extension of infection, and size of vegetation are easily evaluated by echocardiogram repeatedly. With effective treatment, vegetation size generally decreases. Increase in size of vegetation is a risk marker for embolism or poor prognosis. Echocardiography should not be done as a screening test for patients with fever in whom IE is not likely.

DIAGNOSIS

The diagnosis of IE is a clinical diagnosis. Although modified Duke's criteria (**Tables 4A and 4B**) are widely recognised as important in the diagnosis of IE, it cannot be overemphasised that the comprehensive picture of the patient should be taken into account. Bacteraemia with typical organisms known to cause IE and vegetations on echocardiogram combined make the diagnosis of IE definite. These are considered major criteria for the diagnosis in Duke's criteria. In the absence of one of these major criteria, minor criteria need to be looked into. Since, we have large number of culture negative cases, the modified Dukes criteria that involve the minor criteria are important for us. As such, performance of Dukes scheme has not been rigorously evaluated in Indian setting, but the basic principles are useful for uniformity. The diagnosis of IE is considered rejected if alternative diagnosis is firmly established or if fever disappears before 4 days of treatment without recurrence. The differential diagnosis of PUO is long, but tuberculosis, autoimmune diseases, malignancy like lymphoma pose major problems.

Practically, the most difficult differential diagnosis in a known RHD patient involve the consideration of rheumatic activity versus IE as both can cause fever, raised ESR, arthralgia, worsening failure and even vegetations. In rheumatic fever, the symmetrical small vegetations are different, ASO is raised, nodules may be present, and fever is not long-lasting. However, a careful appraisal of entire clinical picture is always required.

Table 4A: Original Duke Criteria for the Diagnosis and Classification of Infective Endocarditis

Major Criteria	Minor Criteria	Diagnosis
Positive blood culture Typical organism in >2 blood cultures in the absence of a primary focus (*Staphylococcus aureus*, enterococci, *Streptococcus viridans*, *Streptococcus bovis*, HACEK) Persistently positive blood culture drawn more than 12 hour apart or all ¾ drawn at least 1 hour apart between first and last **Evidence of endocardial involvement** Positive echocardiogram (TEE) Oscillating intracardiac mass on valve, implanted material or supporting structures in path of regurgitant jets Abscess New partial dehiscence of prosthetic valve New valvular regurgitation	Predisposition Heart condition Drug abuse Fever >38°C Vascular phenomena Major arterial emboli Janeway's lesions Septic pulmonary infarcts Immunologic phenomena Osler's nodes Roth's spots Rheumatoid factor Glomerulonephritis Microbiologic evidence Positive blood culture Positive serologic finding Echocardiographic evidence consistent with infective endocarditis but not meeting the major criteria	Definite 2 Major 1 Major and 3 minor 5 Minor Pathologic/histologic findings Possible Findings fell short of the definite but not rejected categories Rejected Alternate diagnosis Resolution of the infection with antibiotic therapy for less than 4 days No pathologic evidence after antibiotic therapy

Table 4B: Suggested Modifications of Duke's Criteria

Major criteria: consider the following as major criteria

Staphylococcal bacteraemia (irrespective of community or nosocomially acquired, or with or without a focus)

Positive serology for coxiella, chlamydia, bartonella

Positive molecular diagnosis for specific gene targets of bacteria and fungi

Minor criteria: add the following as minor criteria

Raised CRP (>100 mg/L),

Raised ESR (>30 for <60 yrs, and >50 for older)

Newly diagnosed clubbing

Splinter haemorrhages

Microscopic haematuria

Splenomegaly

Petechiae, or purpura

Delete the following from minor criteria

Echocardiogram consistent with IE but not meeting major criteria

Diagnosis

Possible IE can be diagnosed either with one major and one minor, or three minor criteria alone

TREATMENT

The treatment of IE entails long course of bactericidal antibiotics intravenously, monitoring for response, decision for surgical treatment if required, attention to portal of entry if possible, and ancillary measures for patients well-being including anticipatory guidance for preventing recurrence. Recommended antibiotic treatment charts are available in all standard texts, the principles of drug therapy are summarised.

1. Therapy has to be of sufficient dose and duration to eradicate bacteria, prevent mortality, and relapse. Usually 4 weeks therapy is required. All patients should be hospitalised for at least 2 weeks initially.
2. Longer-term treatment (6 to 8 weeks) is recommended if the symptoms have been present for >3 months, if IE is complicated by embolism, poor response, likely resistant bacteria, atypical organisms, or for prosthetic valve endocarditis (8 weeks).
3. In penicillin sensitive organism, penicillin is better than vancomycin. The dose of penicillin to be used in a patient (12-24 million units in 4-6 divided doses) depends on the available or perceived sensitivity of the organism, or clinical IE.
4. Intermittent bolus or continuous infusion are probably equally effective, boluses are usually preferred. Attention to planning of veins to be used, changing intravenous lines 48 hourly, use of central lines and aseptic precautions are customary details.
5. Therapy for staphylococcal sp. is based on methicillin sensitivity and not coagulase status. Almost all *Staphylococcus* are penicillin resistant, methicillin sensitive strain respond better to methicillin congeners.
6. Rifampicin is utilised in patients with prosthetic valves, or foreign materials and staphylococcal IE.
7. Fluoroquinolones can be substituted for *Staphylococcus* resistant to aminoglycosides as additional therapy.
8. Aminoglycosides are added carefully and therapy is only for few days in *Staphylococcus*, or for 2 weeks. In some organism, 4 weeks duration is required with careful attention to renal and vestibular functions.
9. Enterococci do not respond to methicillin, cephalosporin and often have resistance to aminoglycosides as well. Combination therapy is preferred.
10. Linezolid, daptomycin are increasingly used for vancomycin resistant enterococci or *Staphylococcus aureus*, and others.
11. A consultation from infectious disease specialist should be obtained in difficult circumstances.
12. Culture negative endocarditis can be treated with vancomycin, ceftriaxone and gentamicin pending further insight into the possible organism (some prefer only vancomycin and gentamicin).
13. Ideally trough drug levels should be measured, but is not possible in most circumstances.
14. Surgery should be considered early, rather than late, in some situations.

Treatment of common organisms is shown in the **Table 5**. Therapy of atypical organisms need special considerations and consultations with infectious disease specialists. Therapy for brucella include doxycycline with streptomycin, (with or without rifampicin), and in children trimethoprim-sulphamethoxazole and rifampicin, Q fever needs doxycycline with hydroxychloroquine (possibly with fluoroquinolones), bartonella can be treated with amoxicillin with gentamicin or tetracyclines/macrolides antibiotics. These are not detailed here.

Surgery for Infective Endocarditis

Surgical treatment during IE may be required because of (1) severe congestive heart failure from mechanical complications, (2) uncontrolled infection, and (3) repeated embolism. While complications of surgery is higher during IE than without IE, but the mortality without surgery in such patients is very high and surgery is preferred and should be done early without waiting for infection to subside. Although, mortality despite operation in these circumstances may be as high as 20% to 40%, mortality without operation is in the range of 60% to 90%. The chances of postoperative IE in the replaced valves are not higher than 2% to 3%. Early prosthetic valve endocarditis, paravalvular leak, annular abscesses, fungal endocarditis, persistent fever >2 weeks despite antibiotics in the absence of other causes, and embolisms are typical indications for consideration of operative treatment.

Various types of operative procedures may be required. Thorough debridement, patch repairs, vegetectomy and valve repair may be done, usually valve replacement is needed. The choice of valve is individual preference and outcomes are not different between mechanical or biological valves. Some may prefer homografts. If the patient has suffered a CNS event, it is better to postpone surgery, if possible. Open heart surgery should be postponed by 3 to 4 weeks after a haemorrhage in the brain and at least a few days to weeks after an infarct because of the use of anticoagulation during open heart surgery and the risks of adverse neurological outcomes.

Anticoagulation in Infective Endocarditis

Anticoagulation increase the chances of CNS bleed and should be avoided. In a patient with mechanical prosthetic valve, careful titration of minimal possible anticoagulation should be used. It is preferable to stop oral anticoagulant and rely on heparin for the duration of therapy.

Table 5: Treatment of Infective Endocarditis (Common Organisms)

Microorganism	Antibiotics	Dose (Per Day)	Duration
Streptococcus viridans	Penicillin G	12 to 24 MU/6 doses[1]	4 weeks[2]
Streptococcus bovis	Amoxicillin or	100 to 200 mg/kg	4 weeks[2]
	Ceftriaxone	2g in (100 mg/Kg) single dose	4 weeks[2]
	If penicillin allergy-vancomycin	30 mg/kg in 2 doses	4 weeks[2]
Enterococcus	Amoxicillin or ampicillin with	200 mg/kg in 4 to 6 dosage	4 to 6 weeks
	gentamicin	3 mg/kg in 2 to 3 doses	
	If penicillin allergic vancomycin with gentamicin[3]	30 mg/kg in 2 to 3 doses	
Staphylococcus	Flucloxacillin or oxacillin	12 g/d in 4 to 6 doses	4 to 6 weeks
	If penicillin – allergic vancomycin	30 mg/kg in 2 doses	4 to 6 weeks
	Optional gentamicin	3 mg/kg	5 days
Prosthetic valve IE	Vancomycin with	30 mg/kg in 2 dose	≥ 6 weeks
Or MRSA	rifampicin with	1,200 mg in 2 dose	≥ 6 weeks
	gentamicin	3 mg/kg in 2 dose	2 weeks
Fungal endocarditis	Amphotericin	1 to 1.5 mg/kg[4]	6 to 8 week or more
	Flucytosine	100 to 150 mg/kg in 4 doses	
	or fluconazole (second line only)	600 to 800 mg or 10 to 12 mg/kg	
		oral or IV in 2 doses	
Culture negative	Vancomycin with	30 mg/kg in 2 dose	4 to 6 weeks
	Gentamicin and	3 mg/kg in 2 dose	
	Ceftrioxone[5]	2 g in single dose	
IE HACEK	Ceftriaxone or	2g single dose	4 to 6 weeks
	Ampicillin-sulbactam	12 gm (2 g Ampicillin and 1 g Sulbactam)	
	If allergic, ciprofloxacillin	in 4 doses or 300 mg/kg ampicillin 6 hourly,	
		800 mg IV or 1,000 mg oral in 2 doses	

1 = Dose of penicillin depends on the MIC for the orgonism, in the absence of that doto, empiricolly decided; 2 = The durotion of theropy should be 6 weeks if the symptoms hove losted for more thon 3 months. For uncomplicated and responsive endocorditis, some authors hove reported cure with 2 weeks therapy of ceftrioxone; 3 = for uncommon voncomycin resistont or multidrug resistont enterococci, Linezolid 600 mg IV or orol BD hos been used; 4 = Amphotericin has to be built up slowly to this dose after initiol test dosages, lipid soluble formulations may be better toleroted. Newer ontifungals like caspofungin and newer ozoles are being tried; 5 = Treatment of culture negative endocorditis varies with the clinical background. Some outhors recommend adding ceftriaxone to cover Grom-negative organisms.

Monitoring During Therapy

Monitoring the patient during long course of treatment is vitally important. Most patients start showing clinical improvement and become afebrile within a week. Some may respond slowly. The diagnosis is doubted if the patient becomes afebrile in less than 4 days of therapy. Appetite, body weight, sense of well being should be evaluated routinely and thorough physical examination daily is mandatory. Echocardiography should be repeated weekly. Blood cultures, haemogram, ESR, chest radiographs, renal parameters, are monitored frequently. Recurrence of fever after initial response may occur (**Table 6**) due to several reasons. Drug fever may occur without rash and

Table 6: Fever During the Treatment

Cause	Indicators	Treatment
Uncontrolled infection	Continuing ill-health, metastatic foci, extension of infection in heart	Review choice or dosages of antibiotics
Annular abscess	Conduction disturbance on ECG, pericarditis suggest the diagnosis, often missed, TEE useful	Consider change in antibiotics, surgery
Organ infarcts	Renal, pulmonary or spleen, may become infected Splenic common, ultrasound/CT required	Splenic abscess may need precutaneous drainage or splenectomy
Mycotic aneurysms	Common in CNS, may cause cerebral haemorrhage, not routinely searched	Aneurysm can decrease with antibiotics, surgery may be required
Thrombophlebitis	Minor phlebitis more often incriminated as cause than actual, may miss more serious cause	Change IV lines frequently, if peripheral
Drug fever	Common with penicillin after 3rd week, rash, eosinophilia may not be present Patient appear less toxic despite high fever	Require to change antibiotics, total duration of treatment should count
Super infection	May be nosocomial fungal or Gram-negative infection Reflects poor hospital practices, broad index of suspicious required	Addition of appropriate therapy required
Immunologic phenomenon	For example, a patient with glomerulonephritis, or immune mediated phenomena in otherwise responding patient	Glomerulonephritis may remit after surgical removal of infection
Wrong diagnosis or double disease	SLE, lymphoma, tuberculosis may masquerade, double disease diagnosis is against the law parsimony (i.e. diagnose one condition in a patient), but very rarely does occur	Treat according to the diagnosis

can be high grade. Other investigations like abdominal ultrasound and CT are utilised as required. Splenic infarct or abscess can be diagnosed with both. Mycotic aneurysms are not routinely searched in the absence of symptoms. MR angiography can detect CNS aneurysms if suspected.

SPECIAL SITUATIONS

Prosthetic Valve Endocarditis

IE in patients with prosthetic valve occurs nearly in 1% in the first year and 0.5% per year afterwards. Early prosthetic valve endocarditis (PVE) occurring within 2 months of operation results from contamination in the operative or post-operative period and carry very high mortality. Organisms like coagulase negative *Staphylococcus* or *S. aureus*, *Pseudomonas*, *Candida* predominate. Some authors consider early PVE till 1 year period. Surgical treatment is the rule for early PVE and antibiotics are required for 6 to 8 weeks. IE later is due to the usual organisms but carries a higher-risk. PVE is essentially an annular infection, and therefore, chances of annular abscess are higher.

Culture Negative Endocarditis

Culture negative endocarditis, although thought of as a group, actually encompass different entities. Culture could be negative because of (1) prior antibiotic therapy in otherwise a usual endocarditis, the commonest cause, (2) poor culture techniques, inadequate sample, media, transport, etc., (3) fastidious organisms needing special media like abiotrophia, HACEK, etc., and (4) organism that do not grow in blood culture like aspergillus, tropheryma whipplei, coxiella. The approach to these groups should be different. As discussed above, serological tests are useful in the diagnosis of brucella, Q fever, etc., and PCR is being utilised for many bacteria and improves the positive yield. In the absence of any clinical clues, suggested broad-spectrum cover include vancomycin with gentamicin and ampicillin or ceftriaxone.

Infective Endocarditis in Children

IE is uncommon before 2 years of age, except as nosocomial infection in neonates in presence of intravenous cannula and central lines. *Staphylococcus aureus* and candida dominate. Tricuspid valve endocarditis may present with unexplained dyspnoea due to unanticipated pulmonary embolism. Most other IE in children occur in the presence of a CHD or RHD. IE in the VSD or tetralogy of Fallot patients occurs as right-sided endocarditis (**Figures 2 and 3**). Systemic embolism does not occur unless there is a right to left shunt or IE occur in the left-sided structures also. Pulmonary complications like infiltrate, infarct, abscess, pulmonary artery pseudo-aneurysm occur. Response to therapy can be satisfactory. Surgery might have to be resorted to in the presence of active infection in unsatisfactory responders. Ligation of ductus arteriosus is frequently followed by response to therapy in patients with ductus arteriosus and pulmonary valve endocarditis.

Infective Endocarditis in Drug Addicts

IE in drug addicts usually affects normal tricuspid valve, but may also occur on aortic, and mitral valves. Right-sided IE responds well to therapy. Some may have HIV, but IE in them also responds well, unless CD4 counts drop low. Polymicrobial IE or IE due to unusual organisms like bartonella may occur. Addicts using pentazocine have high chances of pseudomonas, and heroine addicts injecting brown heroine in lemon juice frequently have candida.

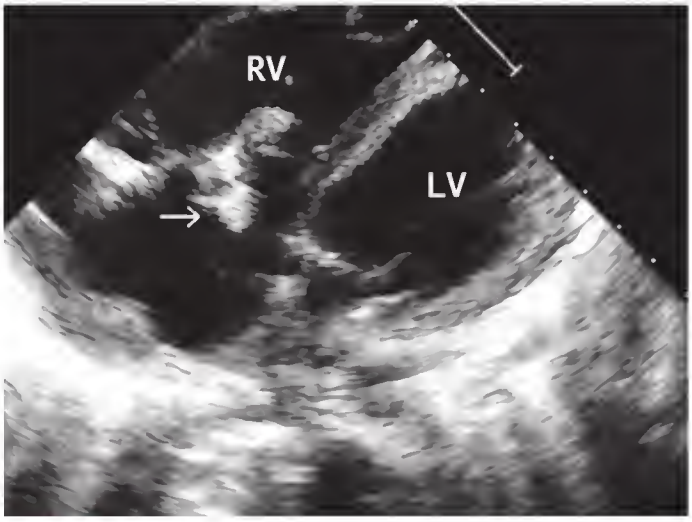

Figure 2: Echocardiogram in four chamber view showing vegetations (arrow) on tricuspid valve in a patient of small ventricle septal defect (not seen).

LV = Left ventricle; RV = Right ventricle

Figure 3: Chest radiograph of a patient of tetralogy of Fallot having right-sided infective endocarditis. Note the shadow in right lower chest from a pulmonary infarct.

In Elderly

IE in elderly is increasingly seen and is more common in males. The underlying predisposing lesion often is mitral valve prolapse with mitral regurgitation or degenerative valvular aortic stenosis. Co-morbidities decide the clinical course. Drug therapy will need extra care and dose adjustments with attention to renal and hepatic functions.

MORTALITY

Without treatment IE is invariably fatal. Rare case reports of recovery in the pre-antibiotic era may be misdiagnosis. Antibiotics reduced the mortality but IE has a mortality of 20%

Table 7: Prevention of Infective Endocarditis

Underlying Lesions	Procedures	Antibiotics
Rheumatic heart disease Prosthetic valves Previous infective endocarditis Congenital heart disease Unrepaired cyanotic CHD including palliative shunts and conduits Within 6 months of repair, devices Residual lesions near patches, or prosthesis Valve disease after cardiac transplant	Dental procedure Involving periapical region of teeth or perforation of the oral mucosa or gingival tissues Respiratory procedures Respiratory tract that involves incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy, (none for bronchoscopy) Skin and soft tissue Surgical procedure that involves infected skin, skin structure, or musculoskeletal tissue Genitourinary or Gastrointestinal procedures None	Oral amoxicillin 2 g (50 mg/kg), or Intravenous/intramuscularly ampicillin 2 g, cefazolin, ceftriaxone 1 g (50 mg/kg) In allergic to penicillin: Oral cephalexin 2 g (50 mg/kg), or azithromycin/clarithromycin 500 mg (15 mg/kg), or intravenous clindamycin 600 mg

to 40% even in current era. Further reduction in mortality is expected with more frequent surgical treatment. Mortality rates depend on several factors, but large size vegetations, heart failure portends poorer prognosis. Some subsets have particularly high mortality. Prosthetic valve IE has a mortality of 30% to 55% with surgery and 60% to 90% without surgery. The mortality in fungal IE is 60% to 90% despite treatment. With concerted efforts, protocol driven management and teamwork of cardiologist, microbiologists, surgeons and infectious disease specialist, the mortality of *Streptococcus viridans* IE can be as low as 7% to 10%, but enterococci and *Staphylococcus* mortality remains about 10% and 10% to 20% respectively. Right sided IE in drug addicts have a better response and lower mortality.

PREVENTION

In experimental settings, antibiotics administration before inoculating bacteria prevented colonisation and IE, and hence for years, elaborate recommendations were made for drugs to be given before procedures expected to cause bacteraemia. With time, it became clear that bacteraemia occur in daily living activities (like brushing, chewing, etc.) far more frequently than procedure induced, and that very few episodes of IE, if at all, could be prevented by such administration as previously advised. Further, costs and adverse effects of antibiotics use (including development of resistance) are not negligible. Therefore, it is prudent to advise all patients on maintaining good oral health and routine dental visits. Such is not the routine in India, but that can help reducing IE burden more than any antibiotic prophylaxis. Antibiotics before procedures are recommended only to patients in whom risks of occurrence and consequences of IE (if it occurs) are considered high (**Table 7**). No IE prophylaxis is recommended for gastrointestinal or genitourinary procedures in the American Heart Association recommendations. Dental procedures which may cause gum bleeding or apical tissue handling would cause bacteraemia are specified. Only single dose 2 gm amoxicillin is recommended where required.

There have been no new data about RHD, and these patients could have poor oral hygiene. Individual judgement should still be used in advising prophylaxis. No prophylaxis is required for vaginal delivery, tattooing, ear piercing, or TEE.

CONCLUSIONS

The following parameters recapitulate important aspects of management of infective endocarditis.

Do's and Don'ts of Infective Endocarditis

1. Prevent IE by anticipatory guidance on oral hygiene in RHD, CHD and other at risk patients.
2. Think of IE in all susceptible patients with fever, anaemia, weight loss, or heart failure.
3. Do not rely overly on any test including echocardiogram as false positive and false negatives are not uncommon.
4. Think of plausible portal of entry/organism before deciding on therapy.
5. Do not jump to the latest antibiotics, nor slavishly follow the regimens, think critically.
6. Monitor trends carefully, anticipate the complications but do not change antibiotics frequently with any minor alterations including 1 to 2 days fever.
7. Keep the surgeon in the loop for decision regarding early surgery, if required.
8. Prevent recurrence, relapse by appropriate advice and management.

12.16 Atherosclerosis

KK Sethi, S Lahiri

INTRODUCTION

Atherosclerosis is multi-focal, multi-factorial smouldering inflammatory disease that affects the intima of medium sized and large arteries, resulting in intimal thickening that may lead to luminal narrowing and inadequate blood supply. Atherosclerosis derives its name from the Greek word 'adhere'—means gruel or porridge, and 'sclerosis' means hardening, i.e. hardening of gruel-like material inside the blood vessels.

According to the original concept, atherosclerosis was thought to be just a bland proliferative process. The advent of cell biology era of atherosclerosis modified the earlier view and implicated inflammatory mechanism in disease development. According to that concept, endothelial denudation resulted in platelet aggregation and release of platelet-derived growth factor (PDGF) which led to the proliferation of smooth muscle cells in the arterial intima. Current evidence integrates inflammation as a key regulatory process with multiple other risk factors in atherosclerosis.

PATHOGENESIS

Early Atherosclerotic Lesions

The earliest lesions of atherosclerosis, i.e. fatty streaks, are present in the aorta from early childhood and may even begin to develop early in foetal life. They are highly cellular inflammatory lesions consisting of macrophage foam cells (intracellular lipid) and T-lymphocytes (immune reaction). Fatty streaks do not protrude into the lumen and hence are not symptomatic. Fatty streaks develop under an intact but activated, dysfunctioning endothelium particularly atherosclerosis prone areas with pre-existing intimal thickening. Hypercholesterolaemia is associated with increased endothelial permeability, increased transcytosis and intimal retention of lipoproteins and endothelial activation with focal expression of vascular cell adhesion molecule 1 (VCAM-1) leading to monocyte and T-lymphocyte adhesion. It is thought that inflammatory cells are recruited by adhesion molecules and chemokines such as monocyte chemoattractant protein-1 (M-CSF) and activated in the intima by factors such as oxidised lipids and cytokines. Within the intima, the monocyte-derived macrophages engulf the blood derived low-density lipoprotein (LDL), possibly through their scavenger receptors after oxidative modification and become lipid-filled foam cells. These inflammatory cells constitute the major part of the early fatty streak lesions (**Figure 1**).

Fate of Fatty Streaks

Fatty streaks can progress to more advanced lesions because they occur at the same anatomic sites. A smaller fraction of fatty streaks appears to progress to more advanced symptomatic lesions.

Advanced Atherosclerotic Lesions

When lipids begin to accumulate, extracellular atherogenesis has passed beyond the fatty streak stage. Two different processes

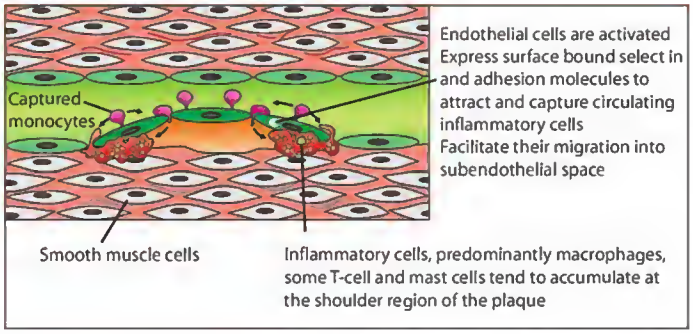

Figure 1: Formation of fatty streak.
Source: Weissberg, Heart 2000;83:247-52.

are responsible for the extracellular accumulation of lipids. Blood-derived atherogenic lipoprotein particles may be trapped directly within the proteoglycan-rich extracellular matrix and/or lipid may be released from the macrophage foam cells after their death by apoptosis. Within a lipid-rich core, erythrocytes and their lipid-rich membranes may contribute to the expansion of the core (plaque rupture and haemorrhage).

There is accumulation of smooth muscle cells which gives rise to a heterogeneous spectrum of plaques ranging from fibro-fatty plaques (abundant smooth muscle cells) to thin-cap fibroatheroma (scanty smooth muscle cells with rich lipid core). With the passage of time endothelial denudation takes place and adherent platelets can be seen over mature plaques. Growth factors released from the adherent platelets and micro thrombi may stimulate the smooth muscle cells within the plaque to produce more connective tissue matrix.

Neovascularisation

Neovascularisation is frequently present at the base of advanced atherosclerotic plaques and is thought to be derived from vasa vasorum derived new vessels. Vasa vasorum developing from the adventitial layer of vessel wall also serve the purpose of transit of leukocytes and other growth factors inside the plaque.

Vulnerable Plaque and Plaque Instability

Pathological studies indicate that certain plaques are more prone to develop acute myocardial infarction (MI) than others. These are called vulnerable plaques, i.e. plaques which are at high risk of for disruption or thrombosis leading to symptomatic cascade of acute coronary events. Vulnerable plaques are characterised by the following:

- A thin fibrous cap (thin cap fibroatheroma or TCFA),
- A large lipid pool of cholesterol esters,
- Heightened inflammation,
- Positive remodelling of the vessel (outward expansion of the opposite wall of the vessel), and
- Extensive neovascularisation.

Vulnerable plaque ruptures due to uneven thinning of the fibrous cap. Rupture usually occurs often at the shoulders of the lesion where macrophages enter, accumulate and are activated. Degradation of the fibrous cap results from elaboration of matrix metalloproteinases such as collagenases, elastases and stromelysins. The metalloproteinases are stimulated by activated T-cells which promote plaque instability and rupture (**Figure 2**).

Source: Weissberg, Heart 2000; 83: 247-52.

Role of Innate and Adaptive Immunity

Innate immunity is the primitive arm of inflammation and constitutes immune response that is elicited without 'education' of the immune system. This response is very rapid and combats perceived foreign invaders. Natural antibodies, certain complement proteins and families of cell surface receptors recognise microbial products and provide primordial host defence responses. These receptors include scavenger receptors which cause uptake of modified lipoproteins, and are toll-like receptors (TLR) that recognise microbial structures and products. These receptors trigger a complex intracellular signalling cascade that stimulates the production of pro-inflammatory cytokines and other inflammatory mediators. The cellular recruitment seen very early in atherosclerosis is an example of innate immunity. The mononuclear phagocytes get attached to activated endothelial cells by leucocyte adhesion molecules. Maturation of monocytes into macrophages, their multiplication and production of mediators ensues. Recent evidence suggests that mononuclear recruitment is a continuous process which is also seen in established lesions and could be a therapeutic target for targeting monocytes for treatment. In the presence of hyperlipidaemia, there is an enrichment of proinflammatory subset of monocytes. Apart from monocytes, there is now firm evidence that mast cells release vasoactive small molecules such as histamine and leukotrienes, serine proteinases and heparin — a cofactor in growth factor action and angiogenesis. Certain pharmacological agents can modulate mast cell function and this can have therapeutic implications. There are links between lipoproteins and innate immunity. Modified lipoproteins such as oxidised lipoproteins and oxidised phospholipids may drive inflammation. A lipoprotein-associated phospholipase-A2 (Lp-PLA2) currently targeted in clinical trials may generate proinflammatory derivatives of oxidatively modified lipoproteins (apolipoproteins).

Recent data suggest that CIII, a constituent of certain triglyceride-rich lipoproteins incites inflammation by binding to TLR2. The activation of platelets results in secretions of proinflammatory cytokines such as CD40-ligand and also myeloid-related protein (MRP) 8/14. The MRP serves as a biomarker for adverse cardiovascular events and can promote endothelial cell apoptosis, a process thought to be vital in plaque thrombosis.

Adaptive immunity requires antigen presenting cells, such as dendritic cells. The dendritic cells populate atherosclerotic plaques and present antigens to T-lymphocytes, thus forming the key limb of adaptive immunity. These antigens in relation to atherosclerosis are heat shock proteins (HSP), components of plasma proteins and some microbial structures. T-cells proliferate and produce cytokines that amplify inflammation. There are several types of T-cells. Helper T-cells (Th1) response appears to aggravate atherosclerosis as it amplifies proinflammatory pathway by gamma interferon production. The Th2 cells produce cytokines that modulate inflammation. These cytokines such as interleukin (IL)-4 can promote humoral immunity. Regulatory T-cells can, however, dampen atherosclerotic response. There is also a role of CD8 marker T-cells or cytotoxic T-cells or CD8 cells. CD8 T-cells are capable of killing smooth muscle cells and macrophages and cause lesion growth and complications.

Humoral immunity is mediated by B-lymphocytes. B-lymphocytes secrete antibodies which attenuate rather than aggravate atherosclerosis. Splenectomy aggravates athero-sclerosis by eliminating some population of B-cells. Humoral immunity against oxidised LDL might protect against atherosclerosis and may be a potential target of vaccine therapy.

RISK FACTORS FOR ATHEROSCLEROSIS

Classic risk factors of atherosclerosis are also known as traditional risk factors. These risk factors can predict atherosclerotic coronary events to a certain extent. The NCEP ATP- III is based on traditional (old) risk factors of age, sex, total cholesterol, HDL cholesterol, systolic BP and smoking. In a more recent scoring system (PROCAM), eight risk variables are identified: age, LDL cholesterol, diabetes, smoking, HDL cholesterol, triglycerides (TG), systolic BP, family history of premature coronary artery disease. **Table 1** presents risk factors for atherosclerosis.

Hypertension

Hypertension is considered to be one of the traditional risk factors of atherosclerosis. Concentrations of angiotensin-II, the principal product of renin-angiotensin system are often elevated in patients with hypertension. Angiotensin-II is a potent vasoconstrictor. In addition to cause hypertension, it can contribute to atherogenesis by stimulating the growth of smooth muscle cells. Angiotensin binds to specific receptors in smooth muscle cells resulting in activation of phospholipase C, which can lead to increase in intracellular calcium and smooth muscle contractions, increased protein synthesis and smooth muscle hypertrophy. It also increases smooth muscle lipooxygenase activity which can increase inflammation and oxidation of LDL. Hypertension also has proinflammatory actions such as increasing the formation of hydrogen peroxides and free radicals such as superoxide anions and hydroxyl radicals in plasma. These substances reduce the formation of nitric oxide (NO) by endothelium, increase leucocyte adhesion and increase peripheral resistance.

Table 1: Old, Old/New, and New Risk Factors for Atherosclerosis

Old	Old/New	New
Sex (men > women)	High-normal blood pressure	Apolipoprotein B; Apolipoprotein A-1
Age	Metabolic syndrome	Triglycerides; triglyceride-rich lipoprotein remnants
Family history of premature cardiovascular disease	Diabetes mellitus; impaired glucose tolerance; impaired fasting glucose	Small, dense LDL; oxidised LDL; antibodies against oxidised LDL
Total cholesterol; LDL cholesterol; HDL cholesterol (negative risk factor)		Lipoprotein(a)
Hypertension		Homocysteine
Smoking		High-sensitivity C-reactive protein
Overweight/obesity		

LDL = Low-density lipoprotein; HDL = High-density lipoprotein.

Smoking

Smoking increases the risk of atherosclerosis by several mechanisms. Cigarette smoking is associated with increased levels of lipoproteins and the effects of oxidants in cigarette smoke renders LDL more susceptible to peroxidative modification by cellular elements such as macrophages and vascular smooth muscle cells. The inflammatory cells recruited in the atherosclerotic plaques are increased in smokers. Nicotine activates the complement system as well, which causes increased inflammation in the vessel wall. Certain chemicals in tobacco smoke tend to activate factor XII and favour thrombus formation. The risk associated with smoking diminishes slowly after smoking cessation and equals to non-smokers after 3 years of cessation.

Diabetes Mellitus

In the first 20 years of the Framingham Heart Study, the incidence of cardiovascular disease among men with diabetes mellitus was twice than that among men without diabetes. Among women with diabetes, the incidence of cardiovascular disease was three times than that among women without diabetes. Microalbuminuria and silent myocardial ischaemia at baseline has predictive value for future coronary heart disease (CHD) in asymptomatic patients with type II diabetes. Subjects with impaired glucose tolerance and those with insulin resistance are more likely to have subclinical atherosclerosis (Framingham Offspring Study) and it is no wonder that NCEP considers diabetes as a CHD risk equivalent. Type II diabetes is associated with insulin resistance. Insulin resistance reduces the ability of adipose tissue to clear/store circulating lipids, in part because of reduced lipoprotein lipase activity. This results in paradoxical elevation in serum TG and free fatty acids (FFA). There is also elevation in the apoB due to increased lipogenesis by the liver. Insulin resistance is characterised by the formation of more atherogenic (small dense) LDL. It can also stimulate inflammation. The secretion of proinflammatory mediators initiated by systemic insulin resistance stimulates several intracellular cascades of nuclear factor kappa beta pathway.

Metabolic Syndrome

Metabolic syndrome encompasses a range of cardiovascular risk factors such as elevated TG (> 150 mg/dL), low HDL cholesterol (men < 40 mg/dL; women < 50 mg/dL), impaired fasting glucose (≥ 110 mg/dL), high blood pressure (≥ 130/85 mm Hg) and increased waist circumference (men > 90 cm, women > 80 cm in Asians) is believed to increase the risk for CHD at any level of LDL cholesterol. Further, the presence of metabolic syndrome has a greater impact on the incidence of CHD in women than men. Leptin is a protein that plays a role in fat metabolism and closely correlates with insulin resistance and is an independent risk factor for CHD.

Lipid Risk Factors

Triglycerides and triglyceride-rich remnant lipoproteins

Though there was some initial debate on the role of hypertriglyceridaemia as an independent CHD risk factor, data from the PROCAM study showed a significant relation between hypertriglyceridaemia and CHD risk independent of LDL cholesterol and/or HDL cholesterol. Triglyceride-rich lipoproteins comprise a great variety of nascent and metabolically modified lipoprotein particles. The capacity to enter the subintimal area of the vasculature is inversely related to the size of the lipid particles. Whereas chylomicrons and large very low-density lipoprotein (VLDL) particles are unable to pass through the endothelial layers, smaller VLDL, IDL and LDL particles can enter the suboptimal space. In the Framingham Offspring Study, both remnant lipoprotein (RLP)-cholesterol and RLP-TG were significantly increased in diabetic men and women compared to non-diabetes. Remnant lipoproteins were independent risk factors for atherosclerosis. Lipoprotein (a) [Lp (a)] is formed by joining a lipoprotein that is structurally similar to LDL in protein and lipid composition to a carbohydrate-rich hydrophilic protein Apo (a). The Lp (a) particles contain Apo (a) and Apo (B) in a 1:1 molar ratio. Most of the data on Lp (a) comes from retrospective studies. Prospective studies, however, have mixed results. However, plasma Lp (a) is indeed an independent risk factor for CHD in both men and women. The Lp (a) levels above 33 mg/dL and high LDL cholesterol (>163 mg/dL was associated with increased cardiovascular risk compared with Lp (a) levels below 33 mg/dL.

Homocysteine

Homocysteine is formed during demethylation of methionine, whereas its degradation takes place via remethylation and/or trans-sulphuration). Impaired homocysteine metabolism has been implicated as a risk factor in atherosclerosis, cerebrovascular disease and peripheral vascular disease. Hyperhomocysteinaemia results from genetic cause (enzyme deficiencies), vitamin deficiency (folic acid, B12, B6), use of certain medications and impaired renal function. Direct relations between homocysteine, cigarette smoking, diabetes, obesity and hypertension have been suggested. The exact mechanism by which hyperhomocysteinaemia may translate into increased CHD and/or thrombotic risk remains speculative. Both direct toxic effects on endothelial cells, in part due to oxidative stress as well as more indirect mechanisms have been postulated. However, treating hyerhomocysteinaemia with vitamins has not shown to be beneficial in large studies both in terms of stroke and cardiovascular event reduction.

Thrombogenic/Haemostatic Factors

Elevated plasma fibrinogen and factor VII are potential risk factors for CHD. Other thrombogenic/haemostatic factors that have been investigated in their potential role in atherogenesis and/or thrombosis include von Willebrand factor and plasminogen activator inhibitor-1.

High-Sensitivity C-Reactive Protein and Other Inflammatory Markers

Since atherosclerosis represents a chronic inflammatory state, inflammatory parameters (e.g. IL-6, tumour necrosis factor-alpha) have predictive value for future cardiovascular events. Data shows that CRP has additive value for predicting CHD risk on top of traditional risk factors. hs-CRP is associated with subclinical pericardial coronary calcification in men and women and is significantly elevated in patients suddenly dying of severe coronary artery disease. Elevated hs-CRP constitutes an independent predictor of advanced plaques in dyslipidaemic subjects and early onset carotid atherosclerosis with increased intima-media thickness and elevated serum levels of inflammatory markers. Matrix-metalloproteinase 9 concentration has been identified as a novel predictor of cardiovascular mortality in patients with coronary artery disease. Elevated IL-10 has a more favourable prognosis in patients with acute coronary syndrome (ACS) and elevated CRP levels.

Though there is no definite hard evidence of a causal relation between infection and atherosclerosis, studies are accumulating that indicate a possible role of infection. Viral agents such as cytomegalovirus (CMV), enterovirus, influenza virus, human parvovirus B19, herpes simplex viruses and bacterial agents such as *Chlamydia* have been studied extensively. Other potential agents such as *Helicobacter pylori* and periodontitis have been implicated. In a recent meta-analysis, it has been shown that influenza vaccination in patients with CHD can lower the risk of acute myocardial infarction.

Periodontitis is associated with atherosclerotic cardiovascular disease, though direct causal relation is not yet established. The incidence of atherosclerotic cardiovascular events increase in patients with chronic inflammatory diseases such as rheumatoid arthritis, systemic lupus erythematosus (SLE) and psoriasis.

Biomarkers such as hs-CRP, IL- 6, IL- 8, soluble CD40 ligand are all markers of widespread inflammatory process in the vessel wall and can be identified by laboratory assays to detect subclinical atherosclerosis. There was an association between CRP and carotid atherosclerosis as assessed by ultrasono-graphy among 3,173 men and women enrolled in the Framingham Offspring Study. Overall, they found that increasing levels of CRP were predictive of carotid artery disease. Elevated levels of CRP may reflect the presence of vulnerable plaque that is at high-risk of rupture, as opposed to solely reflecting the burden of atherosclerosis. Emerging data, however, suggest that CRP may be a mediator as well as marker of atherosclerosis. CRP induces expression of cellular adhesion molecules, IL-6 and endothelin-1 by endothelial cells. Recently, interest has focused on the measurement of a circulating soluble form CD40 L (sCD40) for risk stratification of patients with or at risk of developing coronary artery disease. However, in a large multiethnic population-based sample, sCD40L was not associated with most atherosclerotic risk factors or subclinical atherosclerosis.

Technology has now made it possible to image atherosclerosis and the day is not far when it will be routinely used in identifying vulnerable plaques which are prone to rupture. It is yet unproven that therapies directed at sealing such plaques are beneficial. Techniques to image "vulnerable" plaque is given in **Table 2**.

Positron emission tomography/computed tomography
Molecular imaging

TREATMENT/PREVENTION

Systemic pharmacotherapy is the cornerstone of plaque stabilisation, with reductions in lipid content, inflammation and vasa vasorum neovascularisation. Statin therapy in high-dose has been documented to be beneficial in atherosclerotic plaque regression. In the A study to evaluate the effect of Ultrasound rosuvastatin an Intravascular derived coronary Atheroma Burden trial, rosuvastatin 40 mg per day led to an absolute regression in atheroma volume. Increasing HDL levels have been found to be antiatherogenic. However, even with the best combination consisting of high dose statins, ACE-inhibitors and aspirin, there is still a 22% recurrent coronary event rate in 2 years. Regional therapy such as photodynamic therapy and cryotherapy as intravascular treatment of coronary segments may be beneficial in near future. Plaque sealing with balloon expandable stents may tackle the vulnerable plaque.

Vaccine development for atherosclerosis

Historically, vaccines have been proven to be safe and efficient for protection against infectious diseases. Several antigen targets have been proposed for vaccine design, implementation and efficacy for atherosclerosis. Ideal vaccines for atherosclerosis should provide protective immunity against infection-derived pro-atherogenic antigens and also immune tolerance for auto-immunogenic selfantigens. LDL was the earliest target for vaccine therapy as it is a major mediator of atherosclerosis. Studies focusing on a knockdown of Ox-LDL showed a decrease in atherosclerotic lesion size. Immunisation with phosphatidylcholine (PC) containing *Streptococcus pneumoniae* generated vaccine which showed reduced atherosclerosis. However, the major problem with Ox-LDL is the chance of cross-reactivity. For greater OX-LDL specificity, more recent studies have targeted ApoB-100 peptide fragments. Studies to target the potential antigenicity of heat shock protein (HSP) mycobacterial HSP 65 elicit a pro-atherogenic response. Immunisation of patients with HSP 70 also showed decreased atherosclerosis. Following the idea that molecular mimicry is the mechanism responsible for cross-reactivity with foreign HSP, vaccination against infectious agents like influenza virus has been examined in the context of atherosclerosis. Vaccines

against more risk factors and proteins like nicotine, angiotensin-1, gherkin and periodontitis have also been examined with some interesting results. Thus, vaccine development for atherosclerosis is already underway and showing promising results.

12.17 Ischaemic Heart Disease

Inder S Anand, Shibba Takkar Chhabra

Ischaemic heart disease (IHD) is characterised by myocardial impairment due to imbalance between coronary blood flow and myocardial requirement. The commonest cause of IHD is atherosclerotic coronary artery disease (CAD). Non-atherosclerotic causes of myocardial ischaemia are rare and include coronary spasm (Prinzmetal's angina), coronary artery embolism, coronary arteritis (polyarteritis nodosa, Takayasu's disease, systemic lupus erythematosus), cocaine abuse or spontaneous dissection of coronary arteries.

CORONARY CIRCULATION

The left main and right coronary arteries arise from the left and right coronary sinuses of the aortic root, distal to the aortic valve. Within 2.5 cm of its origin, the left main coronary artery divides into the left anterior descending artery (LAD), which runs in the anterior interventricular groove, and the left circumflex artery (LCX), which runs in the atrioventricular groove. The LAD gives branches to supply the anterior part of the septum (septal perforators) and the anterior, lateral and apical walls of the left ventricle (diagonals). The LCX gives obtuse marginal branches that supply the lateral, posterior and inferior segments of the left ventricular (LV).

The right coronary artery (RCA), runs in the right atrio-ventricular groove, giving acute marginal branches that supply the RA, RV and inferoposterior aspects of the LV. The posterior descending artery runs in the posterior interventricular groove and supplies the inferior part of the interventricular septum. It arises from the RCA in approximately 85% of people (dominant right system) and from the LCX in the remainder (dominant left system). The coronary anatomy varies greatly from person to person and there are many normal variants.

The RCA supplies the sino-atrial (SA) node in about 60% of individuals and in the remaining 40% SA node is supplied by LCX. The AV node is supplied by a small AV nodal artery which arises from the dominant coronary artery (RCA in 85%) (**Figure 1**). Proximal occlusion of the RCA, therefore, often results in sinus bradycardia and may also cause AV nodal block. Abrupt occlusions in the RCA, due to coronary thrombosis, result in infarction of the inferior part of the LV and often the RV. Abrupt occlusion of the LAD leads to anterior wall or anteroseptal myocardial infarction (MI). LCX causes infarction in the anterolateral territory of the LV. Acute occlusion of the left main coronary artery is usually fatal.

PHYSIOLOGY

The myocardium relies almost exclusively on oxidative metabolism for its energy needs. Even at rest the transmyocardial oxygen extraction is near maximal with a coronary venous O_2 saturation that is lowest in the body (25% to 35%). Any increase in myocardial O_2 demand can only be met by proportional increase in myocardial blood flow, chiefly mediated by reduction in coronary arteriolar resistance. The left coronary artery fills only in diastole while the RCA shows both systolic and diastolic coronary flow.

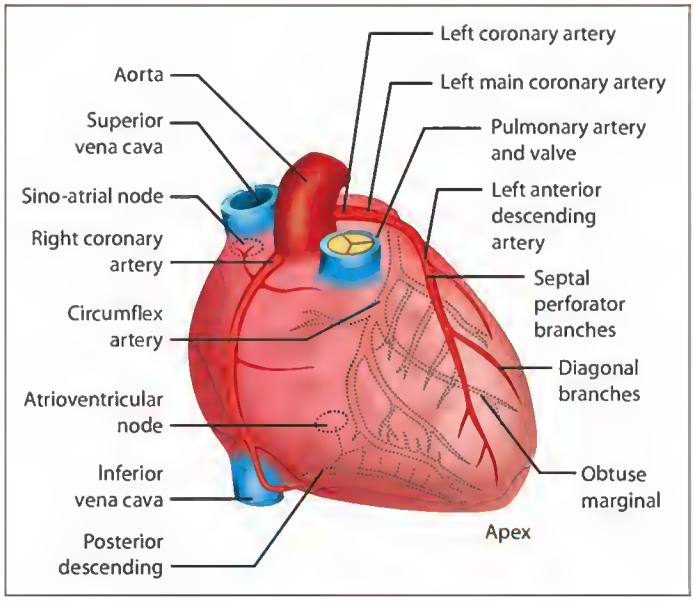

Figure 1: The coronary arteries of the heart. Diagram of the anterior view.

MAGNITUDE OF THE PROBLEM

Cardiovascular disease accounts for approximately 12 million deaths annually and is the commonest cause of death globally. Previously considered a disease of the affluent, the past three decades have seen considerable decline in the incidence and prevalence of atherosclerotic CAD in the industrialised western world; whereas at the same time, this problem is assuming epidemic proportions in the developing world. Asian Indians, whether living in their own country or elsewhere, have much higher incidence of CAD as compared to all other ethnic groups.

While the incidence of coronary artery disease has reduced by 50% in the west, in India it has doubled in the last 25 years. The prevalence of coronary artery disease in the years 1960, 1980, 1990 and 2000 progressively increased (2%, 4% to 6%, 9.5% and 10% to 15% respectively). In the rural India, the CAD prevalence increased two-fold from 2% to 4%. In urban India, the increase was three-fold from 3.45% to 9.45%. In 1990, 25% deaths in India were attributable to cardiovascular disease compared to 9% due to diarrhoeal disease, 12% due to respiratory infections and 5% due to tuberculosis.

RISK FACTORS

The National Heart Lung and Blood Institute of USA initiated the Framingham Heart Study in 1949 and by 1961, the concept of risk factors for CHD was established with hypertension and hypercholesterolaemia being identified for intervention.

The classically defined eight risk factors for CAD are hypertension, dyslipidaemia, diabetes, physical in activity and sedentary lifestyle, central obesity, stress and type A personality, family history of CAD and smoking. Of these, smoking, diabetes, hypertension and family history of premature CAD are particularly important. **Table 1** enlists the modifiable and non-modifiable risk factors for CAD.

Table 1: Risk Factors for Clinical Atherosclerosis

Non-Modifiable	Modifiable
Age	Dyslipidaemia
Male gender	Hypertension
Family history of CHD	Diabetes
Presence of CHD	Abdominal obesity
Menopause	Smoking
Physical inactivity	Diet

Asian Indians have the highest ethnic risk of CAD despite lower rates of smoking, hypertension, obesity and higher vegetarianism. The insulin resistance syndrome (metabolic syndrome X), lipoprotein(a), atherogenic dyslipidaemic phenotype and some newer emerging risk factors [homocysteine, tissue plasminogen activaetor (tPA), plasminogen activator inhibitor (PAI-1), fibrinogen, infections and inflammation] may be more relevant as underlying genetic susceptibility associated with a modest abnormality in lipid and lifestyle factors makes CAD assume an aggressive course in Asian Indians. Important risk factors in Asian Indians have been listed in **Table 2**. The INTERHEART study (2004) on 25,000 myocardial infarction patients confirmed nine risk factors attributing to CAD—ApoB/ApoA-1, smoking, diabetes, hypertension, abdominal obesity, psychosocial, fruits and vegetable intake, exercise and alcohol. Of these ApoB/ApoA-1 and smoking were especially associated with increased incidence of myocardial infarction in younger patients.

Table 2: Coronary Risk Factors for Asian Indians

Fixed
- Male age >35 years
- Female age >45 years
- Family history of premature CAD (at age <55 years)

Modifiable: Non-lipid
- Hypertension
- Cigarette smoking/tobacco abuse
- Diabetes mellitus/insulin resistance syndrome
- Apple obesity or body mass index >23
- Homocysteine >10 mmol/L
- High PAI – 1

Modifiable: Lipid
- Total cholesterol >150 mg/dL
- Triglycerides >150 mg/dL
- LDL cholesterol >100 mg/dL
- ApoA lipoproteins <100 mg/dL
- HDL <40 mg/dL males, <50 mg/dL females

Modifiable: Lipoprotein ratios
- TC/HDLc >4.5
- LDLc/HDLc >3.5
- ApoA/ApoB <1.2

SPECTRUM OF MYOCARDIAL ISCHAEMIA

The ischaemic heart disease can present as stable effort angina, unstable angina, non-Q wave MI, Q wave MI, heart failure and sudden cardiac death (**Table 3**). The understanding of the conversion of a stable atherosclerotic lesion to a plaque rupture with thrombosis has provoked a unifying hypothesis for the aetiology of acute coronary syndromes.

Table 3: Nomenclature of Myocardial Ischaemia

Old	Present
Asymptomatic	Asymptomatic
Stable effort angina	Stable effort angina
Unstable angina	Acute coronary syndromes, unstable angina without necrosis
Non-Q wave MI	Non-ST elevation MI (NSTEMI) (evidence of myocardial necrosis)
Q wave MI	ST elevation MI (STEMI)
Sudden death	Sudden death
Silent ischaemia	Ischaemic cardiomyopathy

CLINICAL PRESENTATION

Symptoms

The typical clinical presentation of angina refers to poorly localised retrosternal discomfort with radiation to neck, shoulders, arms, jaws, epigastrium or back; usually, not above the jaw and not below the umbilicus. Angina is typically triggered by physical activity, emotional stress, exposure to cold, consuming a heavy meal or smoking.

Pain is poorly localised, vague chest discomfort which may be described as squeezing, burning, tightness, choking, heaviness, hot or cold sensation, dyspnoea, fatigue, weakness, lightheadedness, nausea, diaphoresis, altered sensorium and syncope. These symptoms have been called angina equivalents.

Pain lasts for 2 to 8 minutes. Ischaemia seldom lasts more than 30 minutes without causing acute myocardial infarction (AMI). Pain is relieved with rest or sublingual nitroglycerine in 2 to 5 minutes.

It is less likely to be angina if it is localised (finger pointing), less than 30 s, or more than 30 min without AMI, exclusively at rest (except unstable/Prinzmetal), pricking or jabbing and changing sites of pain (**Figure 2**).

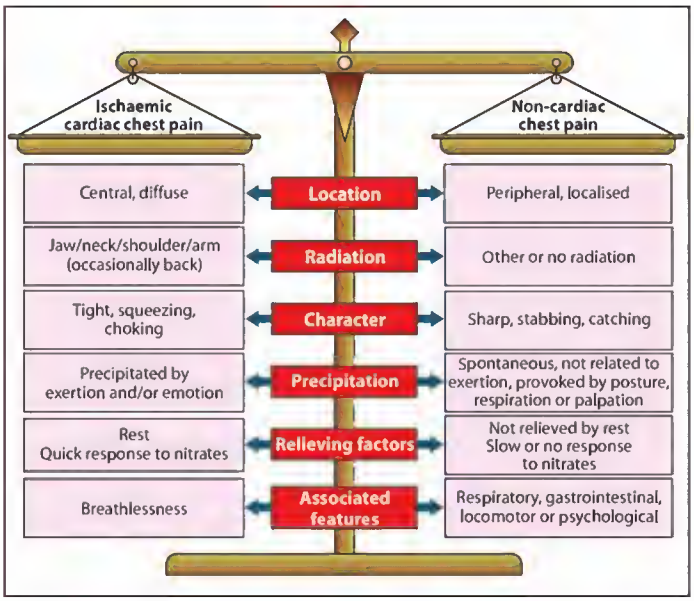

Figure 2: Identifying ischaemic versus non-cardiac chest pain.

The location of pain and its relation with exertion are two important factors in patient's history for determination of cause of chest pain. In presence of both factors (diffuse retrosternal pain and aggravation with exertion; relief on rest), chest pain is likely to be due to underlying CAD in 90% of patients. In presence either of one factor (atypical chest pain), underlying CAD is likely in 50% of patients. If both the factors are absent, the cause of pain is most likely non-cardiac.

A few patients have walk-through angina (pain gets relieved while the patient continues to walk). Decubitus angina is believed to be caused by blood volume shifts towards the lungs, resulting in rise in LV end-diastolic pressure. Nocturnal angina may be associated with nightmares.

Prinzmetal's angina attributable to intense coronary vasospasm was described first in 1959 by Prinzmetal with a consistent yet atypical pattern of angina at rest (non-threshold angina) precipitated by cold, emotional stress and smoking which was associated with ST-segment elevation. Paradoxic responses consistent with endothelial dysfunction have been described. Intense vasospasm is also seen in subjects who abuse cocaine and amphetamine. Provocative testing by inducing hyperventilation or administering intracoronary acetylcholine or ergonovine typically precipitate an attack of variant angina associated with focal spasm.

Grading of angina is based on NYHA classification, specific activity scale index and Duke activity status index. **Table 4** lists the conditions to be considered in differential diagnosis of coronary pain.

DIAGNOSTIC TESTING

For a patient with stable CAD, investigations are aimed at excluding non-cardiac cause of chest pain, assessment of risk factors for modification, risk stratification, stress testing to evaluate inducible ischaemia, LV function assessment, assessment for silent myocardial ischaemia and assessment of coronary anatomy where indicated.

Risk Factors

The patient should be evaluated for presence of underlying diabetes mellitus (Fasting and post-prandial blood sugar levels, HbA1C), dyslipidaemia (raised total cholesterol, LDL-C, VLDL-C, triglycerides, ApoB and reduced HDL-C). The presence of markers like hs-CRP, lipoprotein (a), homocysteine, tPA, PAI-I, fibrinogen, etc. can be indicators of underlying atherosclerosis.

Baseline Electrocardiogram

This is likely to be normal in over 90% cases and only helps to recognise LVH, bundle branch block, old MI or pre-excitation. A normal ECG does not exclude ischaemia as being a cardiac cause.

Stress Testing

Exercise is a common physiological stress used to elicit cardiovascular abnormalities not present at rest and to determine the adequacy of cardiac function. As exercise progresses, in individuals with underlying CAD, there occurs a mismatch between oxygen supply and demand which may manifest with electrocardiographic, regional wall motion or myocardial perfusion abnormalities. The commonly used exercise stress tests to diagnose underlying CAD are—treadmill stress test, dobutamine stress echocardiography and stress perfusion imagining.

Treadmill stress test

Treadmill stress test remains a cornerstone of cardiovascular evaluation. It is a simple, safe and cost-effective test in the diagnosis of coronary artery disease. The average present

Table 4: Common Causes of Chest Pain Mimicking Chronic Stable Angina

System	Syndrome	Clinical Description	Key Distinguishing Features
Cardiac	Angina	Retrosternal chest pressure, burning, or heaviness; radiating occasionally to neck, jaw, epigastrium, shoulders, or left arm	Precipitated by exercise, cold weather, or emotional stress; duration < 2 to10 minutes
Oesophageal	Acid peptic disease, gastro-oesophageal reflux	History of retrosternal burning, bloating sensation and reflux (linked angina)	Association with meals and posture, may be relieved by S/L nitrates
Musculoskeletal	Costochondritis	Sudden onset of intense fleeting pain	May be reproduced by pressure over affected joint; occasional patients have swelling and inflammation over costochondral joint
	Cervical disc disease	Sudden onset of fleeting pain	May be reproduced with movement of neck
	Trauma or strain	Constant pain	Reproduced by palpation or movement of chest wall or arms
Infections	Herpes zoster	Prolonged burning pain in dermatomal distribution	Vesicular rash, dermatomal distribution
Psychological	Panic disorder	Chest tightness or aching, often accompanied by dyspnoea and lasting 30 minutes or more, unrelated to exertion or movement	Patient may have other evidence of emotional disorder

Physical Findings

The physical finding may reveal risk factors of CAD. These include elevated BP, corneal arcus, xanthelasma, retinal arteriolar changes, diagonal earlobe crease, etc. The cardiovascular system (CVS) examination is normal (except for audible S4) in most individuals with stable angina. The presence of systolic murmur may suggest underlying aortic stenosis, mitral valve prolapse (MVP) or hypertrophic obstructive cardiomyopathy (HOCM) as cause of angina.

sensitivity and specificity of exercise testing in diagnosing coronary artery disease in 68% and 77%. In single vessel disease, the sensitivity ranges from 25% to 71% while that for left main and triple vessel disease is 86%. The results are less specific with more false positive outcomes in patients with marked resting ST-segment depression, digitalis effect, valvular heart disease, hypokalaemia and young female subjects with non specific T wave changes. Stress echocardiography and thallium stress testing increase the diagnostic yield especially in the above subsets.

Prognostic yield of exercise testing results should not be considered in isolation. Exercise parameters associated with adverse prognosis include duration of symptom limiting exercise, more than 5 METs, exercise-induced ST-elevation, sustained ventricular tachycardia, down-sloping ST-segment depression involving more than 5 leads and 5 minutes into recovery. On the other hand, excellent exercise tolerance more than 10 METs generally indicates good prognosis regardless of anatomical disease.

Stress perfusion imaging and myocardial cellular metabolism assessment

See chapter 7 of this section.

Echocardiography and stress echocardiography in CAD

Use of ultrasound for analysing the structure and function of the heart provides useful non-invasive information in the overall assessment of a patient of CAD. Global LV systolic function frequently guides the choice of therapy. Segmental wall motion abnormalities are useful and specific. These wall motion abnormalities can be segmentally scored. Various complications of CAD such as dyssynergic areas, aneurysm, intramural clot, free wall rupture, pseudoaneurysm formation, pericardial effusion, mitral filling patterns, assessment of aetiology and severity of mitral regurgitation, assessment of tricuspid regurgitation, deduction of PA pressure and LVEDP can be performed. Myocardial viability assessment can be performed using dobutamine stress echocardiography in patients with CAD and LV dysfunction. Stunned myocardium is a transient myocardial dysfunction that occurs after an acute episode of ischaemia and may occur despite the restoration of normal blood flow. This may last several days to weeks. Contrast echocardiography and cardiac MRI are techniques that reliably identify 'stunned myocardium'. Impaired regional myocardial energy production, calcium overload, free radical injury and ischaemic damage to extra-cellular matrix may be underlying mechanisms for stunning.

Hibernating myocardium refers to persistently dysfunctional myocardial segments in chronic low flow state who have potential for recovery of function with restoration of flow. Positron emission tomography comparing a perfusion tracer rubidium and metabolism tracer, flurodeoxy glucose (FDG), cardiac MRI and dobutamine stress echocardiography are techniques developed to identify hibernating myocardium. Dobutamine stress echocardio-graphy has been found to be the best predictor of improvement following revascularisation ('contractile reserve') although cardiac MRI may be more specific for diagnosis of viability.

Dobutamine echocardiography is an established technique for the identification of hibernating myocardium. A segmental comparison of systolic thickening before and after administration of dobutamine is performed using recorded images. Low-dose dobutamine inducing increased systolic thickening at low dose that deteriorates at high dose ('biphasic response') is most specific for predicting response to revascularisation. The greater the number of viable segments, the greater is the chance of survival after revascularisation.

There are thus several techniques for identification of viability. PET is the 'gold standard' but dobutamine echocardiography may be the most specific for prediction of improvement following revascularisation. However, cardiac MRI probably identifies scar tissue the best with excellent reproducibility and will probably be used more extensively to make decisions about intervention in the future.

Ambulatory Electrocardiographic Monitoring

Silent myocardial ischaemia is defined as documented episodes of ischaemia not associated with any typical or atypical symptoms that occur among patients with obstructive coronary artery disease. Holter monitoring is required to identify these clinically asymptomatic events. The asymptomatic MI and ischaemic episodes are common in diabetics.

Coronary Angiography

The coronary arteries can be visualised by either invasive or computed tomography (CT) coronary angiography. While CT coronary angiography presently cannot be considered a routine replacement for invasive coronary angiography, clinical application, especially to rule-out coronary stenoses in patients who do not have a high pretest likelihood of disease, is conceivable.

The major epicardial branches and their second- and third-order branches can be visualised using coronary arteriography. CAD is considered to be significant when more than 70% stenosis of arterial diameter is seen in one or more of these vessels or more than 50% of left main coronary artery is involved. Stenoses of less than 50% has major prognostic implications because these lesions most commonly lead to plaque rupture and acute MI. Subcritical stenoses of less than 50% are best characterised as non-obstructive CAD; obstructive CAD is classified as one-, two- or three-vessel disease.

Cardiac Biomarkers

See chapter 18 and 19 of this section.

Multislice CT Coronary Angiogram

CT scan in CAD has multiple potential uses: assessment of ventricular function, visualisation of coronary arteries and evaluation of coronary artery calcification. Coronary calcium is a surrogate marker for coronary atherosclerotic plaque but only non-linear correlations exist between amount of coronary calcium and angiographic severity of CAD. Therefore, the detection of even large amounts of coronary calcium does not imply the presence of significant stenosis, but the complete absence of coronary calcium rules out significant CAD. Thus, multislice CT, in experienced hands is a modality that can rule-out significant CAD in low-risk population non-invasively. Applications beyond this are still subject to validation but the non-invasive nature of this investigation makes it an attractive application for intense scrutiny.

THERAPY OF CORONARY ARTERY DISEASE

Goals of treatment are to improve quality of life, reduce incidence of unstable angina and MI, decrease frequency and severity of anginal episodes and to improve the longevity. The modalities of treatment are risk factor modification, lifestyle modification, pharmacological measures and revascularisation shown in **Table 5** and **Figure 3**.

Table 5: Methods of Treatment of CAD

- Lifestyle modification
- Pharmacologic
  - Anti-platelets
  - Lipid lowering agents
  - Nitrates
  - Beta-blockers
  - Calcium channel blockers
- Adjunctive treatments
  - Metabolic modulation: Trimetazidine
  - LV Dysfunction
    - ACE-inhibitors
    - Aldosterone antagonists
  - Gene therapy
  - Stem cell therapy
- Percutaneous coronary intervention
- Surgical revascularisation

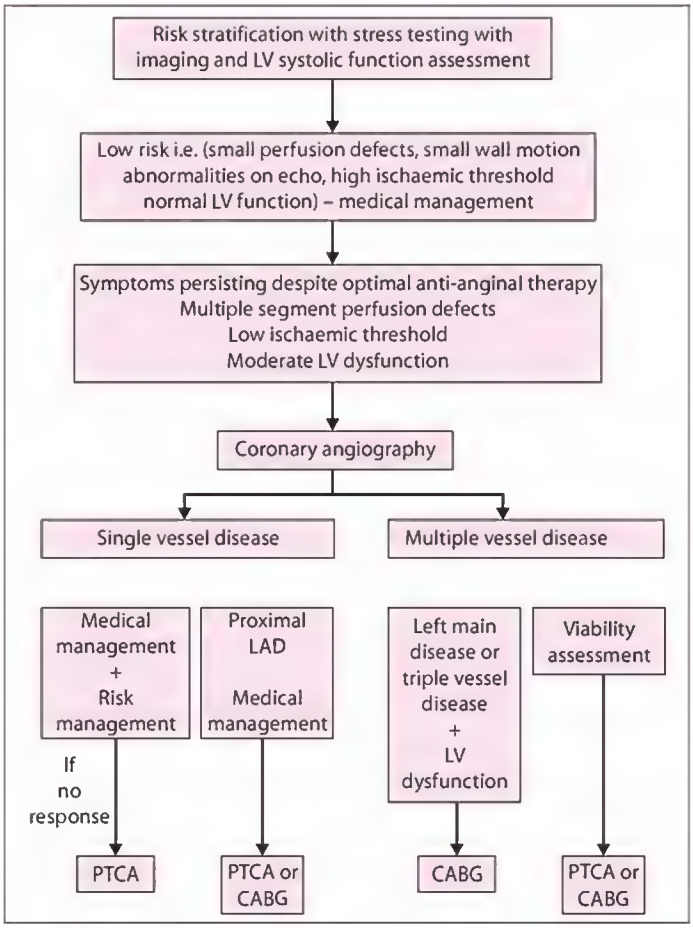

Figure 3: Approach for management of patient with stable angina.

CABG= Coronary artery bypass grafting; PTCA= Percutaneous transluminal coronary angioplasty.

Risk Factor Modification

Control of hypertension

Patients of angina and hypertension benefit with control of BP to less than 140/90 mm Hg (more aggressive reduction in diabetics). A meta-analysis of nine major trials of antihypertensive treatment of elderly patients showed 12% reduction in all-cause mortality, 25% reduction in CAD mortality and 30% reduction in stroke mortality. The totality of available data suggests that BP control favourably influences outcome. There is a debate about the best agent for BP control in uncomplicated hypertension, but beta-blockers have a definite role in symptomatic CAD. ACE-inhibitors and calcium channel blockers can be used in patients with CAD for effective BP control.

Diabetes mellitus and insulin resistance

Strict control of diabetes has beneficial effects in reducing the incidence of microvascular complications such as retinopathy and renal disease. The effect on macrovascular complications is less established. Diabetes is considered a CAD equivalent and patients should be started on treatment for secondary prevention of CAD. Diabetes accelerates atherosclerotic process and leads to more severe, extensive diffuse disease with higher left main disease and less collaterals. The major risk factors are amplified in diabetics with diabetic dyslipidaemia (high TG and small dense LDL and low HDL), increased prevalence of hypertension and insulin resistance syndrome. Efforts to target all risk factors among diabetics must be undertaken with exercise, control of body weight and blood sugar, smoking cessation, lipid lowering and aggressive control of blood pressure.

Dyslipidaemia

Dyslipidaemia, especially hypercholesterolaemia, elevated LDL and decreased HDL levels are strongly associated with increased risk for CAD. 1% reduction in cholesterol causes a 2% to 3% reduction in CHD risk. NCEP ATP-III guidelines recommend different therapeutic targets depending on a patient's overall risk. Patients with existing CHD (or a CHD risk equivalent, such as diabetes or peripheral vascular disease) are at the highest risk for a cardiovascular event and thus have the lowest LDL target (less than 100 mg/dL), with the option of setting the goal at less than 70 mg/dL for those who have had a recent acute coronary event or who have CVD combined with either diabetes or severe or poorly controlled risk factors.

Lipoprotein(a) is an LDL-like particle with apolipoprotein(a) attached to apolipoprotein B. A large body of literature links Lp(a) to CAD especially among Asian Indians. Cardiovascular risk appears to increase incrementally with Lp(a) but more with Lp(a) greater than 30 mg/dL.

Lifestyle Modification

Smoking cessation, a healthy diet and regular exercise, maintaining ideal body weight, improving fitness levels can only be achieved by lifestyle modification, dietary advice and counselling. These may forestall the need for pharmacologic measures to reduce coronary risk.

Cigarette smoking may be the single-most preventable cause of death and its cessation reduces risk of CAD mortality by 50% in 1 year. After 10 years, the coronary mortality risk is reduced to that of non-smokers. Exposure to second-hand smoke increase risk to death due to CAD by 30%. Cigarette smoking activates platelets, increase circulating fibrinogen, increases heart rate and blood pressure.

Exercise

Exercise conditions the skeletal muscles, which decreases oxygen consumption for the same workload. It also lowers heart rate for any level of exertion. It is recommended that aerobic isotonic exercises with a goal of 85% age predicted maximal heart rate for 20 to 30 minutes be achieved 3 to 4 times a week for secondary prevention.

Diet

Vegetarian diets with less than 10% fat and no dairy products have been shown to be beneficial. It is recommended to limit saturated fat intake to less than 7% of calories, keep trans fatty acids as low as possible and use dietary adjuncts to improve the likelihood of attaining LDL-C goals like dietary fibre, dietary plant stanol/sterol esters, etc.

Obesity

Obesity especially central obesity is associated with increased risk of developing CAD. Obese patients have higher all cause mortality rates and are more likely to be diabetic. Hence, regular exercise is recommended in obese patients for adequate weight loss and risk reduction.

Stress and type A personality

In patients with stress and type A personality, biofeedback relaxation techniques and yoga can help modify anger, hostility and stress.

Pharmacological Measures

Patients with chronic stable angina need to be treated with anti-anginal medications. The three conventional anti-anginal class of drugs are nitrates, beta-blockers and calcium channel blockers. Beta-blockers are the preferred agents and should be used in all unless contraindicated. Target resting heart rate of 60 and post-activity heart rate of less than 100 is to be achieved with adequate beta-blocker doses. Cardioselective agents like metoprolol and bisoprolol are preferred. Nitrates—short-acting (isosorbide dinitrate) and long-acting are used 3 times and 2 times a day, respectively. Nitrates are good agents for acute relief of angina for which amyl nitrate and isosorbide dinitrate are used. In patients with class III and IV angina, polytherapy with all three class of agents is used. All these patients need to be on aspirin. Statins (simvastatin, atorvastatin, rosuvastatin, etc.) should be used to achieve LDL goals of less than 70 mg/dL. ACE-inhibitors (preferably ramipril) retard the progress of atherosclerosis in patients with CAD and have mortality reducing effects as documented in HOPE study.

Revascularisation

The modalities available for revascularisation in patients with CAD are coronary artery bypass grafting (CABG) and percutaneous transluminal coronary angioplasty (PTCA). The option of treatment strategy is based on risk stratification with stress testing and LV systolic function assessment. Low-risk patients (small perfusion defects, small wall motion abnormalities on echo, high ischaemic threshold, normal LV function) can be managed medically. Persistence of symptoms despite optimal anti-anginal therapy, presence of multiple segment perfusion defects, low ischaemic threshold and moderate LV dysfunction warrant coronary angiography (CAG). In patients with single vessel disease, medical management can be the treatment option in low-risk patients. In case of persistent symptoms and high-risk patients (e.g. proximal LAD involvement), double vessel disease, PTCA is recommended. Surgical revascularisation is the treatment of choice for significant left main disease and triple vessel disease with diminished LV function. Registry based data suggests that multivessel stenting may be as efficacious in the short term as CABG. Diabetics often have small-sized vessels with diffuse disease and are poor candidates for PCI-based therapies. In insulin-requiring diabetics, CABG is definitely better. The grafts used in CABG patients include venous (reversed saphenous vein grafts harvested from legs) and arterial grafts [left internal mammary artery (LIMA) and radial artery grafts]. The arterial grafts (LIMA) have better patency and long-term outcomes (especially in diabetics).

Acute complications of PTCA include death (<1.0%), periprocedural MI (0.4%), abrupt closures due to dissections and thrombus, etc. A 15% to 20% restenosis rate has been reported with the bare metal stents. The advent of DES has reduced restenosis rates to 8% to 12%. However, subacute and late stent thrombosis have emerged as a small but definite risk in patients who undergo intervention with a DES.

Percutaneous intervention and medical therapy should be viewed as complimentary rather than opposing strategies. While PTCA improves coronary blood flow considerably more than lipid lowering, its effects are restricted to the target vessel and need to be followed with lipid lowering and medical management.

Compared to medical treatment CABG improves survival among high-risk patients with stable angina such as left main disease, three vessel disease with impaired LV function and two vessel disease including proximal LAD stenosis associated with LV dysfunction. The greater use of arterial conduits, minimal access surgery and surgery without cardio-pulmonary bypass has improved surgical results.

Newer Approaches

Therapy with direct infusion of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) have been shown to increase collaterals flow. Approaches using gene therapy to overexpress endogenous growth factors to improve development of collaterals have been proposed. However, initial optimism was not supported by trial-based evidence.

Stem cell therapy has been used in all situations in CAD and currently is under intense scrutiny in the immediate post-MI situation. There are conflicting data in this situation and the verdict is still not out. Currently, stem cell therapy is only being used in clinical trial situations.

CORONARY ARTERY DISEASE IN WOMEN

Women with CAD may present differently than men, have different pathophysiologies and risk profiles and are often significantly older and thus often have poorer outcomes. Plaque compositions are different (more cellular and fibrous), more endothelial dysfunction, more plaque erosion compared to rupture and more thrombogenesis (higher fibrinogen). They also have worse outcomes after CABG (more LVH, smaller coronary size). Women also have higher incidence of microvascular angina, vasospastic angina and abnormal coronary vasodilator reserve. However, they also have a higher incidence of atypical chest pain, a fact that often complicates evaluation of chest pain in women. Non-invasive diagnostic testing is more often false-positive in women and mortality after MI is worse in women after 60 years as compared to men. Diabetes eliminates the 'female advantage' of women. Obesity and fat distribution appear to be more independent risk factors than in men. The premenopausal female has a relative protection against CAD and a multitude of observational studies have suggested that oestrogen replacement therapy reduces risk. The recently reported heart and oestrogen/progestin replacement study (HERS) showed no reduction in recurrent coronary events in the active treatment arm in postmenopausal female survivors of AMI.

CONCLUSION

In summary, the treatment of coronary artery disease is continuously evolving. Current treatment involves constant risk stratification, modification of risk factors, optimising anti-platelet therapy, controlling blood pressure and blood sugar, symptomatic relief and revascularisation. Prevention of CAD should be an important part of health education as it may be the most cost-effective measure towards reducing the disease burden of this modern epidemic.

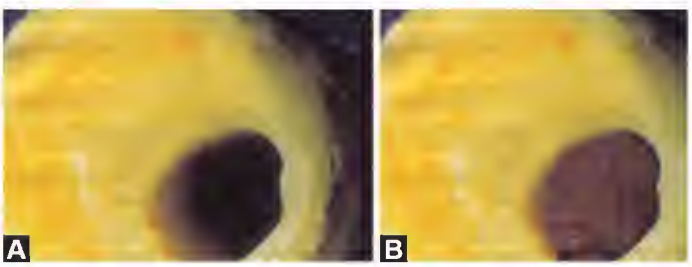
12.18 Acute Coronary Syndrome

Gurpreet Singh Wander, Naveen Kumar Gupta



The term acute coronary syndrome (ACS) refers to any group of clinical symptoms compatible with acute myocardial ischaemia and covers the spectrum of clinical conditions ranging from unstable angina (UA) to non-ST-segment elevation myocardial infarction (NSTEMI) to ST-segment elevation myocardial infarction (STEMI). Unstable angina was the term used earlier and now NSTEMI is used more commonly. The present chapter deals with UA and NSTEMI which are closely related conditions but they differ in severity. STEMI (acute myocardial infarction) is discussed in next chapter.

EPIDEMIOLOGY

According to OASIS registry, Indian patients are 7 to 8 years younger than Western patients with mean age of 57 years as against 65 years in Western population. Also, our patients are more often diabetic. A large registry – CREATE registry was done in 2008, involving 20,000 patients admitted in multiple centres in India. Thirty three per cent of these patients were less than 50 years of age. Patients of NSTEMI/STEMI reached hospital later as compared to the Western patients. In young patients coming from poorer socio-economic strata, smoking was the risk factor in 50% of the patients. In older individuals from rich areas, diabetes and hypertension were more important risk factors. The mortality rate of NSTEMI in CREATE registry was 4% which is 1% more than in Western registries.

PATHOPHYSIOLOGY

Atherosclerosis is the ongoing process of plaque formation that involves primarily the intima of large and medium-sized arteries; the condition progresses overtime, before manifesting itself as an ACS. The pathogenesis of ACS involves an interplay among the endothelium, the inflammatory cells, and the thrombogenicity of the blood. After plaque rupture (or endothelial erosion), the subendothelial matrix (which is rich in tissue factor, a potent procoagulant) is exposed to the circulating blood; this exposure leads to platelet adhesion followed by platelet activation and aggregation and the subsequent formation of a thrombus (**Figure 1**). Two types of thrombi can form: a platelet-rich clot (a *white clot*) that forms in areas of high shear stress and partially occludes the artery, or a fibrin-rich clot *(a red clot)* that is the result of an activated coagulation cascade and decreased flow in the artery. Red clots are frequently superimposed on white clots, and cause total occlusion resulting in STEMI. When occlusion is subtotal, UA/NSTEMI are usually the result (**Figure 2**).

Figures 1A and B: (A) Atheromatous plaque; (B) Ruptured plaque with thrombus.

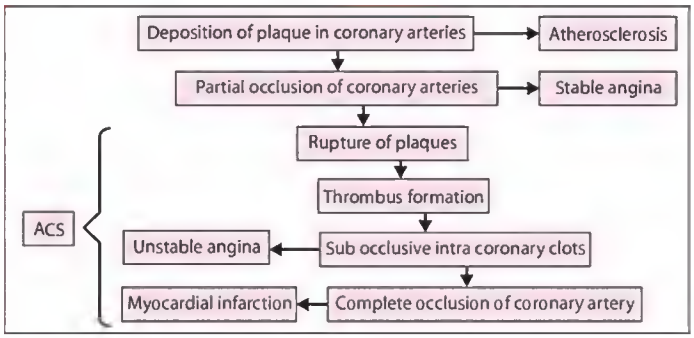


Figure 2: The spectrum of acute coronary syndromes.

The high-risk or vulnerable plaques are characterised by a large lipid core, thin fibrous caps, a high density of macrophages and T lymphocytes, a relative paucity of smooth muscle cells, locally increased expression of matrix metalloproteinases that degrade collagen, eccentric outward remodelling, and increases in plaque neovascularity and intraplaque haemorrhage. Inflammation, an important determinant of the 'vulnerability' of plaques, is related to an increase in the activity of macrophages at the site of plaque. Seventy per cent of lesions on coronary angiography that cause ACS are less than 50 per cent stenosis of arterial diameter. So most ACS episodes are due to rupture of non-obstructive plaques. The plaque usually ruptures at shoulder point.

CLINICAL FEATURES

History

ACS occurs more commonly in males. As compared to stable angina, the discomfort associated with UA is more severe, occurs at rest, lasts longer and is usually described as frank pain (**Figure 3**). It is located in the substernal region (sometimes,

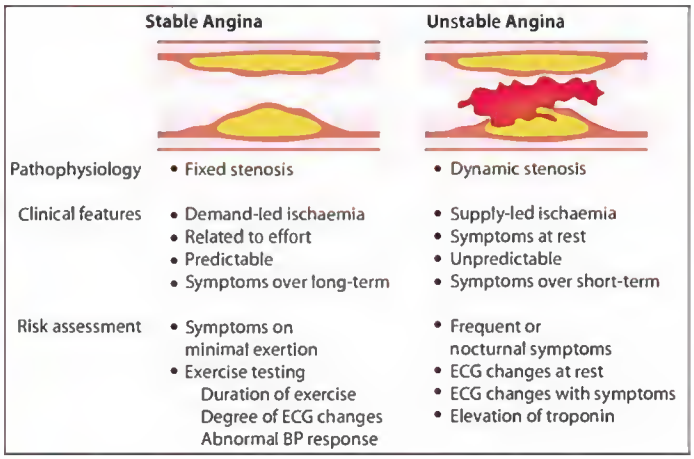

Figure 3: Clinical features and risk assessment of patients with stable or unstable angina.

the epigastric area), radiates to the neck, jaw, left shoulder, and left arm. The discomfort is often accompanied by burping and eructations and is at time mistaken as 'gas' by the patients. Some patients may present with symptoms other than chest discomfort; such 'angina equivalents' symptoms include dyspnaea (most common), nausea and vomiting, diaphoresis, and unexplained fatigue. Atypical presentations are more common among women, elderly people and in diabetics. Rarely, syncope may be the presenting symptom of ACS. Besides characteristics of pain other factors that help to identify pain of CAD are older age, male sex, a history of CAD and number of traditional risk factors present.

Unstable angina was sub classified by Dr. Eugene Braunwald as class I, II, III according to severity and prognostic significance. It is also sub classified as A,B, C according to clinical circumstances (**Table 1**).

A diagnosis of NSTEMI can be made when the ischaemia is sufficiently severe to cause myocardial damage that results in the release of a biomarker of myocardial necrosis into the circulation (cardiac-specific troponins T or I, or muscle and brain fraction of creatine kinase [CK-MB]).

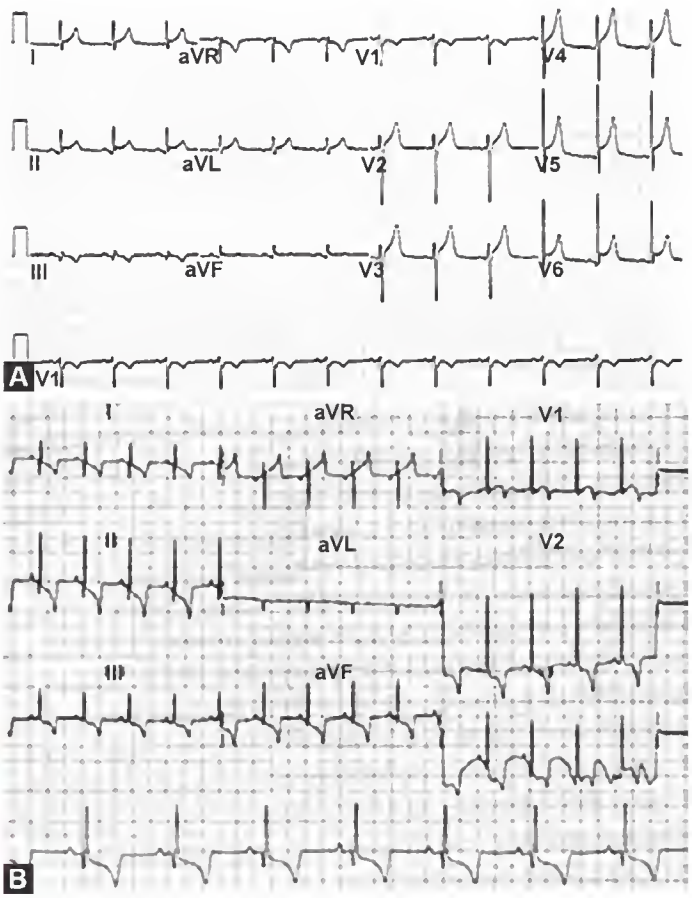
Table 1: Braunwald Clinical Classification of Unstable Angina

	Secondary UA (A)	Primary UA (B)	Post-MI Angina (C)
New onset angina (I)	I A	I B	I C
Angina at rest not within preceding 48 hours (II)	II A	II B	II C
Angina at rest within 48 hours (III)	III A	III B-T Positive III B-T Negative	III C

Arrow indicates that with increasing severity prognosis worsens.

Clinical Examination

The cardiovascular examination is mostly normal. The findings that indicate a large area of ischaemia and high-risk include diaphoresis; pale, cool skin; sinus tachycardia; a third or fourth heart sound; basilar rales; and hypotension. The physical examination may also provide clues that can help in determining the differential diagnosis. For example, unequal pulses or a murmur of aortic regurgitation indicates possible aortic dissection, whereas a pericardial friction rub suggests acute pericarditis.



INVESTIGATIONS

Electrocardiography

Findings on ECG associated with UA include ST-segment depression, transient ST-segment elevation, T-wave inversion, or some combination of these changes. Depending on the severity of the clinical presentation, these findings are present in 30% to 50% of the patients. New ST-segment deviation, even of only 0.05 mV, is an important and specific measure of ischaemia and prognosis. T wave inversion is sensitive for ischaemia but is less specific. Patients with no ECG changes are at a lower risk of complications than those with ECG changes. Myocardial ischaemia is dynamic and patients hospitalised for UA/NSTEMI should undergo serial ECG tracings or continuous ST segment monitoring (**Figure 4**).

Cardiac Biomarkers

Markers of myocardial necrosis should be measured in all patients of acute coronary syndromes and include CK-MB and troponin-T/troponin-I. They are used for the diagnosis of NSTEMI and for prognostication. Troponins are more sensitive and specific than any other biomarker. Both qualitative as well as quantitative measurements are available. There is a direct relationship between the degree of troponin elevation and mortality. Patients with elevated Troponin levels have 25% risk of death or MI at 6 months as compared to less than 5% risk in patients with normal Troponin levels. Troponins are not released before 4 to 5 hours of symptoms, so these should be measured after 4 to 5 hours of symptom onset and if results are negative, these are measured after 8 to 12 hours of symptom onset. Troponins remain elevated up to 10 to 14 days of symptom onset. Levels of CK-MB start increasing after 10 to 12 hours of symptom onset and remain elevated for 24 to 36 hours. It is rapid, cost- efficient and detects early reinfarction but lacks specificity in setting of skeletal muscle disease or injury, including surgery.

Figures 4A and B: Electrocardiographic changes in ACS. (A) Normal or non-diagnostic ECG; (B) ST depression or dynamic T wave inversions.

Other Laboratory Tests

A chest X-ray is usually obtained at the time of admission. A full lipid profile should be obtained within 24 hours of the onset of ACS. Elevated CRP levels relate to an increased risk of mortality. B-type natriuretic peptide (BNP) provides useful prognostic information across the entire spectrum of patients with ACS as a marker of heart failure which may be associated in some high-risk patients.

Echocardiography

Echocardiography is the rapid bed side tool for assessment of regional wall motion abnormalities (RWMA), LV functions and mitral regurgitation. It also helps to rule out conditions like aortic

stenosis (AS), hypertrophic obstructive cardiomyopathy (HOCM) and mitral valve prolapse (MVP) which may have similar presentations.

Risk Stratification

Patients of ACS have variable prognosis. At one end of spectrum are young patients with new onset angina, no ECG changes, non-elevated biomarkers and no haemodynamic instability. These patients are managed pharmacologically and they should undergo non-invasive testing (TMT, stress echocardiography) after 10 days of symptom onset. At the other end are patients with history of recurrent/rest angina, fresh ECG changes, elevated biomarkers and, haemodynamically unstable patients who need early invasive treatment strategy in the form of PCI.

Patients with ACS are risk stratified on the basis of certain criteria, to assess which of them would benefit from early invasive therapy (percutaneous coronary intervention) and who will be managed conservatively (**Table 2**). Many risk profile models like TIMI (**Table 3**), GRACE have been proposed for triage assessment. The TIMI risk score is determined by seven variables, each of which is assigned one point. Patients with scores of five or more have been shown to have a higher risk of adverse events and a higher mortality and these patients should be considered for early coronary angiography and revascularisation.

Forty per cent of rich and 8.5% of the poor patients had coronary angiography done in the CREATE registry. So besides above listed factors, socio-economic status also effects the decision for invasive strategy.

Table 2: Selection of Initial Treatment Strategy: Invasive versus Conservative

Invasive	Recurrent angina or ischaemia at rest or with low-level activities despite intensive medical therapy
	Elevated cardiac biomarkers (TnT or TnI)
	New or presumably new ST-segment depression
	Signs or symptoms of HF or new or worsening mitral regurgitation
	High-risk findings from non-invasive testing
	Haemodynamic instability
	Sustained ventricular tachycardia
	PCI within 6 month
	Prior CABG
	High-risk score (e.g. TIMI, GRACE)
	Reduced left ventricular function (LVEF < 40%)
Conservative	Low-risk score (e.g. TIMI, GRACE)
	Patient or physician preference in the absence of high-risk features

CABG = Coronary artery bypass grafting; GRACE = Global registry of acute coronary events; HF = Heart failure; LVEF = Left ventricular ejection fraction; PCI = Percutaneous coronary intervention; TIMI = Thrombolysis in myocardial infarction; TnI = Troponin I; TnT = Troponin T.

Coronary Angiography

Coronary angiography is done in all patients who are stratified as high-risk by risk profile models as described above. Angiography is the key in diagnosing the extent, location and severity of lesions and in planning revascularisation [percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG)]. More than 80% patients with UA/NSTEMI show significant coronary lesions on coronary angiography.

Table 3: The TIMI Risk Score

TIMI Risk Score (No. of Risk Factors)*	Risk of Death, MI, or Urgent Revascularisation (%)
0 or 1	~ 5%
2	~ 10%
3	~ 15%
4	~ 20%
5	~ 25%
6	~ 40%

** Risk factors include: Age ≥ 65 years; ≥ 3 CAD risk factors; Known CAD (>50% stenosis); Prior aspirin therapy; ≥ 2 anginal episodes in last 24 hours; ST deviation ≥ 0.5 mm; Elevated Troponins.*

MANAGEMENT

The principles of management are general measures, pharmacological therapy and revascularisation.

General Measures

Patients with definite ACS are admitted to the hospital for further treatment. Admission to the coronary care unit (CCU) is recommended if there is an evidence of active, ongoing ischaemia or haemodynamic or electrical instability. The other measures include bed rest till patient is pain free for at least 24 hours, mild sedation, quiet environment, morphine or pethidine if pain is not substantially relieved by nitrates and beta-blockers and stool softeners to avoid straining.

Pharmacological Therapy

In general, all patients should receive dual anti-platelet agent therapy (aspirin and clopidogrel), antithrombotic therapy (unfractionated heparin or low molecular weight heparin), beta-blockers, statins and ACE-inhibitors.

Dual anti-platelet therapy includes aspirin and clopidogrel. Aspirin blocks the synthesis of thromboxane A2 by irreversibly inhibiting cyclooxygenase 1, thereby diminishing platelet aggregation. Randomised trials demonstrate that, compared with placebo, aspirin reduces the risk of death or MI by more than 50% for patients presenting with UA/NSTEMI.

Clopidogrel is a thienopyridine derivative that blocks the P2Y12 adenosine diphosphate (ADP) receptor on platelets. This action decreases platelet activation and aggregation, increases bleeding time, and reduces blood viscosity. Therapy with clopidogrel and aspirin is recommended for essentially all patients with UA/NSTEMI.

The platelet GP IIb/IIIa inhibitors are potent and specific inhibitors of platelet aggregation. They act by interrupting the final common pathway of fibrinogen-mediated cross-linkage of platelets. Several large trials involving patients with UA/NSTEMI have shown that the GP IIb/IIIa inhibitors are of substantial benefit for patients at high-risk, those undergoing PCI, or both. Three agents are currently available for use: abciximab, eptifibatide, and tirofiban. The main risk associated with GP IIb/IIIa inhibitors is an increased rate of haemorrhage, usually at the site of vascular intervention.

Low molecular weight heparins (LMWH) have several advantages over conventional heparins, including ease of administration (twice a day), a lower rate of thrombocytopaenia, more bioavailability, and less binding to plasma proteins, a factor that renders monitoring the level of anticoagulation unnecessary.

The factor Xa inhibitor fondaparinux is equivalent for efficacy compared with enoxaparin with a lower risk of major bleeding and have the better benefit risk ratio besides once daily dosing.

Direct thrombin inhibitors have several potential advantages over indirect thrombin inhibitors (such as UFH or LMWH): do not require a cofactor such as anti-thrombin for their action and directly inhibit clot-bound thrombin, no interaction with plasma proteins and no thrombocytopaenia. Bivalirudin is used for the treatment of patients with UA/NSTEMI selected for an early invasive strategy.

Nitrates act as vasodilator, thereby reducing myocardial oxygen demand via venodilatation and enhance myocardial oxygen delivery by dilating large coronary arteries and improving collateral flow to ischaemic areas. Nitrates relieve chest pain but do not reduce mortality in ACS.

Beta-blockers can be used IV initially, if there is ongoing ischaemia and pain, followed by oral therapy. Beta-blockers inhibit β-1 adrenergic receptors in the myocardium and decrease myocardial contractility and heart rate, thereby reducing myocardial oxygen demand. They reduce the incidence of subsequent MI, recurrent ischaemia, or both.

Calcium channel blockers are used in patients with resistant ischaemia despite beta-blocker therapy and in those with contraindications to beta-blockers. Calcium channel blockers inhibit the contraction of both the myocardium (thereby reducing myocardial oxygen demand) and the vascular smooth muscle (thereby causing coronary vasodilatation and improving myocardial blood flow). These agents should not be administered to patients with severe LV dysfunction or pulmonary oedema.

In the absence of contraindications, lipid-lowering therapy with statins should be initiated for all patients with UA/NSTEMI, regardless of baseline LDL cholesterol levels.

Revascularisation

Revascularisation consists of measures to open the culprit vessel/(s) to improve the perfusion to the ischaemic myocardium, after identification of the location and extent of the lesions on coronary angiography (CAG). It can be done by percutaneous coronary intervention (PCI), i.e. percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass grafting (CABG).

The choice of the revascularisation procedure depends on several factors, including the patient's age, clinical status, location and extent of lesions and especially, in the Indian setting—financial status. In CREATE registry, 6.7% of the patients of NSTEMI get PCI as compared to 30% patients in Western registries. This major difference is due to cost factor. In general, patients with significant triple vessel disease, left main coronary artery lesions and with lesions that are anatomically difficult to stent, are candidates for CABG.

In the field of PCI, many advances have been made. Earlier, it involved simple balloon dilatation of lesions (with consequent high restenosis rates). With the availability of bare metal stents (BMS), restenosis rates were significantly reduced across the coronary lesions. The development of special stents coated with drugs like sirolimus and paclitaxel [drug-eluting stents(DES)], further reduced restenosis rates to single digit percentages. These drugs have an anti-mitotic effect, whereby they inhibit neointimal proliferation, which is considered the major mechanism of in stent restenosis. To prevent the rate of progression of late restenosis, newer polymer free stents are under investigation.

12.19 Acute Myocardial Infarction

Gurpreet Singh Wander, Naved Aslam

Acute myocardial infarction (AMI) is a clinical syndrome that results from occlusion of a coronary artery with resultant death of cardiac myocytes in the region supplied by that artery. When these patients present in emergency, they have ST elevation in ECG and so are referred as ST elevation myocardial infarction (STEMI). Depending on the distribution of the affected coronary artery, AMI can produce a wide range of clinical sequelae, varying from a small, clinical silent region of necrosis to a large area of infarcted tissue resulting in cardiogenic shock and death.

AMI is the leading cause of death in the developed and developing countries, including India. The true incidence of AMI is difficult to judge because of varied reporting pattern. Moreover, up to 1/3rd cases die at home before they reach hospital or are examined by qualified practitioner. The risk of having an AMI increases with age, male gender, smoking, dyslipidaemia, diabetes, hypertension, abdominal obesity, a lack of physical activity, low daily fruit and vegetable consumption and psychosocial factors. As much as 90% of risk of AMI has been attributed to these modifiable risk factors in the INTERHEART study.

PATHOPHYSIOLOGY

AMI usually occurs when coronary blood flow decreases abruptly after a thrombotic occlusion of a coronary artery (vascular injury) previously affected by atherosclerosis. As discussed in previous chapter, acute coronary syndrome occurs due to rupture of atheromatous plaque and subsequent formation of thrombus over it. STEMI and AMI occur when this thrombus causes complete occlusion of coronary artery, thus resulting in myocardial necrosis. Myocardial necrosis starts early within 15 to 20 minutes of occlusion and is complete by 6 to 9 hours depending on collateral circulation and recanalisation. It is for this reason that first 6 hours are most risky (time for primary ventricular fibrillation) and also any reperfusion therapy has to be done within this period. The central area of myocardial necrosis is surrounded by area of myocardial injury which is surrounded by area of myocardial ischaemia. Initially, inflammatory cells reach the site of myocardial necrosis and endocardium becomes eroded. Over period of 2 to 6 weeks, scarring occurs and results in myocardial scars which subsequently, remodels over months in the form of dilatation of infarcted segment and latera also of the non-infarcted segment in case the size of infarct is large.

In rare cases, AMI may be due to coronary artery occlusion caused by coronary emboli, congenital abnormalities and coronary spasm. The amount of myocardial damage caused by coronary occlusion depends on the territory supplied by the affected vessel, the duration of coronary occlusion, the quantity of blood supplied by collateral vessels to the affected tissue, the demand for oxygen of the myocardium whose blood supply has been suddenly limited, native factors that can produce early spontaneous lysis of the occlusive thrombus, and the adequacy of myocardial perfusion in the infarct zone when flow is restored in the occluded epicardial coronary artery.

CLINICAL PRESENTATION

A precipitating factor is present before AMI in ~15% cases, such as vigorous physical exercise, emotional stress, or a medical or surgical illness. Circadian and seasonal variations have been reported with increased incidence in the morning within a few hours of awakening and during winter months.

The most common presentation for AMI is abrupt onset chest, neck or jaw discomfort, which is usually described as pressure, burning or squeezing in character. Pain in AMI is usually very severe, persistent and is relieved only with opiates. The pain of AMI may radiate up to the jaw and to the umbilicus. AMI can be the first presentation of CAD or it can occur in a patient with known angina pectoris. Symptoms typically last more than 20 minutes. It is often accompanied by weakness, sweating, nausea, vomiting, anxiety, and a sense of impending doom. In about quarter of patients, the infarction may not be recognised because of atypical symptoms. About 20% patients have silent infarction, usually in diabetics and elderly.

Physical Findings

Most patients are anxious and restless, attempting unsuccessfully to relieve the pain by moving about in bed, altering their position, and stretching. Pallor associated with perspiration and cold extremities occurs commonly. Usually, patients have sinus tachycardia due to pain and anxiety. Patients are often tachypnoeic. About one-fourth of patients with anterior infarction have manifestations of sympathetic nervous system hyperactivity (tachycardia and/or hypertension), and up to one-half with inferior infarction show evidence of parasympathetic hyperactivity (bradycardia and/or hypotension). The jugular venous pulse should be carefully examined, its elevation in the setting of inferior myocardial infarction (MI) without left heart failure suggests right ventricular myocardial infarction (MI). Detection of right ventricular MI is vital because it portends a much worse prognosis than isolated inferior MI and the management strategy is different than isolated inferior MI.

The praecordium is usually quiet, and the apical impulse may be difficult to palpate. In patients with anterior wall infarction, an abnormal systolic pulsation caused by dyskinetic bulging of infarcted myocardium may develop in the periapical area within the first days of the illness and then may resolve. Other physical signs of ventricular dysfunction include fourth and third heart sounds. A transient mid-systolic or late systolic apical systolic murmur due to dysfunction of the mitral valve apparatus may be present. A pericardial friction rub is heard in many patients with transmural AMI at some time in the course of the disease, if they are examined frequently. The carotid pulse is often decreased in volume, reflecting reduced stroke volume.

Temperature elevations up to 38°C may be observed during the first week after AMI.

DIFFERENTIAL DIAGNOSIS

The pain of AMI can simulate pain from acute pericarditis, pulmonary embolism, acute aortic dissection, costochondritis, and oesophageal rupture, café coronary. Pain of aortic dissection radiates to back and can be suspected in presence of unequal peripheral pulses. Acute pericarditic pain increases with inspiration.

Laboratory Findings

Myocardial infarction progresses through the following temporal stages: acute (first few hours to seven days), healing (7 days to 30 days), and healed (>29 days). When evaluating the results of diagnostic tests for AMI, the temporal phase of the infarction must be considered. The laboratory tests of value in confirming the diagnosis may be divided into four groups: (1) ECG, (2) serum cardiac biomarkers, (3) cardiac imaging, and (4) coronary angiography.

Electrocardiogram

During the initial stage, total occlusion of an epicardial coronary artery produces ST segment elevation. Most patients initially presenting with ST segment elevation ultimately evolve Q waves on the ECG. The most rapid and helpful test in assessing patient with suspected AMI is the 12-lead, ECG. It should be performed as soon as possible, after the patient's arrival in the emergency, since the presence or absence of ST elevation determines the preferred management strategy. Tall T wave and ST elevation is first sign and occur within minutes. ST elevation changes from concave upwards to coving (convex upwards) within few hours and is then accompanied with T wave inversion. Q waves are formed in 6 to 12 hours. The central area of necrosis is represented by Q waves, surrounding area of injury by ST segment changes and outer area of ischaemia by T wave changes. The Q wave persists for whole life. ST and T wave changes revert to normal by 6 weeks to 3 months. For a diagnosis of ST elevation MI (AMI), ST elevation must be present in at least two contiguous leads. For anterior MI, the precordial (V_1 to V_6) leads demonstrate ST elevation and if there is lateral wall involvement, lead I and aVL may also show ST elevation. In inferior MI leads II-III and aVF are affected (**Figures 1 to 3**). In addition to standard ECG leads, right ventricular leads should be recorded in all patients with inferior MI. In posterior MI, usually due to circumflex artery occlusion, changes seen on a standard ECG may be reciprocal ST depression and R waves

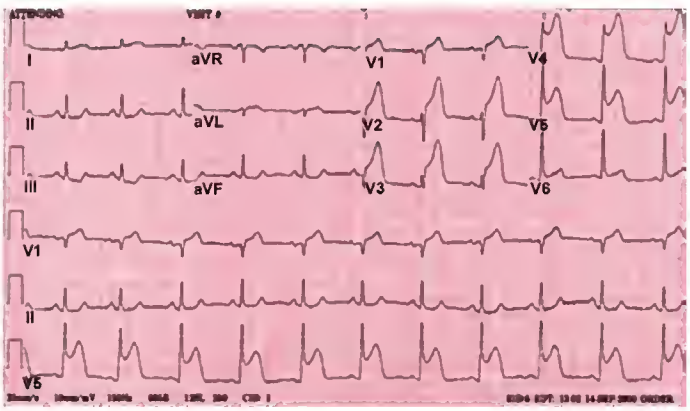

Figure 1: Anterior wall myocardial infarction.

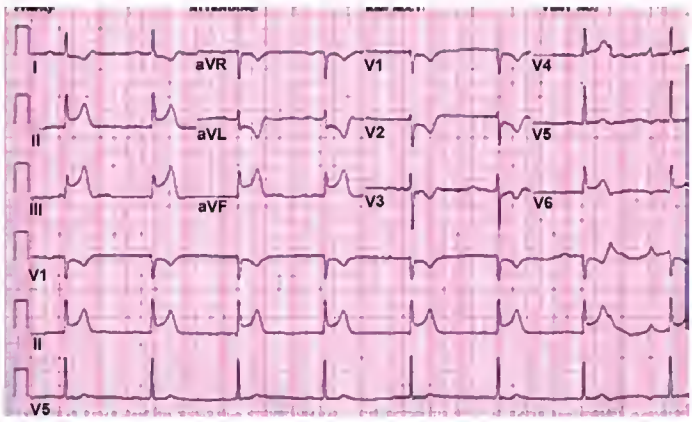

Figure 2: Inferior wall myocardial infarction.

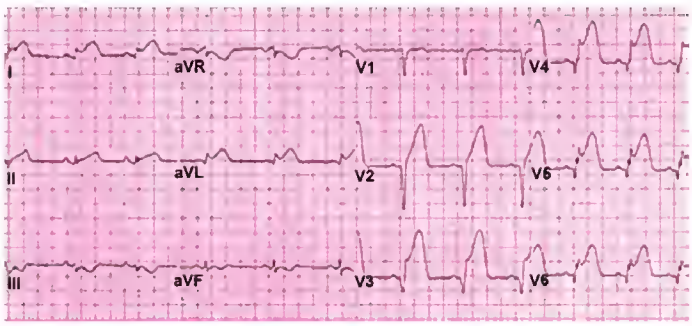

Figure 3: Anterolateral wall myocardial infarction.

(reciprocal of Q waves) in the anterior leads. The ECG pattern should prompt the use of posterior ECG leads V_7 to V_9 which may show ST elevation. Sometimes determining whether ECG changes are new or old may be difficult, serial ECGs are necessary to diagnose dynamic changes.

Cardiac Biomarkers

Cardiac biomarkers become detectable in the peripheral blood once the capacity of the cardiac lymphatics to clear the interstitium of the infarct zone is exceeded and spill over into the venous circulation occurs. CPK-MB is used most commonly. Myoglobin is the first to rise but since it is non specific, it is not used clinically. Troponins are also useful. The use of these markers is shown in **Tables 1 and 2**.

The *nonspecific reaction* to myocardial injury is associated with polymorphonuclear leucocytosis, which appears within a few hours after the onset of pain and persists for 3 to 7 days; the white blood cell count often reaches levels of 12,000/mL to 15,000/mL. The erythrocyte sedimentation rate rises more slowly than the white blood cell count, peaking during the first week and sometimes remaining elevated for 1 or 2 weeks.

Cardiac Imaging

Abnormalities of wall motion on two-dimensional echocardiography are almost universally present. Early detection of the presence or absence of wall motion abnormalities by bedside echocardiography can aid in management decisions. Echocardiography may also identify the presence of right ventricular (RV) infarction, ventricular aneurysm, pericardial effusion, and LV thrombus. In addition, Doppler echocardiography is useful in the detection and quantitation of a ventricular septal defect and mitral regurgitation, two serious complications of AMI.

Table 1: Various Cardiac Markers in AMI

	CK-MB	Myoglobin	Cardiac Troponins
Description	High energy transfer cytoplasmic protein	O_2 binding haem protein, rapidly released myocyte injury	Regulatory proteins for calcium – dependent interactions between actin and myosin
Origin	Cardiac and skeletal muscle	Cardiac and skeletal muscle	Cardiac muscle
Release kinetics peak rise	2 to 3 hours; sensitivity 94% at 8 hours and <50% at 2 hours	1.5 to 2 hours	3 to 4 hours
Return to normal	24 to 48 hours	8 to 12 hours	10 to 14 days
Advantages	Able to detect early reinfarction	Marker to detect very early MI	More sensitive and specific than CK-MB best marker for MI with skeletal muscle injury, small MI or late MI (>2 to 3 days)
Disadvantages	Low sensitivity for detection of very early (<6 hr) MI small MI; false positive with skeletal muscle trauma, CPR, cardioversion, cardiac surgery	Low sensitivity for detection of late MI with skeletal muscle trauma, CPR and renal failure	Low sensitivity for detection of early (<6 hr) MI or late reinfarction

Table 2: Use of Serum Cardiac Markers in Relation to Time

Subset	Total CK	CK-MB	Myoglobin	Cardiac Troponins
MI < 4 hours	–	–	+	–
MI 4 to 12 hours	+	+	+	+
MI >2 to 10 days	–	–	–	≥
Early reinfarction	+	+	≥	–
Small MI	–	–	–	+
MI after operation of trauma	–	≥	–	+

+ Useful, ≥ some volue, – not useful.

Myocardial perfusion imaging can be useful in some cases with doubtful diagnosis.

Coronary Angiography

Coronary angiography is done either at admission prior to primary PCI or pre discharge for assessment of disease. In a conservative approach, patients of MI are subjected to non-invasive stress evaluation (TMT, stress echocardiography, myocardial perfusion imaging) and those with inducible ischaemia are taken-up for coronary angiography while those with no inducible ischaemia are treated medically.

INITIAL MANAGEMENT

Pre-Hospital Care

The prognosis in AMI is largely related to the occurrence of two general classes of complications: (1) electrical complications (arrhythmias) and (2) mechanical complications ('pump failure'). Most out-of-hospital deaths from AMI are due to the sudden development of ventricular fibrillation. The vast majority of deaths due to ventricular fibrillation occur within the first 24 hours of the onset of symptoms, and of these, over half occur in the first hour. Therefore, the major elements of pre-hospital care of patients with suspected AMI include:

1. Recognition of symptoms and seeking of medical attention.
2. Emergency medical team for resuscitative manoeuvres and defibrillation.
3. Transportation to hospital for managing arrhythmias and providing advanced cardiac life support.
4. Reperfusion therapy.

The biggest delay usually occurs not during transportation to the hospital but rather between the onset of pain and the patient's decision to call for help which can be best reduced by health care professionals educating the public concerning the significance of chest discomfort and the importance of seeking early medical attention.

Management in the Emergency Department

Many aspects of the treatment of AMI are initiated in the Emergency Department and then continued during the in-hospital phase of management.

Aspirin is essential in the management of patients with suspected AMI. Rapid inhibition of cyclooxygenase-1 in platelets followed by a reduction of thromboxane A_2 levels is achieved by buccal absorption of a chewed 160 to 325 milligram tablet in the emergency department. Six hundred mg of loading dose of clopidogrel followed by 60 mg once daily should be given to all patients of AMI (dual anti-platelet therapy).

When hypoxaemia is present, oxygen should be administered by nasal prongs or face mask (2 to 4 L/min) for the first 6 to 12 hours after infarction; the patient should then be reassessed to determine if there is a continued need for such treatment.

Sublingual nitroglycerin can be given safely to most patients with AMI. Up to three doses of 0.4 mg should be administered at about 5-minute intervals. Therapy with nitrates should be avoided in patients who present with low systolic arterial pressure (< 90 mm Hg) or in whom there is clinical suspicion of right ventricular infarction (inferior infarction on ECG, elevated jugular venous pressure, clear lungs, and hypotension).

Morphine is a very effective analgesic for the pain associated with AMI. Morphine is routinely administered by repetitive (every 15 min) intravenous injection of small doses (2 to 4 mg) rather than by the subcutaneous administration of a larger quantity, because absorption may be unpredictable by the latter route.

MANAGEMENT STRATEGIES

The primary tool for screening patients and making triage decisions is the initial 12-lead ECG. When ST-segment elevation of at least 2 mm in two contiguous precordial leads and 1 mm in two adjacent limb leads is present, a patient should be considered a candidate for reperfusion therapy.

Reperfusion, either pharmacologically (by fibrinolysis) or by PCI, accelerates the opening of infarct-related arteries in those patients. Timely restoration of flow in the epicardial infarct–related artery, combined with improved perfusion of the downstream zone of infarcted myocardium, results in a limitation of infarct size.

Pharmacologic or Mechanical Reperfusion

Although primary PCI is considered the reperfusion strategy of choice, it is clear that this advantage is time dependent and limited to specific patient populations. Most patients in India are given thrombolytic therapy due to cost factor and also since cardiac catheterisation lab facilities are not available widely. In the CREATE registry almost ~8% patients of AMI get primary PCI in our country for this reason. In 2008, 55% of the patients of AMI got thrombolysed as against 30% in 1990s since patients are now reaching hospitals early.

Fibrinolytic therapy of STEMI significantly improves mortality rates; treatment within six hours of the onset of symptoms leads to a reduction in mortality between 26 and 65 per 1,000 patients treated which has been extensively documented.

Fibrinolytic agents

The fibrinolytic agents differ in several properties, as summarised in the text and **Table 3**.

Streptokinase: Streptokinase (SK) is a bacterial protein with half-life of 23 minutes. SK is antigenic, has less fibrin specificity, and causes systemic lytic effects in clinical doses. It is least expensive of fibrinolytics and still widely used globally. SK is administered by short-term (1 hour) infusions. This is the agent of choice of our country.

Tissue-type Plasminogen Activator (tPA): Tissue-type plasminogen activator (tPA) is the major intrinsic (physiologic) plasminogen activator. The short half-life has necessitated bolus/infusion regimens (over 1 to 3 hours). tPA is given as 15 mg bolus, then 0.75 mg/kg over 30 min (maximum 50 mg), then 0.50 mg/kg over 60 min (maximum 35 mg).

Reteplase: It is a non-glycosylated, single chain deletion variant of human tPA. It is given in two bolus injections 30 minutes apart.

Tenecteplase: Tenecteplase (TNK) is a triple mutant and is given as single bolus dose (30 to 50 mg) over 1 to 2 minutes. The ease of administration of TNK, together with its reduced transfusion requirements, has led to its general acceptance and favoured status. Lower rates of dosing errors with bolus fibrinolytics such as TNK also contribute to superior clinical outcomes. TNK is dosed by weight (supplied in 5 mg/mL vials): 60 kg = 6 mL; 61–70 kg = 7 mL; 71–80 Kg = 8 mL; 81–90 kg = 9 mL; 90 kg = 10 mL.

The absolute and relative contraindications to fibrinolytic therapy are summarised in **Table 4**.

Primary angioplasty

Primary percutaneous coronary intervention (PCI) has been very successful in accomplishing mechanical reperfusion of the coronary artery in patients presenting with AMI (**Figures 4A to C**).

Mechanical reperfusion has the potential to overcome many of the limitations of fibrinolytics. The overall risk of intracranial bleeding is significantly lower with PCI. There is a significant superiority of primary PCI, especially among patients in which it was logistically feasible to accomplish reperfusion within 90 minutes of presentation. Primary PCI is preferred modality of reperfusion over fibrinolytic therapy. However, this is available to small percentage of patients in India and also in Western world: 10% and 35% respectively.

When performing primary PCI for patients presenting with STEMI, coronary stents, either Bare metal stent (BMS) or Drug eluting stent (DES), should be used whenever technically feasible. Significant clot burden may complicate acute STEMI, management.

Bypass surgery may be required owing to anatomic considerations, such as left main disease or coronary disease not suitable for immediate PCI, or mechanical complications from the MI such as acute severe mitral regurgitation, ventricular septal defect or a failed PCI.

Table 3: Comparison of Fibrinolytic Agents Approved by the US FDA for Intravenous Use

	SK (Streptokinase)	tPA (Alteplase)	tPA (Reteplase)	TNK (Tenecteplase)
Dose	1.5 million units (MU) in 30 to 60 min	100 mg in 90 min	10 u + 10 u 30 min apart	30 to 50 mg Over 5 seconds
Circulating half life (min)	20	6	18	20
Antigenic	Yes	No	No	No
Allergic reactions	Yes	No	No	No
Systemic fibrinogen depletion	Severe	Mild moderate	Moderate	Minimal
Intracerebral haemorrhage	0.4%	0.7%	0.8%	0.7%
Patency (TIMI-2/3) rate, 90 min	51%	73% to 85%	83%	77% to 88%
Lives saved per 100 treated	3	4	4	4

Based on the finding from the GUSTO trial that tPA saves 1 more additional life per 100 treated than dose SK.

Adjuvant therapy

All patients should be treated with ASA and a thienopyridine (currently clopidogrel) as soon as possible following diagnosis. The choice of anticoagulant therapy, in part, is dictated by the method of reperfusion undertaken. Following fibrinolytic therapy, both fondaparinux and LWWHs improve clinical outcomes compared with UFH. Direct thrombin inhibitors (Bivalirudin) appear to be a reasonable alternative to UFH, and preferred in settings of thrombocytopaenia or prior heparin-induced thrombocytopaenia.

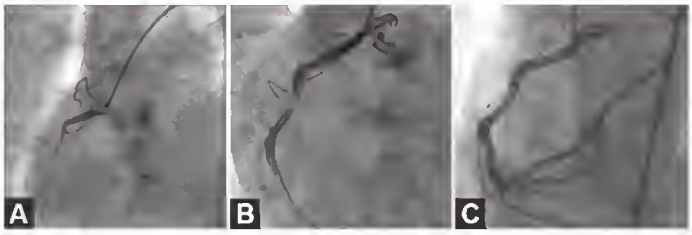

Table 4: Contraindications and Cautions for Fibrinolysis in STEMI

Absolute contraindications

- Any prior ICH
- Known structural cerebral vascular lesion (e.g. arteriovenous malformation)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 months EXCEPT acute ischemic stroke within 3 hours
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed head or facial trauma within 3 months

Relative contraindications

- History of chronic, severe, poorly controlled hypertension
- Severe uncontrolled hypertension on presentation (SBP greater than 180 mm Hg or DBP greater than 110 mm Hg)
- History of prior ischaemic stroke greater than 3 months, dementia, or known intracranial pathology not covered in contraindications
- Traumatic or prolonged (greater than 10 minutes) CPR or major surgery less than 3 weeks)
- Recent (within 2 to 4 weeks) internal bleeding
- Non-compressible vascular punctures
- For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction
- Pregnancy
- Active peptic ulcer
- Current use of anticoagulants: the higher the INR, the higher the risk of bleeding

Figures 4A to C: Primary angioplasty of right coronary artery (RCA). (A) Coronary angogram showing RCA filled with thrombus. (B) Partial flow in RCA after thrombus aspiration. (C) TIMI grade III flow after stenting.

In patients undergoing primary PCI, UFH has traditionally been administered, based primarily on theoretical grounds and the experience of experts. There is evidence that the addition of a GP IIb/IIIa receptor antagonist improves outcomes (abciximab, eptifibatide, tirofiban). There is now evidence from a single, moderately sized trial that bivalirudin is as efficacious as the combination of UFH plus a GP IIb/IIIa receptor antagonist.

Bleeding complications in patients with AMI remain relatively common and may be as important to long-term outcome as ischaemic events.

COMPLICATIONS

Complications following AMI are enumerated below.

1. Arrhythmias
2. Heart failure
3. Cardiogenic shock
4. Sudden death
5. Reinfarction, extension and expansion of infarction
6. Infarction of papillary muscle of mitral valve – mitral regurgitation (MR)
7. Rupture of interventricular septum leading to ventricular septal defect (VSD)
8. Thrombus in LV causing peripheral embolism
9. Cardiac rupture
10. Deep vein thrombosis in legs causing pulmonary embolism
11. Pericarditis during massive infarction
12. Aneurysm of ventricle with thrombosis and thrombo-embolic phenomenon
13. Dressler's syndrome (post-myocardial infarction syndrome)

Arrhythmias

Various types of arrhythmias that can follow AMI are listed in **Table 5**.

Table 5: Important Arrhythmias in Acute Myocardial Infarction

Ventricular premature beats
Ventricular tachycardia
Ventricular fibrillation
Accelerated idioventricular rhythm
Atrial premature beats
Atrial tachycardia
Atrial fibrillation

Premature ventricular complexes are the commonest and can be forerunners of lethal ventricular arrhythmia viz ventricular tachycardia or fibrillation. Ventricular fibrillation is the major cause of death in those who die before receiving medical attention.

Bradyarrhythmias and conduction disturbances may also occur in the form of sinus node dysfunction, AV nodal block or distal conduction disturbances (bundle branch block or complete heart block). *The details of arrhythmias are outlined in the respective chapter on Tachyarrhythmias and Bradyarrhythmias Chapters 23 and 24 of section 12.*

Heart Failure

The extent of LV dysfunction is a strong predictor of short- and long-term prognosis after MI. The Killip and Kimball classification stratifies MI patients from low to very high risk based upon clinical signs of heart failure (**Table 6**). It remains a reasonably accurate predictor of short-term survival.

Table 6: Killip and Kimball Classification

Class	Clinical Features	Mortality
Killip I	MI with no HF	6%
Killip II	MI with mild HF (basal rales)	17%
Killip III	MI with severe HF (rales ≥50% of lung fields)	38%
Killip IV	Cardiogenic shock	81%

The presence of clinical signs of left ventricular failure is a strong indicator of a poor long-term prognosis. It is manifested by

breathlessness, cough, haemoptysis, perspiration, S3, S4 gallop and pulmonary rales in some, the symptoms may be minor in others. Measurements of left ventricular function and diastolic volume predict short-term and long-term prognosis after STEMI.

Severe forms of LV failure need haemodynamic monitoring with a balloon-tipped, flow-guided Swan-Ganz catheter placed in the pulmonary artery. Cardiac output is estimated by thermodilution technique. In the absence of mitral valve disease, pulmonary artery diastolic pressure reflects LV filling pressure (normal value 0 to 14 mm Hg) and is high in LV failure. An arterial line to monitor systemic blood pressure is also required. Medical management involves intravenous nitroglycerine infusion. If low, then the infusion of vasopressor like dopamine can be started along with nitroglycerine. Recently eplerenone, aldosterone inhibitor in doses of 25 to 50 mg is used to treat LVF in AMI.

Intra-aortic balloon counterpulsation can be a life-saving measure. The balloon is placed in the aorta distal to the left subclavian artery. It is inflated during diastole, thus improving the flow of blood into the coronaries, and deflated in systole thereby reducing ventricular after load.

ACE-inhibitors unequivocally reduce mortality overall, and the benefit appears to be greatest among patients with depressed LV function, overt heart failure or anterior infarction.

The initiation of ACE-inhibitor therapy early in the course of infarction results in greater improvement in ejection fraction.

All patients with post-MI LV dysfunction should be administered ACE-inhibitors unless contraindicated or not tolerated.

Cardiogenic Shock

Cardiogenic shock is a syndrome characterised by hypotension and peripheral hypoperfusion, usually accompanied by high LV filling pressures. The common clinical manifestations of these haemodynamic derangements include mental obtundation or confusion, cold and clammy skin, and oliguria or anuria. Cardiogenic shock is the most common cause of in-hospital mortality after MI. When cardiogenic shock is not secondary to a correctable cause such as arrhythmia, bradycardia, hypovolaemia or mechanical defect, short-term mortality is 80%.

Inotropic drugs (dopamine, dobutamine, epinephrine, norepinephrine) have been subjected to detailed study and widespread use in cardiogenic shock, but no benefit on mortality has been demonstrated.

One important cause of hypotension which responds to treatment is hypovolaemia. This may be caused by vomiting, diuretics or inadequate fluid intake and is treated by adequate fluid replacement. The pulmonary end-diastolic pressure (PAEDP) must be kept around 15 to 18 mm Hg since the infarcted ventricle needs a higher filling pressure to maintain its cardiac output. If PAEDP is low, colloids must be infused to increase it until the cardiac output is maximised. Raising it beyond 20 mm Hg will aggravate pulmonary oedema.

An aggressive approach with reperfusion therapy and intra aortic balloon pulsation treatment of patients in cardiogenic shock due to predominant LV failure is associated with lower in-hospital mortality rates than standard medical therapy.

Fibrinolysis could be considered for the patient with cardiogenic shock if access to PCI is not readily available.

Reinfarction, Extension and Expansion of Infarction

In STEMI treated with fibrinolysis, reinfarction can occur in 4% to 8% of the patients. The reinfarction rate is significantly lower when primary percutaneous coronary intervention (PCI) is the initial treatment.

Acute Mitral Regurgitation

Mitral regurgitation (MR) complicating acute myocardial infarction (**Figure 5**) ranges from mild papillary muscle dysfunction (no haemodynamic compromise) to severe form (ruptured papillary muscle) leading to heart failure or cardiogenic shock and is more common in females with inferior posterior infarction.

The diagnosis is made clinically with pansystolic murmur, maximal at the apex, and radiation to the axilla. Echocardiographic examination is invaluable in confirming the diagnosis. The persistence of cardiogenic shock or severe failure with preserved LV function usually indicates that an important mechanical complication is present.

Ventricular Septal Rupture

Rupture of the interventricular septum occurs in approximately 2% of the female patients with large anterior wall MI (**Figure 6**). Early diagnosis may offer some hope of early repair. Most

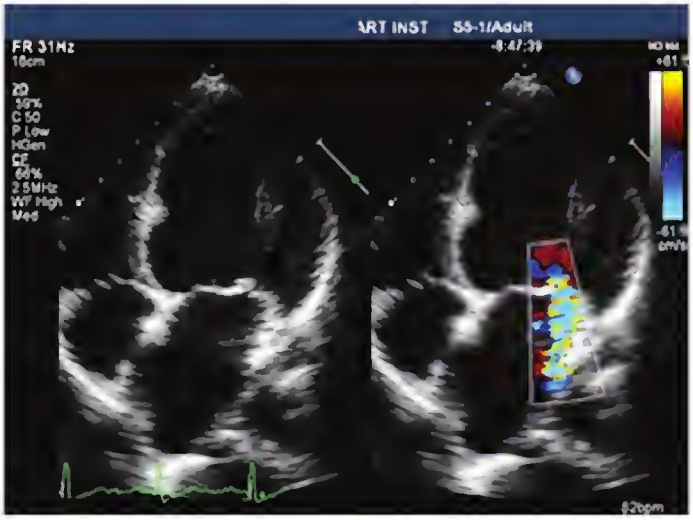

Figure 5: Colour Doppler showing lateral jet of acute mitral regurgitation due to papillary muscle dysfunction.

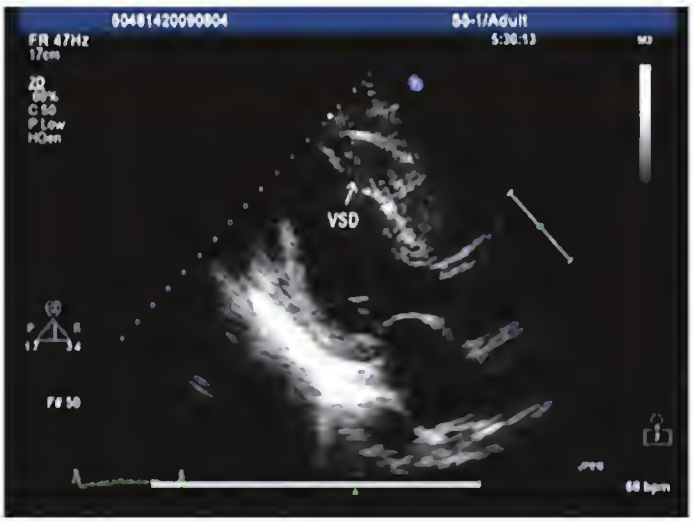

Figure 6: Echocardiogram showing rupture of septum.

patients with septal rupture develop signs of acute right- and left-sided heart failure and a loud pan systolic murmur at the left sternal border along with systolic thrill. Echocardiography with Doppler colour flow mapping localises the defect accurately.

Early closure is now recognised to yield better results. Although early surgical intervention may increase operative mortality, overall mortality is reduced. Transcathethter closure is a feasible alternative to surgical closure of post-MI septal rupture.

Cardiac Thromboembolism

The risk of thromboembolism (**Figure 7**) is more in patients with large anterior infarctions and patients with atrial fibrillation. Emboli are more common within the first few months after infarction than later, and with large, irregular shaped thrombi, particularly those with frond-like appendages.

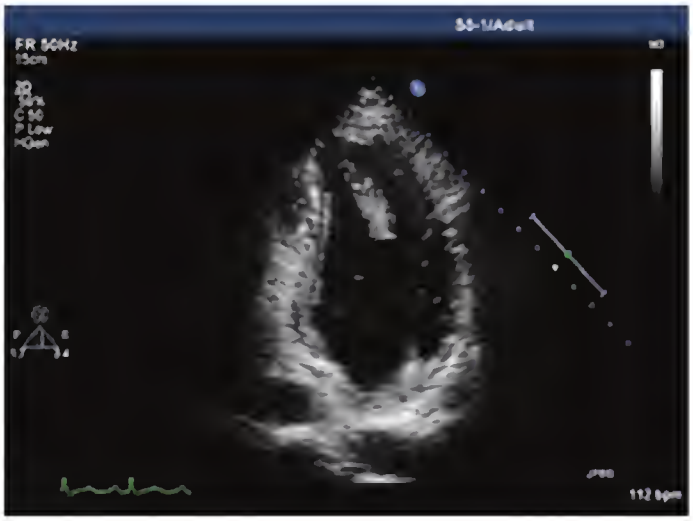

Figure 7: Echocardiogram showing apical aneurysm with formation of thrombus.

Anticoagulation with heparin followed by Warfarin for six months has been shown to reduce the incidence of thromboembolism in patients with documented intra cavitary thrombus.

Free Wall Rupture

Rupture of the free wall of the left ventricle is an almost uniformly fatal, commonly under recognised complication. It occurs most frequently in elderly women with large anterior wall MI who have been given late fibrinolytic therapy. The usual presentation is sudden collapse associated electrical mechanical dissociation, and failure to respond to cardio pulmonary resuscitation. Urgent echocardiography is invaluable in the assessment of a patient who develops the above clinical features.

Pericarditis

Pericarditis occurs in approximately 25% of patients with Q wave infarctions within the first week. A pericardial friction rub may be present with or without symptoms. High-dose aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) are recommended to treat the symptoms of post-infarction pericarditis.

A pericardial effusion can be detected by echocardiography in some of these patients. Cardiac tamponade is a rare complication of fibrinolytic therapy for acute MI.

Left Ventricular Aneurysm (Figure 7)

Left ventricular aneurysms develop most commonly after large transmural anterior MIs. A ventricular aneurysm can often be palpated as a dyskinetic region adjacent to the apical impulse. A third heart sound and signs of heart failure may also be detected. It is recognised by persistent ST elevation in the ECG and dyskinesia seen on echocardiography and radionuclide or contrast ventriculography. It may result in persistent LV failure, arrhythmias and systemic embolism.

A pseudoaneurysm is a rare complication of MI that develops when a myocardial rupture is sealed off by surrounding adherent pericardium. The aneurysmal sac may progressively enlarge but maintains a narrow neck, in contrast to a true ventricular aneurysm. Differentiation of left ventricular pseudoaneurysm from true aneurysms is made with echocardiography or magnetic resonance imaging.

Surgery should be considered in all patients with LV pseudo-aneurysms.

Dressler's Syndrome

A form of post infarction pericarditis, occurring 7 days to 6 weeks after the acute event characterised by prolonged or recurrent pleuritic chest pain, a pericardial friction rub, fever, pulmonary infiltrates or a small pulmonary effusion, and an increased sedimentation rate. The incidence has reduced after the introduction of reperfusion into clinical practice.

Non-steroidal anti-inflammatory drugs and steroids may be required for control of Dressler's syndrome.

Right Ventricular Infarction and Failure

Right ventricular (RV) infarction typically occurs in association with inferior or posterior MI. Patients with RV infarction complicating inferior MI have three times the risk of death of patients without RV infarction.

The clinical features of RV infarction complicating inferior MI include hypotension, jugular venous distension on inspiration (Kussmaul's sign) and clear lung fields, ST elevation of more than 1 mm in V4R.

Echocardiography commonly reveals wall motion abnormalities of the right ventricle and interventricular septum.

Early reperfusion may improve the prognosis in patients who have primary PCI for treatment of their cardiogenic shock, those with right ventricular infarction fared better than patients with cardiogenic shock due to left ventricular infarction.

Volume loading can normalise blood pressure and increase cardiac output. It is the vital step in management of patients with right ventricular MI.

Use of inotropic agents and maintenance of atrioventricular synchrony with atrioventricular pacing is often critical to the maintenance of a satisfactory cardiac output. Successful reperfusion with fibrinolysis or PCI appears to reduce the incidence of RV infarction and is associated with dramatic recovery of right ventricular function and reduced mortality.

Psychosocial Complications

An estimated 20% to 50% of post-infarction patients have high levels of psychosocial stress, including anxiety, depression, denial, hostility, and social isolation and have a significantly adverse effect on outcome.

Cardiac rehabilitation programmes provide psychologic and social support to patients after MI, in addition to education about risk factors and their modification.

POST-MYOCARDIAL INFARCTION MANAGEMENT (TABLE 7)

Most patients after MI, if they can afford, should have coronary angiography done before discharge. Those with left main and triple vessel disease with LV dysfunction and or proximal LAD disease need coronary artery bypass graft (CABG). Those with single vessel disease with significant viable myocardium need PCI. Others can be managed medically with statins, aspirin, beta-blockers and ACE-inhibitors. Revascularihsation of infarcted territory has not been shown to be useful.

Table 7: Late Management of MI

Risk stratification and further investigation

Life style modification

- Cessation of smoking
- Diet (weight control, lipid lowering)
- Regular exercise

Secondary prevention drug therapy

- Anti-platelet therapy (aspirin and/or clopidogrel)
- Additional therapy for control of diabetes and hypertension
- β-blocker
- Aldosterone receptor antagonist
- ACE-inhibitor/ARB
- Statin

Rehabilitation devices

- Implantable cardiac defibrillator (high-risk patients)

PROGNOSIS

In almost 25% of all cases of MI, death occurs within a few minutes without medical care, half the deaths occur within 24 hours of the onset of symptoms and about 40% of all affected patients die within the first month. A 30 days survival is of more than 85% of patients who are admitted in hospital. Early death is usually due to an arrhythmia and is independent of the extent of MI. Late outcomes are determined by extent of myocardial damage; AV block and ventricular arrhythmias. Old age, depression and social isolation are also associated with a higher mortality. Of those who survive an acute attack, more than 80% live for a further year, about 75% for 5 years, 50% for 10 years and 25% for 20 years.

12.20 Hypertension

M Paul Anand

INTRODUCTION AND EPIDEMIOLOGY

Hypertension is a very strong risk factor for cardiovascular diseases (CVDs). It is estimated that it increases the risk at least two-fold for CVDs including coronary artery disease (CAD), congestive heart failure (CHF)/stroke (ischaemic and haemorrhagic), renal failure and peripheral arterial disease. Usually other risk factors like diabetes are also commonly associated with hypertension.

Hypertension is present globally but its prevalence varies amongst countries and sub populations. The prevalence of diabetes increases with growing age and it is estimated that starting from around 15% to 20% in the early age it increases to 75% to 80% in individuals above 70 years of age.

There are no well-coordinated national surveys of the prevalence of hypertension available from the Indian subcontinent. Several regional small surveys in the last two decades with varying protocols have reported a prevalence which varies from 6.15% to 36.36% in men and 2% to 39.4% in women in urban areas and from 3% to 36% in men and 5.80% to 37.2% in women in rural areas.

More recent surveys in urban population have reported higher prevalence. All these surveys with one exception were based on a casual reading taken only on one occasion.

In the survey in Mumbai, diagnosis of hypertension [systolic blood pressure (SBP) 140 mm Hg and/or diastolic blood pressure (DBP) 90 mm Hg] was based on the average of 3 initial readings and confirmed on 2 subsequent occasions in those found to have high blood pressure on the first visit. The overall prevalence based on readings at the time of the first visit was 34.12% and the prevalence based on the average of three readings on the third occasion was 26.9%.

DETERMINANTS

A strong familial and genetic predisposition exists and a number of modifiable predisposing factors have been identified.

Role of Genetics

Epidemiological studies suggest that 20% to 60% of essential hypertension is inherited and the remainder is acquired or environmental.

Age and Sex

Almost all surveys show that blood pressure (BP) rises with age in both men and women. In adult women, BP is lower than in men of comparable age, but the rise is more steep thereafter and around middle-age BP is about the same; in later life it is higher in women.

Weight Gain

Increased weight appears to be a major controllable risk factor for new onset of hypertension. The Framingham Study showed approximately 1 mm Hg rise of SBP for every 1.25 Kg of weight gain. Abdominal obesity as evidenced by waist circumference of 80 cm in women and 90 cm in men has also been found to be associated with the risk for hypertension. Abdominal obesity may well be the most dangerous. It appears that 70% of hypertension in men and 60% in women could be attributed to abdominal obesity.

Salt Intake

Several communities whose intake of sodium chloride is 3 g or less per day have low average BP. The Intersalt Study of 10,079 men and women from 32 countries projected that a 100 mmol/day lower sodium intake over a lifetime would result in a 9 mm Hg smaller rise in SBP from 25 to 55 years age. The Intersalt Study demonstrated a clear relationship between the salt intake and the level of BP among communities.

Alcohol Intake

Excessive alcohol intake is an important risk factor for hypertension. Excess consumption accounts for 5% to 30% of all hypertension. Several studies including the Intersalt Study have shown a strong and independent positive relationship between alcohol intake and increase in BP.

Physical Activity

Sedentary individuals have a 20% to 50% increased risk of developing hypertension. Observational and experimental studies have revealed the role of physical inactivity and its association with high BP.

Smoking

Tobacco smoking has been reported to cause acute rise of BP, whether prolonged smoking leads to sustained hypertension has not been established.

DEFINITION OF HYPERTENSION

There is a continuous relationship between the level of BP and the risk of its complications. All definitions of hypertension, including those issued by Joint National Committee (JNC) in prevention, detection, evaluation and treatment of high blood pressure (seventh report) (JNC-7) and World Health Organization (WHO)/International society of hypertension (ISH) are arbitrary.

At present, hypertension in adults aged 18 years and older who are not acutely ill, is defined as "SBP of 140 mm Hg or greater and/or DBP of 90 mm Hg or greater or any level of BP in patients taking antihypertensive medication". BP is classified into various stages as shown in **Table 1**.

Table 1: Classification of Blood Pressure for Adults Aged 18 Years or Older*

	(JNC VI Category)		(JNC VII Category)	
Category	**Systolic (mm Hg)**		**Diastolic (mm Hg)**	
Optimal	<120	And	<80	Normal
Normal	120 to 129	Or	80 to 84	Prehypertension
High normal	130 to 139	Or	85 to 89	
Hypertension**	140	Or	90	Hypertension
Stage 1	140 to 159	Or	90 to 99	Stage 1
Stage 2	160 to 179	Or	100 to 109	Stage 2
Stage 3	180	Or	110	

** Not taking antihypertensive drugs and not acutely ill. When SBP and DBP fall into different categories, the higher category should be selected to classify the individual's blood pressure status. For example, 160 to 192 mm Hg should be classified as Stage 2 hypertension, and 174/120 mm Hg should be classified as Stage 3 hypertension.*

*** Based on the average of two or more readings taken at each of two or more visits after an intial screening.*

JNC = Joint national committee; SBP = Systolic blood pressure; DBP = Diastolic blood pressure.

PRE-HYPERTENSION

The designation pre-hypertension is intended to identify those individuals in whom early intervention by adoption of healthy lifestyle could reduce BP, decreasing the rate of progression of BP to hypertensive levels with age, or prevent hypertension entirely. Individuals who are pre-hypertensive are not candidates for drug therapy on the basis of their level of BP and should firmly and unambiguously be advised to practice lifestyle modification in order to reduce their risk of developing hypertension in the future. Moreover, individuals with pre-hypertension who also have diabetes or kidney disease should be considered for appropriate drug therapy if a trial of lifestyle medication fails to reduce their BP to 130/80 mm Hg or less.

Apart from being at twice the risk of developing hypertension, compared to persons with normotension, the total morbidity, mortality and economic loss caused by cardiovascular events amongst high normal blood pressure (pre-hypertension) population far exceeds that caused by hypertensive population. The new name suggests that it is urgent for the person so diagnosed to invest time and effort to implement lifestyle changes.

SYSTOLIC BLOOD PRESSURE

In persons older than 50 years, SBP of more than 140 mm Hg is much more important cardiovascular disease (CVD) risk factor than DBP.

A large body of epidemiologic data indicates that SBP is far more important than DBP as a determinant of cardiovascular risk, except in younger age groups. Epidemiologically, systolic hypertension is the most common form of hypertension and far easier to measure correctly.

The National Health and Nutrition Examination Survey (NHANES) has shown that Isolated systolic hypertension (ISH) (SBP 140 mm Hg with DBP 90 mm Hg) was present in 65% of all hypertensives 60 years age in both men and women. Recent data from Framingham Study has further reinforced the prognostic significance of raised SBP. The importance of SBP in risk prediction has been convincingly shown in 12 years data from 316,000 men screened from the multiple risk factors intervention trial (MRFIT) study.

ISOLATED SYSTOLIC HYPERTENSION

Isolated systolic hypertension (ISH) is defined as SBP of 140 mm Hg or greater and DBP below 90 mm Hg and staged appropriately (e.g. 170/82 mm Hg is defined as Stage 2 ISH). ISH is present in two-thirds of all hypertensives 60 years of age.

In older patients aged 60 years and above, in diabetic subjects and patients on antihypertensive medication, the BP should be measured in supine, sitting and in standing positions to detect postural hypotension.

If atrial fibrillation is present, additional readings may be required to estimate the average SBP and DBP.

In young obese persons with hypertension, high BP should be measured with an appropriately large cuff.

HOME MEASUREMENT

Home measurement has the advantage that it distinguishes sustained hypertension from "white-coat hypertension", a condition noted in patients whose BP is elevated in the physician's clinic but normal at other times. There is no universally agreed upper limit of normal home BP, but readings of 135/85 mm Hg or greater should be considered elevated.

AMBULATORY BLOOD PRESSURE MEASUREMENT

Twenty-four hour ambulatory BP measurements have shown marked fluctuations of BP in the same individual. A close correlation has been demonstrated between ambulatory BP levels and the extent of target organ damage.

Ambulatory BP measurements has been found to be useful to identify white coat hypertension, evaluate drug-resistant hypertension, episodic hypertension, hypotensive episodes while on medication and to evaluate antihypertensive drugs. One of the recommended definitions of normal BP and hypertension using ambulatory BP measurements is given in **Table 2**.

Table 2: Blood Pressure Thresholds (mm Hg) for Definition of Hypertension with Different Types of Measurement

	SBP (mm Hg)	DBP (mm Hg)
Office or Clinic	140	90
Ambulatory BP measurement (24-hour average)	125	80

COMPLICATIONS OF HYPERTENSION

Hypertension is a major risk factor for the development of CVD. Its impact for stroke and end-stage renal failure is greatest. Hypertensives when compared to normotensive, develop twice as much coronary heart disease (CHD), four times as much congestive heart failure (CHF) and seven times as much stroke. While there is no critical level, the risk of CVD rises progressively with the level of SBP and DBP.

Cardiovascular risks in hypertensives are also markedly affected by other co-existing risk factors.

PATHOPHYSIOLOGY OF HYPERTENSION

BP is defined as the product of cardiac output and peripheral resistance. Hypertension is, therefore, said to be caused by increased cardiac output and/or increased peripheral resistance.

Each of these primary factors is determined by a complex series of interactions (**Figure 1**). Increased cardiac output, though involved in the initiation of hypertension, does not persists. The typical haemodynamic finding in established hypertension is an elevated peripheral resistance and normal cardiac output. What causes the resistance to go up is not fully understood.

It is also suspected that heredity plays a role as a background to most of these abnormalities, especially along with varying contributions of three environmental factors—sodium, stress and obesity.

Factors Involved in Increased Cardiac Output

Increased circulating fluid volume

Excess sodium intake can cause hypertension by increasing fluid volume and preload, thus, increasing cardiac output, as well as by its effects on vascular reactivity and contractility. Many studies, such as the Intersalt Study, have verified the ability of dietary salt to elevate BP in some populations (salt-sensitive), but not in all individuals. Sodium sensitivity of some individuals may play a pivotal role. Some investigators have also identified a sodium pump inhibitor as being responsible for volume expansion in hypertension.

Renal sodium retention

Excessive sodium retention by the kidney has also been proposed as an important factor. One reason for this could be decreased filtration surface area (FSA) due to decreased nephron number or FSA per glomerulus.

Resetting of pressure-natriuresis

A resetting of the pressure-natriuresis relationship wherein a rise in SBP evokes further sodium retention has been proposed as a possible renal mechanism.

Renin-angiotensin system

The renin-angiotensin system (RAS) plays an important role in salt and water homeostasis and BP control (**Figure 2**).

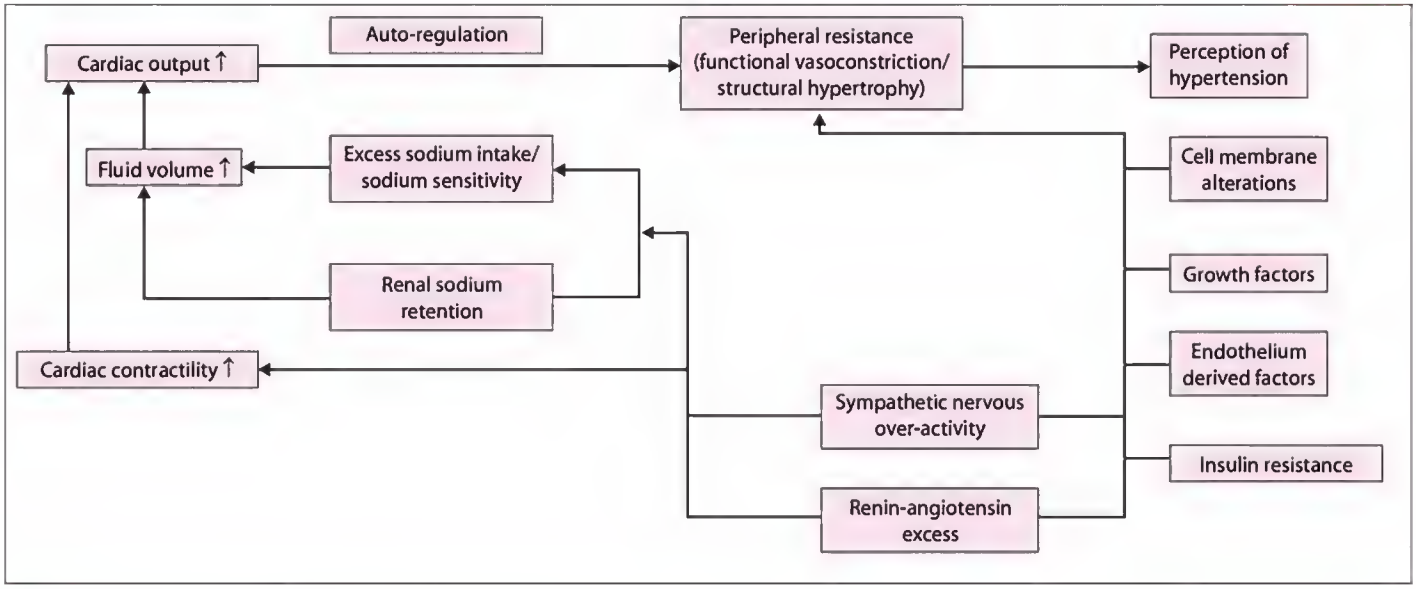

Figure 1: Factors involved in the pathogenesis of hypertension.

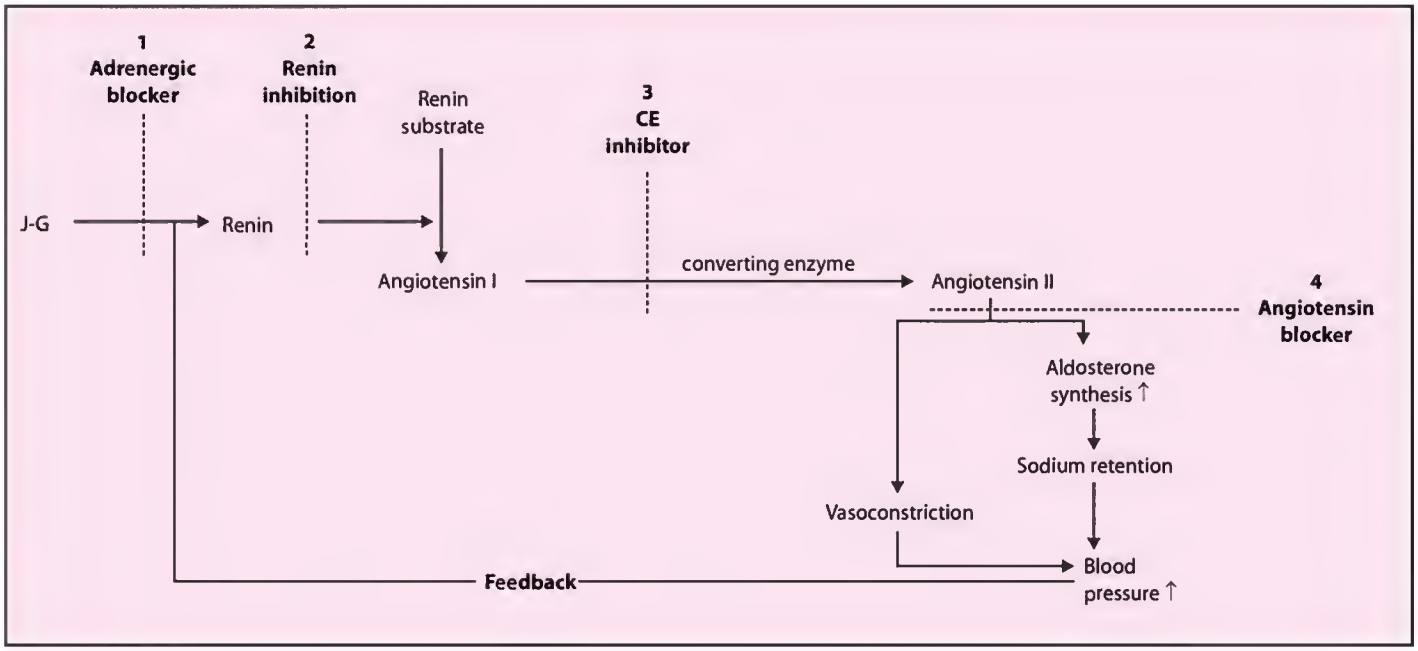

Figure 2: Role of renin-angiotensin system in the pathogenesis of hypertension. Note the effect of drugs at various steps in the pathway.

Inappropriate release of renin culminating in the formation of angiotensin II (which causes vasoconstriction) is also a possible mechanism for hypertension.

Sympathetic nervous over-activity

The sympathetic nervous system (SNS) directly or indirectly dictates the state of cardiac output and systemic vascular resistance. Thus, excessive activity of SNS may increase the BP. Sympathetic over-activity may also augment renin release.

Increased peripheral resistance

The final common feature of established hypertension is a raised peripheral resistance, that can be associated with both functional constriction and structural vascular remodelling and hypertrophy. Direct mediation and interaction of numerous factors such as increased intracellular calcium, growth factors such as angiotensin II and insulin like growth factor, endothelium-derived relaxing factor (EDRF), prostaglandins and endothelin may also be involved.

EVALUATION

Evaluation of patients with documented hypertension has three objectives. These are to identify known causes of high BP, to assess the presence or absence of target organ damage and to identify other cardiovascular risk factors or concomitant disorders that may define prognosis and guide treatment.

Data for evaluation acquired through medical history, physical examination, laboratory tests and other special diagnostic procedures.

MEDICAL HISTORY

Hypertension is largely asymptomatic and is often diagnosed on routine examination. Early morning headache, often localised to the occipital region as a symptom is usually a feature of severe hypertension. Other symptoms, though uncommon, may be dizziness, fatigue and palpitation. In addition, symptoms related to organ damage involving the heart, brain, kidneys and eyes may be present in severe hypertension.

Medical history should include the following: (a) duration and level of elevated BP, symptoms of CAD, heart failure, cerebrovascular disease, peripheral vascular disease and renal disease; (b) symptoms of diabetes mellitus, dyslipidaemia, gout, sexual dysfunction or other co-morbid conditions; (c) family history of high BP, premature CAD, stroke, dyslipidaemia and diabetes; (d) symptoms suggesting secondary causes of hypertension (see chapter on secondary hypertension); (e) history of smoking or tobacco use, physical activity, dietary assessment including intake of sodium, alcohol, saturated fat and caffeine; (f) history of use of all prescribed and over-the-counter medications which may raise BP or interfere with the effectiveness of antihypertensive drugs; (g) history of oral contraceptive use and hypertension during pregnancy; (h) history of previous antihypertensive therapy, including adverse effects experienced, if any; and (i) psychosocial and environmental factors.

PHYSICAL EXAMINATION

In uncomplicated mild to moderate hypertension, physical examination other than raised BP may be normal. The signs, when present, are those of target organ damage or those of the underlying cause of secondary hypertension.

The initial physical examination should include the following: (a) record three BP readings separated by 2 minutes each, with the patient in either supine or sitting position and after standing for at least 2 minutes; (b) record height, weight and waist-hip ratio; (c) examine the pulse and the extremities for delayed or absent femoral and peripheral arterial pulsations, bruits and pedal oedema; (d) look for arcus senilis, xanthelesma and xanthomas; (e) examine the heart for evidence of LVH, CAD, CHF and record rate and rhythm; (f) neurological examination for evidence of past or ongoing cerebrovascular disease; (g) examine the optic fundus to detect hypertensive retinopathy (**Table 3**); (h) examine the lungs for rales and rhonchi; (i) examine the abdomen for bruits, enlarged kidneys, masses, and abnormal aortic pulsation.

Table 3: Keith and Wagner's Grading of Hypertensive Retinopathy

Grade 1	Thickening and tortuosity of arteries showing 'silver wire' appearance
Grade 2	Grade 1 changes plus arteriovenous nipping
Grade 3	Grade 2 changes plus flame-shaped (superficial) haemorrhages and cotton wool exudates
Grade 4	Grade 3 changes plus papilloedema

LABORATORY INVESTIGATIONS

Important laboratory investigations to be carried out in a hypertensive patient are given in **Table 4**.

Table 4: Laboratory Investigations

For most hypertensive patients

- Urine for protein, glucose and microscopic (red blood cells/ other sediments)
- Haemoglobin, fasting blood glucose, serum creatinine, potassium and total cholesterol
- Electrocardiogram

Additional investigations when cost is not a constraint

- Lipid profile, uric acid
- Chest radiography
- Echocardiogram

Tests for secondary hypertension

(see chapter 22 Secondary hypertension in this section)

FACTORS INFLUENCING RISK AND RISK STRATIFICATION

Before initiating therapy, patient's overall risk should be assessed taking into consideration presence of additional risk factors, extent of target organ damage and other associated clinical conditions (**Table 5**).

Prognosis of these patients, choice of drugs and need for urgency of therapy will be dependent on the overall risk stratification (**Table 6**).

MANAGEMENT OF HYPERTENSION

Goals of Therapy

The primary goal of therapy of hypertension is effective control of BP to prevent, reverse or delay the progression of complications, and thus, reduce the overall risk of an individual without affecting the quality of life.

Table 5: Factors Influencing Risk

Risk Factors for Cardiovascular Disease	Target Organ Damage	Associated Clinical Conditions
Age >55 years	Left ventricular hypertrophy detected by electrocardiogram and/or echocardiography	Cerebrovascular Disease
Male sex	Microalbuminuria/proteinuria and/or elevation of serum creatinine (1.2 to 2.0 mg/dL)	Ischaemic stroke
Post-menopausal women	Ultrasound or radiological evidence of atherosclerotic plaques in the carotids	Cerebral haemorrhage
Smoking and tobacco use	Generalised or focal narrowing of retinal arteries	Transient ischaemic attack
Diabetes mellitus		Heart Disease
Family history of premature CAD (Men <55 years, Women <65 years)		Myocardial infarction
Increased waist-hip ratio		Angina
High LDL or total cholesterol, low HDL cholesterol and high triglycerides		Coronary revascularisation
		Congestive heart failure
		Renal Disease
		Diabetic nephropathy
		Renal failure (serum creatinine 2.0 mg/dL)
		Vascular Disease
		Symptomatic arterial disease including non-specific aortoarteritis
		Dissecting aneurysm
		Advanced Hypertensive Retinopathy
		Haemorrhages or exudates
		Papilloedema

Table 6: Risk Stratification

Other Risk Factors and Disease History	Blood Pressure (mm Hg)		
	Stage 1 SBP 140 to 159 or DBP 90 to 99	**Stage 2 SBP 160 to 179 or DBP 100 to 109**	**Stage 3 (Severe Hypertension) SBP ≥180 or DBP ≥110**
No other risk factors	Low risk	Medium risk	High risk
1 to 2 risk factors*	Medium risk	Medium risk	Very high risk
3 or more risk factors or Target organ damage* and/or diabetes	High risk	High risk	Very high risk
Associated clinical conditions**	Very high risk	Very high risk	Very high risk

Risk strata (typical 10-year risk of stroke or myocardial infarction): Low risk < 15%, Medium risk 15% to 20%, High risk 20% to 30%, Very high risk > 30%
SBP = Systolic blood pressure; DBP = Diastolic blood pressure.
** See Table 5; ** See Table 7*

Antihypertensive therapy should achieve and maintain SBP below 140 mm Hg and DBP below 90 mm Hg and lower if tolerated, while controlling other modifiable risk factors.

The ultimate public health goal of antihypertensive therapy is to reduce cardiovascular and renal morbidity or mortality. Since most individuals with hypertension, especially those >50 years age, will reach the DBP goal once the SBP goal is achieved, therefore, the primary focus should be of attaining the SBP goal. Treating SBP and DBP to targets that are <140/90 mm Hg is associated with a decrease in CVD complications. In patients with hypertension and diabetes or renal disease, the BP goal is <130/80 mm Hg. Gradual reduction of BP to the optimal level over a period of 2 to 6 months is prudent therapeutic goal except in stage 3 hypertension.

Threshold of Therapy and Level of Control

Among diabetic patients participating in the hypertension optimal treatment (HOT) study, there was a significantly lower risk of CAD in patients with the lowest target DBP of <80 mm Hg.

The United Kingdom Prospective Diabetes Study (UKPDS) showed that a tight control of BP (average achieved 144/82 mm Hg) in diabetic patients conferred a substantial reduction in the risk of CAD compared to a less tight control of BP (average achieved 154/87 mm Hg).

In view of the above studies, it would seem desirable to achieve optimal or normal BP in young, middle-aged and (below 130/80 mm Hg) in diabetic patients and those with renal disease, at least high normal BP in elderly patients (below 140/90 mm Hg).

MANAGEMENT STRATEGY

Having assessed the patient and determined the overall risk profile management of hypertension should proceed as follows: In low risk patients, institute lifestyle modifications

Table 7: Lifestyle Interventions for Blood Pressure Reduction

Intervention	Recommendation	Expected Systolic Blood Pressure Reduction (Range)
Weight reduction	Maintain ideal body mass index below 23 kg/m^2	5 to 20 mm Hg per 10 kg weight loss
DASH diet	Consume diet rich in fruits, vegetables, low-fat dairy products with reduced content of saturated and total fat	8 to 14 mm Hg
Dietary sodium restriction	Reduce dietary sodium intake to <100 mmol/day (<2.4 g sodium or <6 g sodium chloride)	2 to 8 mm Hg
Physical activity	Engage in regular aerobic physical activity, for example, brisk walking for at least 30 minutes most days	4 to 9 mm Hg
Alcohol moderation	Men 60 mL per day, twice a week Women 30 mL per day, twice a week Abstinence is preferred	2 to 4 mm Hg
Tobacco	Total abstinence	Smoking or consumption of tobacco in any form is the single most powerful modifiable lifestyle factor for the prevention of major cardiovascular and non-cardiovascular disease in hypertensives

and observe BP for a period of three months before deciding whether to initiate drug therapy or not (**Table 7**).

In high risk group, use lifestyle modification therapy with drug therapy forthwith.

In medium risk patients, institute lifestyle modifications and monitor BP on a monthly basis. If after a period of three months, BP remains above 140/90 mmHg then initiate drug therapy. In high and very high risk groups, initiate immediate drug treatment for hypertension and other risk factors. The primary concern should be to lower SBP as recent evidence suggests that the level of SBP control correlates better with reduction of mortality than the level of DBP control.

12.21 Management of Hypertension

Sandhya Kamath

INTRODUCTION

The management of hypertension is a multifaceted blood pressure (BP) exercise. The goal is optimum control so that complications can be prevented.

APPROACH TO THE PATIENT

The first step is to confirm the diagnosis of hypertension by accurate measurement of BP. A detailed history and physical examination should be done to screen for other cardiovascular disease risk factors, secondary causes of hypertension, consequences of hypertension, associated co-morbidities, assess lifestyle and determine what should be the ideal treatment.

History

Most people with primary hypertension do not have any obvious symptoms. The more common symptoms can be: Chronic headache that lasts for days rather than hours frequently present in the occipital area, dizziness or vertigo, blurry vision, double vision, increased sleepiness, nausea, shortness of breath, palpitations, fatigue, general tiredness, flushed face, epistaxis, a strong need to urinate often (especially during the night), tinnitus and many other non-specific symptoms.

Physical Examination

BP should be measured in both arms in sitting, standing and supine position to evaluate for postural hypotension; and at least once in both lower extremities in young hypertensives to rule out aortoarteritis. Heart rate and rhythm should be recorded. Irregularly, irregular pulse suggests atrial fibrillation which is very common in hypertension. Height, weight, waist-to-hip ratio should be measured and body mass index (BMI) calculated. Examine the neck for thyromegaly. Palpation of the blood vessel wall for stiffness, and bruit in the carotids will identify atherosclerotic disease. Cardiovascular system examination may reveal the apex beat to be displaced downward and outward depicting left ventricular hypertrophy. Loud S_2 due to closure of aortic valve and S_4 gallop (attributed to noncompliant left ventricle and diastolic dysfunction) may be heard. Evaluate for signs of congestive heart failure. Auscultate for an abdominal bruit that may be heard in the lower epigastrium on either side of the midline as a sign of renovascular hypertension. An enlarged, palpable kidney is most probably due to polycystic kidney. A thorough neurologic examination including fundoscopy should be performed. Fundus examination has to be done and it may show changes which are shown in **Table 1**. These changes reflect the duration of hypertension roughly.

One should look out for features of secondary hypertension in the history and physical examination.

Table 1: Keith-Wagener-Barker Classification

I	Sclerosis of arterioles—focal, diffuse constriction, copper wire and silver wire arteriolar reflex
II	AV crossing changes
III	Flame shaped haemorrhages, cotton wool spots, retinal oedema, retinal microaneurysms
IV	Grade III changes with papilledoema with or without macular star

Laboratory Investigations

Basic laboratory tests for initial evaluation are enumerated in **Table 2**.

Table 2: Laboratory Investigations

Complete blood count, ESR and haematocrit
Routine urine examination
Albuminuria—for renal involvement
Microscopic haematuria—malignant hypertension
BUN and serum creatinine
Serum potassium, sodium for adrenal involvement and as baseline prior to institution of treatment
Blood sugar, and lipidogram (total cholesterol, triglycerides) for co-morbid conditions
ECG, 2D-echocardiogram for diastolic dysfunction
Abdominal ultrasonography for kidney size, vascular anomalies.

MEASUREMENT OF BLOOD PRESSURE

Various devices for the measurement of BP and their relative merits have already been discussed in the earlier chapter.

MANAGEMENT

The management of hypertension, especially the primary hypertension comprises of two major aspects: (i) lifestyle modification; and (ii) pharmacotherapy of hypertension.

Lifestyle Modifications

These are presented in brief in **Table 3**. In addition the behavioural theory and discussed.

Behavioural techniques, meditation and yoga

Transcendental meditation and yoga are also widely believed to reduce BP. However, larger and more random controlled trials are needed to confirm benefits of these practices.

Antihypertensive Agents

Principles of treatment

The BP remains poorly controlled in many of the patients. The most important reason is lack of awareness about the condition and its ensuing complications. Asymptomatic nature of the condition results in poor compliance; and last but not the least

side effects of antihypertensive agents like weakness, sleepiness, forgetfulness and impotence cause the patients to avoid the drugs. But this can be overcome by prescribing newer agents that have fewer side effects.

Before initiating therapy, additional risk factors, extent of target organ damage and other associated conditions should be assessed (**Table 4**). The prognosis, choice and urgency of therapy will depend on the overall risk stratification (**Table 5**). The algorithm for the management of hypertension in general is depicted in **Figure 1**.

Significance of Systolic and Diastolic Blood Pressure and Pulse Pressure

In the past, recommendations for the treatment were based on diastolic blood pressure (DBP). Today systolic blood pressure (SBP) has assumed prominence. Joint National Committee on prevention, detection, evaluation and treatment of high BP (JNC-7) has stated that SBP is a much more important cardiovascular risk factor than DBP in those older than 50 years. A wide pulse pressure largely reflects a high SBP, and may be the most accurate predictor of all.

Table 3: Lifestyle Modifications for Blood Pressure Reduction

Intervention	Recommendation	Expected BP Reduction
Weight reduction	Maintain body mass index <23 kg/m^2	10 mm Hg/10 kg weight loss
Diet	Rich in fruits, vegetables, low-fat dairy products, and Less of saturated and total fat	8 to 14 mm Hg
Dietary sodium restriction	Reduce dietary sodium intake to <2.4 g sodium or < 6 g NaCl	2 to 8 mm Hg
Physical activity	Regular aerobic physical activity, e.g. brisk walking for at least 30 min most days	4 to 9 mm Hg
Alcohol moderation	Men <60 mL per day. Women <30 mL per day. Abstinence is preferred	2 to 4 mm Hg
Tobacco	Total abstinence	—

Table 5: Risk Stratification of Patients with Hypertension

Stage	Other History	Blood Pressure (mm Hg)		
		Stage 1 SBP 140 to 159 or DBP 90 to 99	Stage 2 SBP 160 to 179 or DBP 100 to 109	Stage 3 SBP >180 or DBP >110
I	No other risk factors	Low risk	Medium risk	High risk
II	1-2 risk factors	Medium risk	Medium risk	Very high risk
III	>3 or more risk factors/TOD/diabetes	High risk	High risk	Very high risk
IV	ACC	Very high risk	Very high risk	Very high risk

SBP=Systolic blood pressure; DBP=Diastolic blood pressure; TOD=Target organ damage; ACC=Associated clinical conditions.
Source: Adapted from Indian Hypertension Guidelines – II.

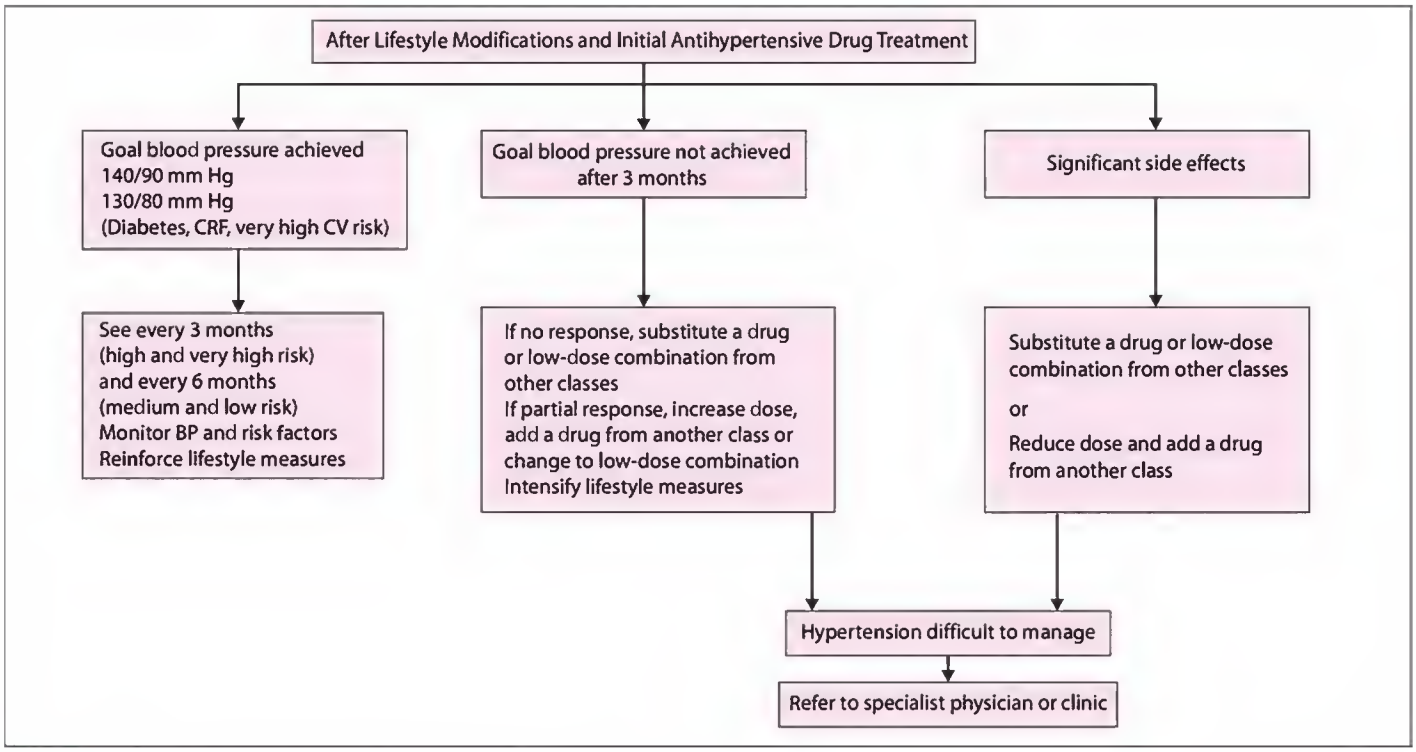

Figure 1: Algorithm for the management of hypertension.

Blood Pressure Level

It is desirable to achieve optimal or normal BP in young and middle aged patients with uncomplicated hypertension. Antihypertensive therapy should achieve and maintain SBP below 140 mm Hg and DBP below 90 mm Hg or lower if possible; simultaneously controlling other modifiable risk factors. The goal BP in diabetic patients should be below 130/80 mm Hg, in those with stroke should be below 130/85 mm Hg and at least high normal (below 140/90 mm Hg) in the elderly.

Choice of antihypertensive agents and their dosage are given in **Tables 6 and 7**. It is cautioned that there can be interactions between antihypertensive agents and other concomitant medications (**Table 8**).

Table 6: Guidelines for Selecting the Most Appropriate Antihypertensive Drugs

Class of Drugs	Definite Indications	Possible Indications	Definite Contraindications	Relative Contraindications
Diuretics	Heart failure Elderly patients Systolic hypertension	Diabetes	Gout	Dyslipidaemia
Beta-blockers	Angina Post-myocardial infarction Tachyarrhythmia Heart failure	Pregnancy Diabetes	Asthma and chronic pulmonary disease Heart block	Dyslipidaemia Peripheral vascular disease
Calcium channel blockers	Angina Elderly Systolic hypertension Diabetes	Peripheral vascular disease Cerebrovascular accident (CVA)	Heart block	Congestive heart failure
Angiotensin converting enzyme (ACE)-inhibitors	Heart failure Left ventricular dysfunction Post-myocardial infarction Significant proteinuria Diabetes	CVA	Pregnancy and lactation Bilateral renal artery stenosis Hyperkalaemia	Moderate renal failure (creatinine levels >3 mg/dL)
Angiotensin II receptor blockers (ARBs)	ACE-inhibitor induced cough or intolerant to ACE-inhibitor	Heart failure CVA	Pregnancy and lactation Bilateral renal artery stenosis Hyperkalaemia	Moderate renal failure (creatinine levels >3 mg/dL)
Alpha-blockers	Prostatic hypertrophy	Glucose intolerance Dyslipidaemia	—	Orthostatic hypotension Congestive heart failure

CVA = Cerebrovascular accident.
Source: Adapted from Indian Hypertension Guidelines – II.

The issue of which drug is the best choice for initial therapy and which is the ideal combination are still debated. JNC VII has advocated a low-dose thiazide diuretic for initial therapy. European Hypertension Society guidelines has recommended that whatever class of antihypertensive seems most appropriate should be used. World Health Organization (WHO) guidelines state that a diuretic is preferred, but any class of antihypertensives may be used. Thus, two of the three major guidelines have given preference to low-dose diuretics as initiating agents in uncomplicated patients. However, because of their metabolic complications these are not very popular. Diuretics combine well with most of the antihypertensives.

Table 7: Commonly Used Antihypertensive Drugs and Their Dosage

Class	Drug	Dosage (mg/day)
Diuretics	Hydrochlorothiazide	6.25 to 25
	Chlorthalidone	12.5 to 25
	Indapamide	1.5 to 2.5
	Amiloride	5 to 10
	Triamterene	50 to 100
	Spironolactone	25 to 50
Beta-blockers	Atenolol	25 to 100
	Metoprolol	25 to 100
	Bisoprolol	2.5 to 10
	Nebivolol	2.5 to 5
Calcium channel blockers (CCBs)	Amlodipine	2.5 to 10
	Diltiazem	90 to 360
	Verapamil	80 to 240
ACE-inhibitors	Enalapril	2.5 to 20
	Lisinopril	2.5 to 20
	Ramipril	1.25 to 10
	Perindopril	2 to 8
	Quinapril	10 to 80
Angiotensin II receptor blockers (ARBs)	Losartan	50 to 100
	Candesartan	8 to 32
	Valsartan	40 to 160
	Irbesartan	150 to 300
	Telmisartan	40 to 160
Alpha-blockers	Prazosin	2.5 to 10
	Doxazosin	1 to 4
Centrally acting drugs	Clonidine	0.1 to 0.3
	Methyldopa	500 to 1500

Source: Adapted from Indian Hypertension Guidelines – II.

Table 8: Drug Interactions

NSAIDs including COX-2 inhibitors decrease efficacy of diuretics, beta-blockers and ACE-inhibitors
Concomitant use of beta-blockers and non-dihydropyridine CCBs can result in heart blocks
Combined use of ACE-inhibitors and potassium sparing diuretics may result in hyperkalaemia
Cyclosporine levels are increased with diltiazem and verapamil
Concomitant use of tricyclic antidepressants with methyldopa is to be avoided

Source: Adapted from Indian Hypertension Guidelines – II.

Diuretics

Diuretics are basically divided into four groups: (i) Thiazide diuretics, (ii) loop diuretics, (iii) aldosterone antagonists and (iv) other potassium sparing diuretics.

Diuretics are recommended as first-line agents in the treatment of hypertension. Their advantage is that these are more effective in reducing cardiovascular mortality, coronary heart disease (CHD), cardiac failure, stroke and overall mortality than other agents. These are inexpensive and combine well with most of the other antihypertensive agents like beta-blockers, angiotensin converting enzyme (ACE)-inhibitors and, angiotensin II receptor blockers (ARBs). However, because of inherent natriuretic property of dihydropyridine calcium channel blockers, this combination is less effective. Low-dose diuretics remain the preferred initial treatment in the elderly and obese hypertensives.

It should be emphasised that diuretics should be prescribed in low dosage equivalent to 12.5 mg of hydrochlorothiazide. High doses of diuretics give rise to metabolic side effects like dyslipidaemia, hyperglycaemia, hyperuricaemia, hypokalaemia and hypomagnesaemia. This is the reason why death due to coronary artery disease (CAD) has not decreased as much as expected. Quality of life is disturbed as impotence is a frequent side effect. Another disadvantage is that the antihypertensive response to diuretics is not immediate, but takes at least two weeks to manifest.

Beta-blockers

The available evidence does not support the use of beta-blockers as first-line drugs in the treatment of hypertension. This conclusion is based on the relatively weak effect of beta-blockers to reduce stroke and the absence of an effect on CHD when compared to placebo or no treatment. These have multiple adverse effects like increased risk of diabetes mellitus due to loss of insulin sensitivity, rise in plasma triglycerides and lowering of HDL, increase in body weight, easy fatigability and reduced exercise tolerance. Indications for the use of beta-blockers in the treatment of hypertension are enumerated in **Table 6**.

The ideal beta-blocker for treatment of hypertension would be one that is long-acting, cardioselective, lipid neutral, glucose neutral and with vasodilating effects. Vasodilator beta-blockers labetalol, carvedilol and nebivolol cause less metabolic side effects and should be used instead of metoprolol or atenolol. However, there are no good outcome data for their use in hypertension without concomitant indications.

Calcium channel blockers

Calcium channel blockers (CCBs) are divided into two groups: dihydropyridine (DHPs—nifedipine, amlodipine, nicardipine, lacidipine) and non-dihydropyridine (verapamil, diltiazem). They reduce the BP primarily by reducing the peripheral vascular resistance (PVR) aided by an initial natriuretic effect. Due to the reduction in PVR, CCBs especially the DHPs cause reflex stimulation of the adrenergic system and tachycardia. Hence, these should be used with caution in patients with CAD especially the short-acting ones. Non-DHPs tend to decrease catecholamine levels. Several studies have shown that CCBs are safe and effective and particularly useful to prevent stroke.

CCBs seem to be particularly suitable for elderly hypertensive patients since these agents do not cause salt and fluid retention, postural hypotension, sedation, depression, or biochemical abnormalities. Moreover, their use is compatible with several common diseases of old age, such as diabetes, obstructive lung disease, and peripheral vascular disease. CCBs should be used as initial monotherapy for hypertension in angina pectoris (non-DHPs), Raynaud's phenomenon and supraventricular tachycardia (non-DHPs). Because of their favourable metabolic profile, CCBs are recommended in diabetes mellitus and dyslipidaemias. Patients on CCBs do not require regular blood chemistry checks.

Potential side effects from taking a CCBs include oedema of lower extremities, headache, light-headedness, dry mouth, skin rash, fatigue, nausea, constipation, gastro-oesophageal reflux disease (GERD).

ACE-inhibitors

The commonly used ACE-inhibitor are listed in **Table 7** along with their dosages. The various ACE-inhibitor have few practical differences except for duration of action. ACE-inhibitor block the conversion of angiotensin I to angiotensin II. Therefore, these lower arteriolar resistance and increase venous capacity; increase cardiac output and cardiac index, stroke work and volume, lower renovascular resistance, and lead to increased natriuresis.

ACE-inhibitor preferentially relax the renal efferent arterioles, thereby reduce intraglomerular pressure, and may cause a rise in serum creatinine. The commonest adverse effect of ACE-inhibitor is intractable cough; others being hypotension, hyperkalaemia, headache, dizziness, fatigue, nausea and angioedema. There is also some evidence to suggest that ACE-inhibitor might increase inflammation-related pain. Contraindications to ACE-inhibition are bilateral renal artery stenosis and pregnancy. Caution should be used when using ACE-inhibitor in patients with serum creatinine >2 mg% and they should be avoided when serum creatinine is >3 mg%.

ACE-inhibitor can be used as monotherapy in mild or moderate hypertension. They form effective combinations with diuretics and CCBs. Moderate salt restriction is essential for optimal effect. They are preferentially used in diabetic hypertensive patients, for cardioprotection post-myocardial infarction and in hypertension with heart failure. These are also known to reduce proteinuria especially in diabetics. Contrary to earlier belief, they are well-accepted in the elderly. These offer vascular protection in diabetics and in renal disease.

Angiotensin-II receptor blockers (ARBs)

ARBs are the fastest growing class of antihypertensive drugs. These are virtually free from side effects.

Angiotensin II receptor antagonists are primarily used for the treatment of hypertension where the patient is intolerant of ACE-inhibitor therapy. These do not inhibit the breakdown of bradykinin or other kinins, and are thus, only rarely associated with the persistent dry cough and/or angioedema that limit ACE-inhibitor therapy. More recently, these have been used for the treatment of heart failure in patients intolerant of ACE-inhibitor therapy, particularly candesartan. These show benefit in hypertensive patients with type II diabetes, and may delay the progression of diabetic nephropathy. The angiotensin II receptor blockers have differing potencies in relation to BP control, with statistically differing BP effects at the maximal doses.

ARBs block the renin-angiotensin system as do ACE-inhibitor, with much the same effects but at greater cost. Thus, it is preferable to use ACE-inhibitor and ARB should be substituted only if ACE-inhibitor intolerance develops.

Alpha-adrenergic blockers

Prazosin, terazosin and doxazosin are the common α-blockers available. They are free from metabolic or lipid side effects, but postural hypotension, dizziness, diarrhoea, tachycardia and fluid retention can be troublesome.

Today, α-blockers are used in patients with features of metabolic syndrome or in men with benign prostatic hypertrophy in whom they provide symptomatic relief. These combine well with other drugs and when used as third-line of therapy provide the required lowering of BP in patients who had not fully responded to full doses of initial two drugs.

Phenoxybenzamine and phentolamine are combined α1 and α2 blockers used in pheochromocytoma. Labetalol and carvedilol also have limited α-blocking activity.

Renin inhibitors

Aliskiren is the agent belonging to this group which is the only new class introduced in the past decade. It provides dose-dependent and sustained 24-hour efficacy, the magnitude of this effect is similar to other classes of drugs when the maximum recommended dose is used (300 mg). Aliskiren adds to the antihypertensive effect of an ARB or concomitant diuretic.

Direct vasodilators

Hydralazine is infrequently used today because it has no effect on regression of left ventricular hypertrophy, and patients taking hydralazine may develop lupus-like syndrome. The use of minoxidil is limited due to its sodium-retaining properties and development of hirsutism.

Centrally acting agents

Alpha-methyldopa still remains the drug of choice in hypertension in pregnancy. Clonidine and guanethidine are not used because of their unfavourable side effect profile.

METABOLIC ABNORMALITIES IN ASSOCIATION WITH HYPERTENSION

The dysmetabolic syndrome of insulin resistance is the common denominator of the complex inter-relation between hypertension, obesity and maturity-onset diabetes. High-doses of diuretics and beta-blockers worsen insulin resistance with risk of overt diabetes and/or lipid abnormalities. Other classes of antihypertensive agents such as ACE-inhibitor, ARBs or alpha-blockers improve insulin sensitivity, and CCBs are neutral. Hence, these classes become the logical first-line antihypertensives for patients with any component of the dysmetabolic syndrome.

HYPERTENSION WITH SPECIAL SITUATIONS

Dyslipidaemias

A statin should be concomitantly administered in patients with hypertension and dyslipidaemia because of the significant cardioprotection and stroke prevention that has been shown by the ASCOT-LLA study. Antihypertensive drugs that can be

used are CCBs, ACE-inhibitor, ARBs and α-blockers. Alpha-blockers are clearly known to improve lipid profile.

Obesity

The characteristics of obesity-related hypertension are increased plasma volume, high cardiac output, and low peripheral vascular resistance. The basic mechanisms include salt and water reabsorption, insulin resistance and increased sympathetic outflow. Weight loss should be advocated very strictly. Low-dose diuretic, ACE-inhibitor and/or ARB is advocated. Beta-blockers should be avoided.

Angina

CCBs (verapamil) and α-blockers are effective anti-anginal and antihypertensives as well. ACE-Is, ARBs and diuretics help indirectly by regression of LVH and/or reduction in BP.

POST-INFARCT HYPERTENSIVE PATIENTS

Beta-blockers, ACE-inhibitor or ARBs are in any case indicated in the post-infarct state and should handle the hypertension as well. Lowering of BP too rapidly may cause sympathetic activation and reflex tachycardia and should be avoided. Hypertension in patients with acute coronary syndrome should be treated aggressively. The target BP should be 130-140/90-95 mm Hg.

HYPERTENSION IN THE ELDERLY

Treatment of hypertension in the elderly definitely protects against the development of stroke. Systolic rather than diastolic hypertension is seen in this age group. SBP should be brought down to at least 140 mm Hg. DBP may also come down. But caution should be exerted to see that it is not lowered below 80 mm Hg in order to avoid coronary hypoperfusion. Also, postural hypotension should be watched for and taken care of immediately. Lifestyle modifications are important for the management of hypertension in the elderly.

Low-dose diuretics are the preferred agents. Dihydropyridine calcium channel blockers are able to reduce morbidity and mortality in the elderly. ACE-inhibitor and ARBs are also used. Beta-blockers are to be avoided. Combination therapy is required in nearly two-thirds of patients.

DIABETIC HYPERTENSIVES

Hypertension is present in nearly 50% of type I diabetics secondary to renal damage and 80% of type II diabetics as a component of metabolic syndrome. The BP goals are stricter than non-diabetics. JNC VII has recommended a goal BP of 130/80 mm Hg. The choice is ACE-inhibitor or ARB. A low-dose diuretic may be used. CCBs can be the third drug. Alpha-blockers are metabolically neutral are also appropriate.

Lifestyle modifications have to be aggressive. Tight control of diabetes, effective BP control and low protein diet improve overall outcome.

HYPERTENSION IN PREGNANCY

Hypertension in pregnancy is diagnosed when the DBP is more than 85 mm Hg. The diagnosis requires two consecutive measurements of BP. DBP more than 110 mm Hg requires urgent attention.

Hypertension in pregnancy can be divided as: (i) pre-eclampsia, (ii) chronic hypertension in pregnancy, (iii) pre-eclampsia superimposed on chronic hypertension in pregnancy, and (iv) gestational hypertension.

The drug of choice for hypertension in pregnancy is alpha-methyldopa. CCBs and labetalol can also be used. ACE-inhibitor, ACE-II receptor blockers are contraindicated. Use of low-dose diuretics is discouraged because pre-eclampsia is a volume-depleted state. Intravenous labetalol and hydralazine are effective agents in emergency situations. Intravenous magnesium sulphate is the drug of choice for prevention and treatment of seizures, and can lower the BP to some extent. In some instances, antihypertensive drugs fail to lower the BP and the only means of controlling BP is to induce delivery.

HYPERTENSION IN SOME SPECIAL SITUATIONS

Cerebrovascular Accidents

In ischaemic stroke, the BP should not be reduced to less than 160/100 mm Hg. This should be done gradually and carefully monitored over 24 to 48 hours. In acute intracerebral haemorrhage, the BP should be maintained below 180 mm Hg and 105 mm Hg respectively.

Renal Disease

The BP goal should be less than 120/80 mm Hg. All patients with microalbuminuria, irrespective of the presence of hypertension need to be treated with antihypertensives in order to retard the progression of renal disease. Low-dose diuretics, CCBs, beta-blockers and alpha-methyldopa can be used in patients with renal disease. ACE-inhibitor and ARBs have shown favourable effects on progression of renal disease, especially in diabetics. However, these should not be used in patients with serum creatinine of ≥ 3 mg/dL. Salt restriction and protein restriction form an integral part of dietary recommendations.

Chronic Obstructive Airway Disease

Long-acting CCBs are safe and effective drugs. Low-dose diuretics may be used. ACE-I, ARBs, beta-blockers, alpha-beta blockers are not recommended.

RESISTANT HYPERTENSION

Resistant hypertension is defined as blood pressure that remains elevated above treatment goals despite administration of an optimal three-drug regimen that includes a diuretic. High BP that is under control, but requires four or more medications to treat it, is also considered resistant to treatment.

It is emphasised that measurement of BP should be accurate before labelling a patient as having resistant hypertension. Proper BP measurement technique must be used, the size of the BP cuff should be accurate and the BP readings must be recorded on two separate occasions.

Causes of resistant hypertension are enumerated in **Table 9**.

Table 9: Causes of Resistant Hypertension

Noncompliance with treatment
Lifestyle factors: obesity, excess salt intake, heavy alcohol consumption
Secondary hypertension
Fluid retention: usually expansion from kidney failure
Medications: corticosteroids, nonsteroidal anti-inflammatory drugs (NSAIDs) like aspirin, sympathomimetic agents present in nasal drops

Management

Resistant hypertension requires special consideration in terms of evaluation and treatment. Confirming resistance is the first step in evaluating difficult-to-treat high BP. Successful treatment of resistant hypertension requires consideration of lifestyle factors that contribute to treatment resistance, diagnosing and treating secondary causes of high BP and using multiple-drug treatments effectively. Uncontrolled hypertension is not the same as resistant hypertension. Uncontrolled BP can be caused by poor medication adherence and/or an inadequate treatment regimen. Additionally, it is important to make sure that what appears to be resistant hypertension is actually not 'pseudohypertension' or 'white coat hypertension'.

Combine agents with different mechanisms of action. A triple drug regimen of an ACE-inhibitor or ARB, CCBs and a thiazide diuretic is effective and generally well-tolerated. Some patients may benefit from adding mineralocorticoid receptor antagonist (MRA) to their treatment regimens. Combinations of three or more drugs must be tailored to the individual.

Dose Timing

Taking at least one antihypertensive medicine at bedtime had better BP control, in particular, lowering night-time BP.

Adherence

Steps should be taken to help patients take medications regularly and properly. Prescriptions should be simplified as much as possible by using long-acting combination drugs and once-daily dosing. More frequent clinic visits and home BP monitoring will generally help patients adhere to their treatment routine. Though an expensive and labour-intense option, a team approach to treatment including nurse case managers, pharmacists and nutritionists can improve treatment results.

HYPERTENSIVE EMERGENCIES

It is the clinical state of the patient, the degree of and/or progression of target organ damage that defines a hypertensive emergency and not the absolute level of BP.

Hypertensive emergencies are severe elevations in BP, often higher than 220/140 mm Hg, complicated by clinical evidence of progressive target organ dysfunction. These patients require immediate admission and BP reduction (not necessarily to normal ranges) to prevent or limit further target organ damage, e.g. hypertensive encephalopathy, intracranial haemorrhage, acute myocardial infarction, acute left ventricular failure with pulmonary oedema, dissecting aneurysm of aorta, acute renal failure, eclampsia of pregnancy. Immediate admission to a monitored unit and parenteral antihypertensive therapy are indicated.

Severe hypertension (urgencies) are marked elevations of BP, usually higher than 180/110 mm Hg. Evidence of target organ damage may be often present, but non-progressive. Manifesting symptoms may include headache, shortness of breath, and pedal oedema. Management in the emergency department with oral agents is sufficient. Follow-up within 24 to 72 hours is recommended. In many cases patients present with BP higher than 180/110 mm Hg, without clinical symptoms and have no clinical evidence of target organ damage. They may be initiated on a two-drug regimen if previously untreated, or an existing treatment regimen may be modified. Emotional distress or non-adherence to prior treatment may be the cause. These patients do not require BP reduction to normal and, after brief observation in the emergency room, can be discharged, with follow-up scheduled within 3 to 7 days.

Drugs used in hypertensive emergencies are enlisted in **Tables 10 and 11**.

Table 10: Preferred Drugs for Select Hypertensive Emergencies

Emergency	Drugs of Choice	Target Blood Pressure
Aortic dissection	Nitroprusside + esmolol	110 to 120 mm Hg SBP as soon as possible
AMI, ischaemia	Nitroglycerin, nitroprusside, nicardipine	Secondary to ischaemia relief
Pulmonary oedema	Nitroprusside, nitroglycerin, labetalol	Improve symptoms 10% to 15% in 1 to 2 hrs
Renal emergencies	Fenoldopam, nitroprusside, labetalol	Target BP 20% to 25% in 2 to 3 hrs
Catecholamine excess	Phentolamine, labetalol	Control paroxysms 10% to 15% in 1 to 2 hrs
Hypertensive encephalopathy	Nitroprusside	20% to 25% in 2 to 3 hrs
Subarachnoid haemorrhage	Nitroprusside, nimodipine, nicardipine	20% to 25% in 2 to 3 hrs
Ischaemic stroke	Nitroprusside (controversial), nicardipine	0% to 20% in 6 to 12 hrs

Table 11: Oral Agents for the Treatment of Hypertensive Urgencies

Agent	Dosage	Onset/Duration of Action	Precautions
Captopril	25 mg PO; repeat as needed; SL, 25 mg	15 to 30 min/ 6 to 8 hrs SL 10 to 20 min/ 2 to 6 hrs	Hypotension, renal failure, bilateral renal artery stenosis
Clonidine	0.1 to 0.2 mg PO, repeat hourly as required to total dosage of 0.6 mg	30 to 60 min/ 8 to 16 hrs	Hypotension, drowsiness, dry mouth
Labetalol	200 to 400 mg PO; repeat every 2 to 3 hrs	1 to 2 hrs/ 2 to 12 hrs	Bronchoconstriction, heart block, orthostatic hypotension
Amlodipine	2.5 to 5 mg	1 to 2 hrs/ 12 to 18 hrs	Tachycardia, hypotension

PO = Per orally; SL = Sublingual.

CONCLUSIONS

Management of hypertension includes not just the control of BP, but also other risk factors and associated conditions with special attention on prevention of target organ damage. A wide variety of agents are available. Diuretics are preferred agents. But there are compelling indications in special disease situations. It is essential to achieve 'goal' BP, in order to retard the development of TOD.

12.22 Secondary Hypertension

BB Thakur, Arohi Kumar

INTRODUCTION

India has a very high prevalence of hypertension which is more in the urban population (20%) than in the rural population (10%). It is estimated that there are 89 million hypertensive people in India and about 180 million can be put under the category of pre-hypertension as per the prevailing criteria of Joint National Committee (JNC) VII definition.

In this large pool of hypertensive population, 93% to 95% comprise of primary hypertension where no definitive cause is discernible. However, 5% to 7% of individuals suffer from secondary hypertension and these patients are amenable to therapy (medical or surgical) depending on the aetiological factors. In the early stages of secondary hypertension if corrective treatment is effectively done, then hypertension can be practically cured or alleviated very significantly.

DEFINITION

Secondary hypertension is usually caused by treatable underlying pathology and it constitutes approximately around 5% to 7% of the total hypertensive population. Amongst the various causative factors, renal hypertension is responsible for the largest proportion followed by the endocrinal hypertension and hypertension due to use of oral contraceptives. A very small proportion is caused by vascular, immunological and neurological abnormalities (**Table 1**).

Table 1: Important Causes of Secondary Hypertension

Primary/Essential Hypertension	93% to 95%
Secondary Hypertension	5% to 7%
Renal causes	3% to 5%
Parenchymal	2% to 3%
Renovascular	1% to 2%
Endocrine causes	0.3% to 1.0%
Phaeochromocytoma	<0.1%
Primary aldosteronism	0.3%
Cushing's syndrome	<0.1%
Other endocrinopathies	
Thyroid disorders	0.5%
Parathyroid disorders	
Pituitary disorders	
Oral contraceptives/drugs	0.5%
Miscellaneous	0.5%

DIAGNOSIS

The importance of early diagnosis has already been emphasised. This will help in effective early intervention so that the disease may be cured even before target organ damage takes place and may provide a long lasting relief to the patient. To diagnose secondary hypertension, basic principles are the same as in any other patient of hypertension. A detailed history, examination and common laboratory tests are to be carried out. The history and the investigations may raise the suspicion of secondary hypertension. Some of the important clinical features include hypertension starting at extreme of ages, in younger age or elderly people above the age of 50 years. The other indicators are refractory hypertension which is difficult to manage and in endocrinal causes of hypertension the bio-chemical abnormalities may be seen. Coarctation of aorta should be suspected in cases with radio-femoral delay. Renal bruits may be heard in renal artery stenosis while episodic accelerated hypertension with neurofibromatosis may point to phaeochromocytoma. The other specific investigations in various categories of secondary hypertension are listed in **Table 2**.

IMPORTANT CAUSES OF SECONDARY HYPERTENSION

Renal Hypertension

Reno-parenchymal causes

This is one of the most common causes of secondary hypertension accounting for 2% to 5% of the hypertensive population. Diabetes, interstitial tubular disease, glomerular disease, polycystic kidney disease (PKD), analgesic and gouty nephropathy are some of the important causes.

The other causes which are renal-mediated are post-renal transplant patients as well as drug-induced due to cyclosporine, steroids, and sustained use of erythropoietin. In most of these patients, the pathophysiological features are expansion of the body fluid, sodium retention and inappropriate activation of the renin angiotensin aldosterone system (RAAS). The salient features of parenchymal hypertension are given below.

Hypertension occurs early in parenchymal and PKD while interstitial renal disorders cause hypertension in terminal stages. Hypertension further aggravates the deterioration of renal function and nephropathy. Treatment of early hypertension is essential for prevention of cardiovascular disease as well as kidney dysfunction. The rise in glomerular capillary pressure in glomerulonephritis and diabetic nephropathy leads to excessive protein loss and therefore aggressive management of hypertension is mandatory.

The protein excretion in interstitial kidney disease, pyelonephritis, PKD and hypertensive nephrosclerosis is minimal. However, if protein loss becomes excessive, aggressive management of hypertension is required. The commonly used drugs are calcium channel blocking agents and other conventional drugs. Angiotensin converting enzyme (ACE)-inhibitors should preferably be avoided in patients with high creatinine values.

Renovascular hypertension

The pathophysiology of renovascular disease resulting in hypertension is depicted in **Figure 1** and the various causes of renal artery stenosis are tabulated in **Table 3**.

Table 2: Clinical Features and Laboratory Investigations in Secondary Hypertension

Clinical and Laboratory Parameters	Suspected Disorder	Further Diagnostic Studies
Systolic/diastolic bruit heard in renal area	Renovascular disease	Ultrasound Doppler imaging, MR angiography, captopril radioisotopic renography, renal arteriography
Mass in renal region, loin pain, colic, stones, haematuria	Nephrolithiasis, UTI, polycystic kidney disease	Ultrasound - KUB, intravenous urography, contrast CT urography
Renal insufficiency, atherosclerotic cardiovascular disease, oedema, elevated blood urea nitrogen and creatinine levels, proteinuria	Renal parenchymal disease	Creatinine clearance, renal ultrasonography
Paroxysmal or persistent hypertension, headache, diaphoresis, tachycardia, palpitations, neurofibromatosis, *café-au-lait* spot (skin)	Pheochromocytoma	Increased urinary catecholamine metabolites (vinyl mandelic acid, metanephrines, normeta-nephrines), plasma free metanephrines
Hypernatraemia, hypokalaemia muscles weakness	Hyperaldosteronism	Ratio of plasma aldosterone to plasma renin activity, CT of adrenal glands
Weight gain, fatigue, weakness, hirsutism, amenorrhoea, moon facies, buffalo hump, purple striae, truncal obesity, hypokalaemia	Cushing's syndrome	Dexamethasone suppression test
Headache, fatigue, visual problems, enlargement of hands, feet, tongue, coarse features	Acromegaly	Growth hormone levels, CECT brain
Heat intolerance, weight loss, tachycardia, palpitations, systolic hypertension, exoph-thalmos tremor, sweating, etc.	Hyperthyroidism	Thyroid profile
Fatigue, weight loss, hair loss, swelling, diastolic hypertension, muscle weakness	Hypothyroidism	Thyroid profile
Kidney stones, osteoporosis, depression, lethargy, muscle weakness	Hyperparathyroidism	Serum calcium, parathyroid hormone levels
Snoring, day-time somnolence, obesity	Obstructive sleep apnoea	Sleep study
Weak pulses, decreased or delayed femoral pulse of low amplitude, pulsations in neck, bruit over inter-scapular region, abnormal chest radiograph	Coarctation of aorta, aorto-arteritis	Doppler or CT imaging of aorta-angiography
High salt intake, excessive alcohol intake, obesity	Dietary effects	Detailed history, alcoholic intake and calculate salt intake
Polycythaemia in COPD, erythropoietin use in renal disease	Side effects of erythropoietin	Trial of drug if possible

MR = Magnetic resonance; KUB = Kidney, ureter, and bladder; CT = Computed tomography; CECT = Contrast enhanced computed tomography; COPD = Chronic obstructive pulmonary disease.

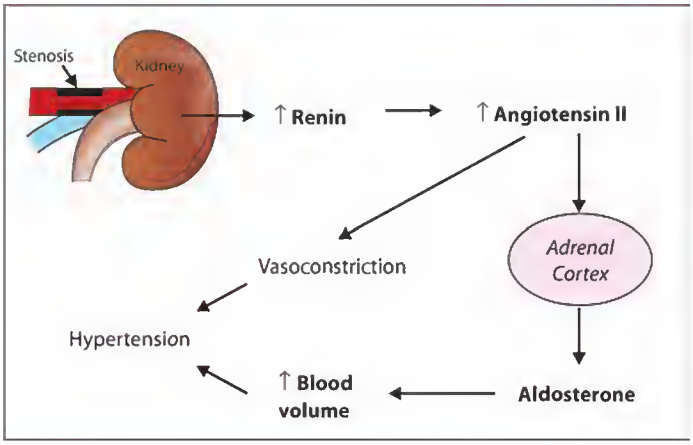

Figure 1: Renovascular hypertension and role of renin angiotensin aldosterone system.

Table 3: Causative Factors for Renal Artery Stenosis

Atherosclerosis	Vasculitis
Fibromuscular dysplasia	Renal artery embolism
Aorto-arteritis	Radiation arteritis

A number of lesions develop in renal arteries which cause hypertension, the most frequent being atherosclerosis. Others include fibromuscular dysplasia which has distinct arteriographic features. The choice of treatment depends on the type and severity of lesion.

Diagnosis

Most patients present in a way similar to essential hypertension. Certain clinical features may point to renovascular hypertension. These include abdominal bruit, drug-resistant hypertension, sudden onset pulmonary oedema, worsening renal function with use of ACE-inhibitors and sudden development of hypertension in the elderly.

Duplex ultrasound screening with colour Doppler flow studies of renal arteries has great potential for diagnosis of occlusive renal arterial disease with high sensitivity and specificity for detecting stenosis in more than 90% cases. Digital subtraction renal arteriography allows direct visualisation of the site and extent of renal artery stenosis. Though this is an invasive procedure and requires the use of contrast agent, it provides highly accurate information. Magnetic resonance angiography

is now often used as a non-invasive alternative. It is one of the definitive diagnostic procedures.

Management

Renal angioplasty and stenting are now the treatment of choice for renal artery stenosis. Anatomic quantification and functional significance of the lesion must be established first. Balloon dilatation alone is not sufficient as the lesion particularly in atherosclerosis is mostly ostial and re-stenosis is common. Therefore, stenting is advocated in most cases. It relieves ischaemia to the kidney and even if it does not normalise the blood pressure (BP), it will allow an easier control of BP. It will also contribute to long-term preservation of renal function. Renal stenting is particularly useful when the lesion is severe but renal function is still relatively well-preserved. When the kidney function has severely deteriorated, renal angioplasty often does not help. The drug therapy is an important factor in the treatment. Any drug other than the ACE-inhibitor can be initiated for control of hypertension. More than one drug may also be used, if necessary.

ENDOCRINAL CAUSES OF SECONDARY HYPERTENSION

Hyperaldosteronism

This endocrinal disorder causes hypertension due to excessive sodium retention, volume expansion and increased peripheral resistance. It can be either primary or secondary. The most common cause of secondary hyperaldosteronism is hyperreninism secondary to renal artery stenosis. The prevalence of primary hyperaldosteronism varies from 0.05% to 2% of the hypertensive population. Aldosterone producing adenoma is usually unilateral and is the most common cause of primary hyperaldosteronism in adults. It is found most commonly in patients of 20 to 50 years of age. Primary hyper aldosteronism presents with hypertension and hypokalaemia. In primary hyperaldosteronism, about 5% to 15% of patients may have normal serum potassium levels.

Idiopathic hyperaldosteronism (IHA) is the second most common cause of primary aldosteronism in adults but it is the most common cause in children. The bilateral adrenal hyperplasia associated with idiopathic hyperaldosteronism is thought to be due to an extra-adrenal stimulus.

Diagnosis

The diagnosis of hyperaldosteronism is made by the measurement of plasma aldosterone and plasma renin activity taking the blood samples in the morning after 15 minutes of rest. Tests that may help to identify the presence of autonomous hypersecretion of aldosterone are the fludrocortisone suppression test, saline loading tests and captopril suppression test.

A computed tomography or magnetic resonance image may identify the presence of an adenoma. An assessment of plasma aldosterone before (supine) and after 2 to 4 hours of upright posture may also be helpful.

Management

The control of BP with antihypertensive agents, correction of hypokalaemia and surgical removal of adenoma are the mainstay of treatment. Removal of an adrenal adenoma cures hypokalaemia within two weeks in all cases but hypertension only in about 70% of cases. Spironolactone is the drug of choice for primary hyperaldosteronism in small dose, e.g. 12.5 mg to 25 mg per day to start with. However, a higher dose of 200 mg to 400 mg per day may be required. Spironolactone can cause impotence, decreased libido, menstrual irregularities and gynaecomastia. Amiloride (10 to 40 mg per day) is the drug of choice for sexually active men. Amiloride blocks sodium channels at the distal renal tubules thus increasing sodium and chloride excretion and decreasing potassium excretion. Side effects include headache, fatigue, impotence, increased uric acid levels, and gastrointestinal complaints. If a second antihypertensive agent is needed, calcium channel blockers and ACE-inhibitors can be added.

Cushing's Syndrome

It occurs due to glucocorticoid excess and the patients have moon facies, truncal obesity, abdominal striae, hirsutism, hyperglycaemia, weak bones, cataracts, muscle weakness and hypertension. Hypertension is present in 80% of patients with Cushing's syndrome which is due to the sodium retaining effects of glucocorticoids and increased production of mineralocorticoids. Other contributory factors are increased production of renin substrate or steroid-induced change in vascular reactivity. Hypertension is common and severe with adrenal malignancy as compared to Cushing's disease. Bilateral adrenalectomy virtually cures all patients with Cushing's disease but it will also require permanent steroid replacement therapy for life. For pituitary adenomas, selective excision of the adenoma is warranted. Post-surgery radiotherapy may be needed to reduce the incidence of relapse.

Phaeochromocytoma

These are catecholamine secreting tumours, most commonly seen in the age group of 30 to 50 years. Up to 80% to 90% of pheochromocytoma are found in one or both adrenal glands. Most patients with pheochromocytoma have headache, sweating or palpitations. Hypertension may be sustained or paroxysmal. A clinical syndrome of baroreflex failure may be confused with pheochromocytoma which occurs from denervation of carotid baroreceptor following carotid body tumour resection, carotid artery surgery, neck irradiation or trauma. In this condition, the patient has labile hypertension with phases of acute severe rise of BP. Pheochromocytomas can be surgically excised. However, it is appropriate that preoperatively a stable alpha-adrenergic blockage is achieved and once this is established, beta-blockers can be added to the treatment as these can help to prevent catecholamine-induced arrhythmias. If the tumour is inoperable, radiation therapy is the most effective treatment modality with β-blockade use. These tumours can be successfully removed surgically in 90% of cases.

Hyperthyroidism

It induces systemic vasoconstriction, an increase in blood volume and increased cardiac activity all of which can lead to hypertension.

Hypothyroidism

Hashimoto's disease is one of the major causes of hypothyroidism. However, it is rarely diagnosed due to hypertension with non-specific symptoms such as malaise,

goitre and hypercholesterolaemia. Treatment of hyperthyroidism (carbimazole, surgical excision or radioablation) is useful. Hypertension can then be easily controlled but use of β-blockers may also be useful. It is not very clear why some patients with hypothyroidism develop hypertension. It may be related to decreased tissue metabolism reducing the release of vasodilator metabolites, thereby producing vasoconstriction, increased systemic vascular resistance and decreased cardiac output.

Other Endocrinal Causes of Hypertension

Acromegaly

Acromegaly is caused by growth hormone producing pituitary adenoma and hypertension is noted in about 40% of patients.

Primary hyperparathyroidism

It is caused by parathyroid adenoma or hyperplasia. Hypertension manifests in about 20% of patients with primary hyperparathroidism.

VASCULAR DISORDERS

Coarctation of Aorta

It is an easily diagnosed congenital defect that leads to hypertension. Absent or weak femoral arterial pulse gives clue to the diagnosis. It can be confirmed by echocardiography, MR angiography or conventional angiography. Early diagnosis and operative treatment before the age of 5 years is essential. Choice of treatment of coarctation is mostly by surgical correction. Balloon angioplasty and stent implantation is also practiced.

Aorto-arteritis

It is a fairly common cause of hypertension in India amongst the younger population. Various regions of the aorta, great vessels and renal arteries are involved resulting in hypertension. Its pathogenesis is uncertain and most likely immune-mediated. Diagnosis is clinically suspected due to absent or unequal peripheral pulsations with thoracic or abdominal bruits. It can be confirmed by MR angiography or digital angiography. Treatment includes immunosuppressive therapy, angioplasty and surgery.

Arteritis Syndrome

Arteritis syndrome involving the renal arteries can cause alternative obstruction and dilatation of renal vessels and this can start from aorta and its major branches. Hypertension is seen in 40% of the patients. The causation of hypertension is multifactorial.

Other Forms of Angiitis

These include polyarteritis nodosa and progressive systemic sclerosis (PSS). All these conditions are autoimmune disorders. Polyarteritis nodosa is complicated by hypertension in about 30% of patients which can progress to renal failure. While PSS presents with malignant hypertension and renal crisis, aggressive and rapid control of BP is the key for preventing kidney damage.

SLEEP APNOEA

It is a disorder in which breathing halts briefly but repeatedly during sleep. Most people with sleep apnoea snore and are overweight. Whether overweight or not, even mild sleep apnoea is associated with high BP. The mechanism of hypertension may be related to sympathetic activation and hormonal changes associated with repeated periods of apnoea-induced hypoxia, hypercapnea and stress associated with the loss of sleep. Sleeping with a nasal continuous positive airway pressure (CPAP) device is the treatment of choice. As the sleep apnoea improves, BP tends to improve as well.

Various drugs that can cause hypertension are listed in **Table 4**.

Table 4: Hypertension Caused by Drugs

Drug Class	Drug Examples
Immunosuppressive agents	Cyclosporine, tacrolimus, corticosteroids
Nonsteroidal anti-inflammatory drugs	Ibuprofen, naproxen, piroxicam
COX-2 inhibitors	Celecoxib, rofecoxib, valdecoxib
Oestrogens	Oestrogen oral contraceptives*
Anti-obesity	Sibutramine, phentermine
Stimulants	Nicotine, amphetamines
Mineralocorticoids	Fludrocortisone
Anti-Parkinsonian	Bromocriptine
MAO inhibitors	Phenelzine
Anabolic steroids	Testosterone
Sympathomimetics	Pseudoephedrine

** Oral contraceptives are one of the common causes of drug-induced hypertension.*

Erythropoietin

The underlying mechanisms in drug-induced hypertension include sympathetically-mediated vasoconstriction, direct pressor effect, stimulation of endogenous vasoactive substances, e.g. endothelin, increase in blood viscosity, salt and water retention, stimulation of renin angiotensin-aldosterone system and interference of central BP regulation.

DISEASES OF BRAIN AND CENTRAL NERVOUS SYSTEM

Hypertension may be observed in cerebrovascular accidents like cerebral haemorrhage, cerebral infarction and chronic subdural haematoma. Hypertension may also been seen due to symptomatic activities in patients with head injury, brain tumours and encephalitis. Release of intracranial pressure offers relief in some of these patients.

CONCLUSIONS

Secondary hypertension has varied and multiple causes but renal and vascular causes account for a large proportion of patients with secondary hypertension. The success of management lies in early diagnosis and effective management.

12.23 Bradyarrhythmias

Yash Y Lokhandwala, Gopi Krishna Panicker

DEFINITION

Bradyarrhythmias are a group of rhythm disorders manifested by a ventricular rate in adults less than 60 beats per minute (bpm) under basal/awake conditions. The prevalence of bradyarrhythmias is more in elderly patients. It is a frequent finding in clinical practice, and its presentation may range from an incidental finding in asymptomatic patients to life-threatening atrioventricular (AV) block.

AETIOPATHOGENESIS

Automaticity or intrinsic impulse formation is the property of every cardiac cell. The sino-atrial (SA) node, as the primary cardiac pacemaker with the highest frequency in impulse formation, maintains the heart rate in response to the metabolic requirements and alterations of the autonomic nervous system. The conduction system of the heart comprising of the SA node, AV node and the His-Purkinje system is responsible for the synchronous conduction of the impulses from the atria to the ventricles.

Bradyarrhythmias occur due to:

1. abnormalities in impulse generation at sinus node (sinus node dysfunction),
2. abnormalities in conduction of impulse (disturbances in atrioventricular conduction system), and
3. a combination of abnormalities in impulse generation and conduction.

SINUS NODE DYSFUNCTION

Sinus node dysfunction is a clinical syndrome, encompassing a wide range of electrophysiological abnormalities, in combination with other clinical manifestations. This is also called 'Sick Sinus Syndrome'. These are due to abnormalities in the automaticity of sinus node cells or transmission of the sinus impulse into atria or increased susceptibility for atrial tachyarrhythmias. Causes of sinus node dysfunction are given in **Table 1**.

Table 1: Causes of Sinus Node Dysfunction

Idiopathic	
Drug induced	
	Anti-arrhythmic drugs, especially beta-blockers, sotalol and amiodarone
	Antipsychotic agents such as lithium, phenothiazines, amitriptyline
	Digitalis
Heart/Systemic disease	
	Acute inferior wall MI
	Hypothyroidism, hypothermia, hyperkalaemia and hypoxia
	Infiltrative disorders such as amyloidosis and sarcoidosis
Autonomically mediated	
	Vasovagal syncope
	Carotid sinus hypersensitivity

Clinical Features

In the early stages, most patients are asymptomatic. The typical symptoms of sinus node dysfunction due to inadequate cardiac output are:

Syncope or near-syncope, dizziness, palpitations, and decreased exercise capacity or fatigue.

The diagnosis of sinus node dysfunction is done by a 12-lead electrocardiogram (ECG) recordings, routine telemetric monitoring in the hospital or 24 hours ambulatory Holter recordings and exercise testing to judge the chronotropic response.

Autonomic testing such as carotid sinus massage, head-up tilt testing and Valsalva manoeuvres also help in establishing the diagnosis. Invasive electrophysiology studies are nearly obsolete for diagnosing sinus node dysfunction (SND).

The various bradyarrhythmias due to SND are:

Sinus Bradycardia

Sinus bradycardia is conventionally defined as sinus rate less than 60 bpm in adults during the wakeful state. However, in fit populations with a higher vagal tone, the normal waking sinus rate can go down to even 50 bpm (**Figure 1**). Sinus bradycardia is often a benign arrhythmia. Association of clinical symptoms is, therefore, essential in evaluating sinus bradycardia as being physiological or indicative of a pathological state.

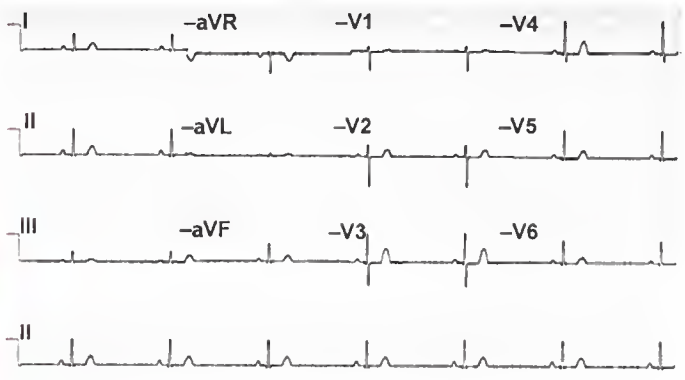

Figure 1: Sinus bradycardia.

Sinus Pause and Sinus Arrest

Sinus pause or sinus arrest is the failure of atrial activation, due to the inability of the sinus node to form impulses. A sinus pause is characterised by the absence of P-waves for a duration of more than 1.5 s. The pause is not an exact multiple of the preceding PP intervals (**Figure 2**). A sinus arrest is a more severe form where the delay is more than 3 (**Figure 3**).

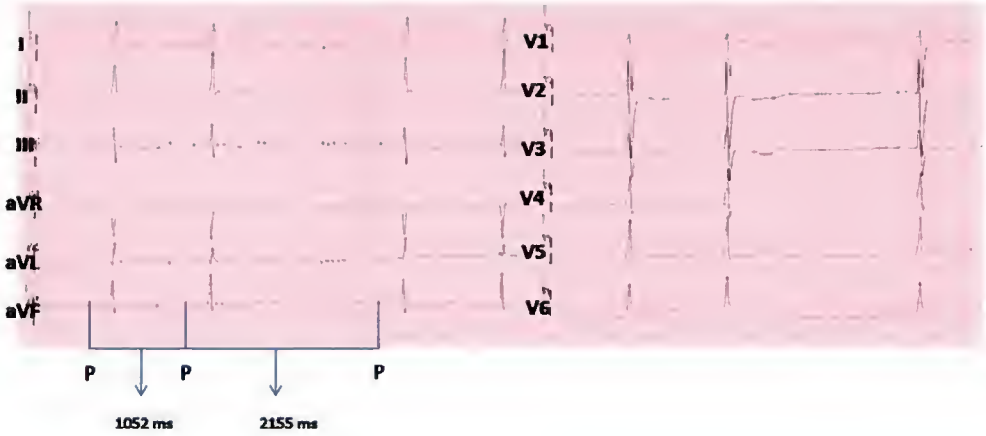

Figure 2: Sinus pause.

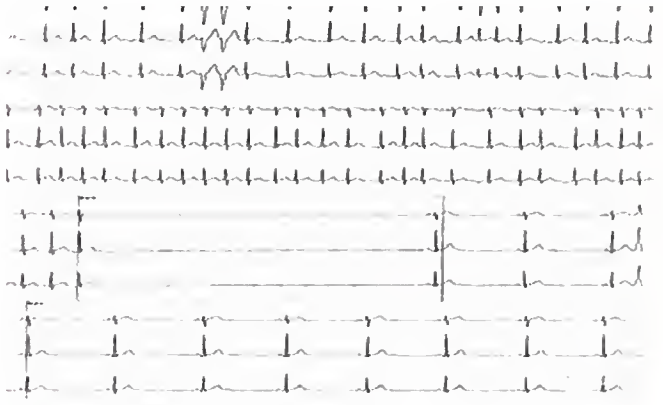

Figure 3: Sinus arrest following termination of atrial fibrillation.

Sino-atrial Exit Block

Sino-atrial exit block is the failure in conduction of sinus impulse into atria. Sino-atrial exit block can be graded into 3 degrees: *first degree, second degree and third degree.*

In a 12-lead surface ECG, SA block is manifest only as a second-degree or third-degree SA block. Electro-cardiographically, SA block is characterised by the absence of normal P waves and the duration of pause recognisable as an exact multiple of the preceding PP interval, unlike sinus pause/arrest.

First-degree SA block

The time for propagation of the sinus impulse into the atria is significantly prolonged. This cannot be identified clinically or electrocardiographically.

Second-degree SA block

Second-degree SA block can be further classified as:

Mobitz type I SA (Wenckebach) block

It is characterised electrocardiographically by progressive lengthening of SA conduction, until no P-wave appears for one beat and the sequence begins again. There is group beating, with gradually shortening PP intervals, followed by a pause which is less than twice the shortest cycle.

Mobitz type II SA block

It is characterised electrocardiographically by fixed PP interval, before and after the pause with the pause being a multiple of the PP interval. Type II SA block is named as 2:1, 3:1 block, etc. according to the ratio of the PP interval with the pause (**Figure 4**).

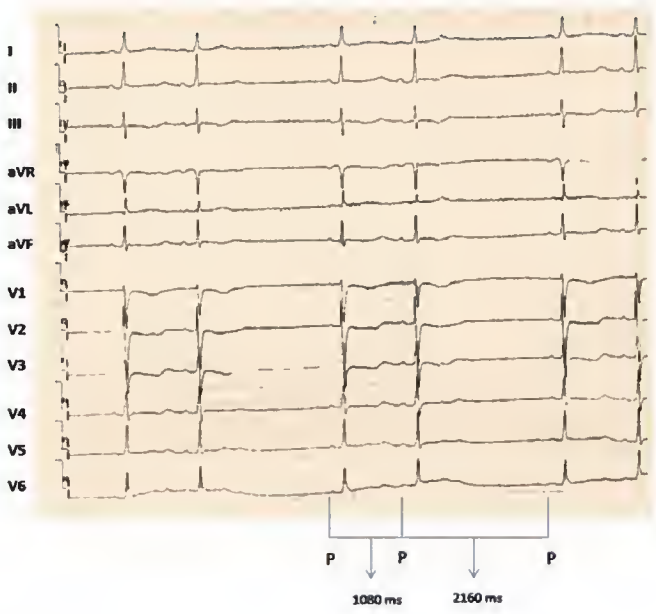

Figure 4: 2:1 Sino-atrial block.

Third-degree or complete SA block

It is manifest as absence of P-waves, with long pauses resulting in ectopic atrial or ventricular rhythms. Complete SA block cannot be differentiated from sinus arrest on a surface ECG.

DISORDERS OF ATRIOVENTRICULAR CONDUCTION

Conduction blocks in the AV conduction system can occur in the AV junction or at different levels in the His-Purkinje system. The blocks in the His-Purkinje system such as bundle branch blocks or intraventricular conduction defects do not necessarily show bradycardia.

AV Block

AV block (erroneously called as heart block) is the failure in regular conduction of the impulse from atria to the ventricle at the AV junction. The diagnosis of the AV block can be done adequately from the ECG from the PR interval, QRS duration and ventricular rates on the surface ECG.

AV block can be also graded into 3 degrees: *first degree, second degree and third degree.*

Causes of AV Block

Causes of AV block are given in **Table 2**.

Table 2: Causes of AV Block

Physiologic
- Athletes
- Sleep

Drug-induced
- Digitalis, verapamil, beta-blockers, amiodarone, etc.

Vagally mediated
- Carotid sinus hypersensitivity
- Neurocardiogenic syncope

Heart/Systemic disease
- Lenegre's disease: sclero-degenerative
- Lev's disease: fibrocalcific
- Myocardial infarction
- Congenital complete AV block
- Viral myocarditis
- Hyperkalaemia
- Traumatic—after surgery or radiofrequency ablation close to the AV node

First-degree AV block

The time for conduction of impulse from the atria to the ventricles is significantly prolonged in first-degree AV block. An ECG with a paper speed of 25 mm/s will show the prolongation of the PR interval by more than 200 ms (**Figure 5**).

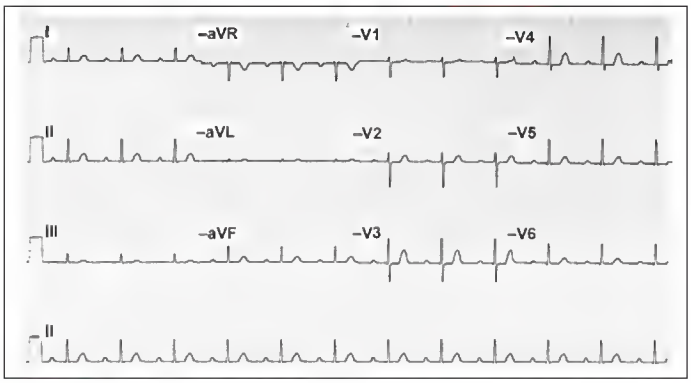

Figure 5: First-degree AV block (PR interval is 260 ms).

Second-degree AV block

Second-degree AV block is further divided into:

Mobitz type I (Wenckebach phenomenon)

It is characterised in an electrocardiogram by a sequence which begins with a normal or prolonged PR interval, and with each successful beat the PR interval lengthens until block of the impulse occurs and a beat is dropped. The R-R interval shortens typically. This type of block invariably is at the level of the AV node (**Figure 6**).

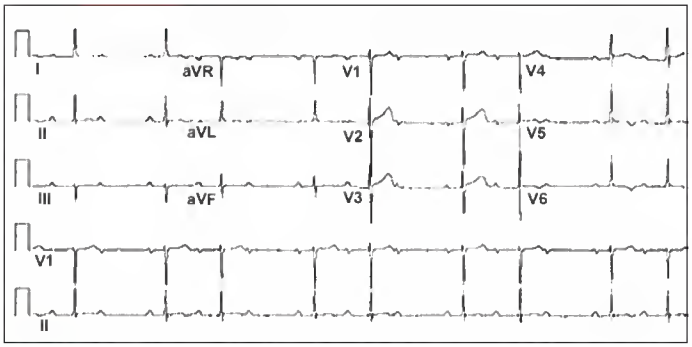

Figure 6: Second-degree AV block Mobitz 1 (AV Wenckebach).

Mobitz type II

It is characterised in an electrocardiogram by a PR interval which is prolonged but constant, but some P waves are not conducted (**Figure 7**).

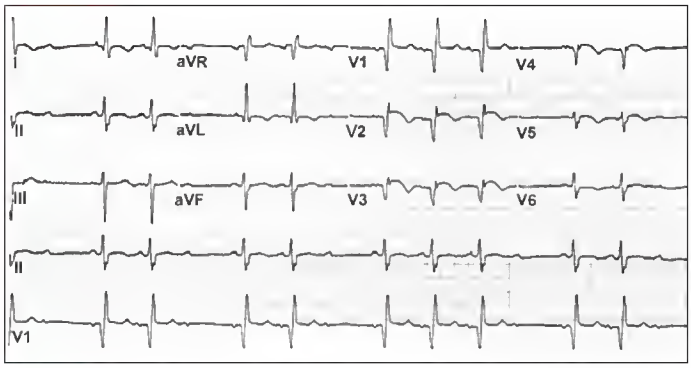

Figure 7: Second-degree AV block Mobitz 2 – RBBB. The ECG also shows an evolved anterior wall myocardial infarction with left-axis deviation.

2:1 AV block

In case of only 2:1 AV block, it is not possible to classify it as type 1 or type 2; hence a separate category of 2:1 AV block in our classification (**Figures 8A and B**).

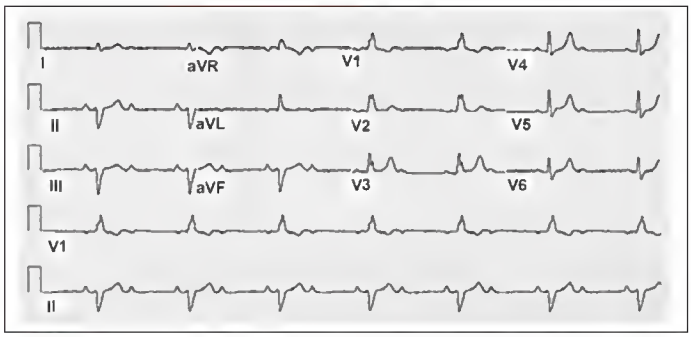

Figure 8A: 2:1 AV block. There is also RBBB and LAFB.

Figure 8B: 2:1 AV block-narrow QRS. The PR interval is also prolonged.

Third-degree or complete AV block

It results in the complete interruption of conduction from the atria to the ventricle. In an ECG, it is characterised by the failure of all P waves to conduct to the ventricle. There is consequently an escape rhythm from a subsidiary pacemaker in the AV junction at heart rates lower than the typical sinus rate for the subject. The QRS complexes are normal or near normal in shape if the subsidiary pacemaker

is situated in the lower AV node (**Figure 9A**) and wide (**Figure 9B**) if the ectopic pacemaker is situated peripherally in the ventricular musculature.

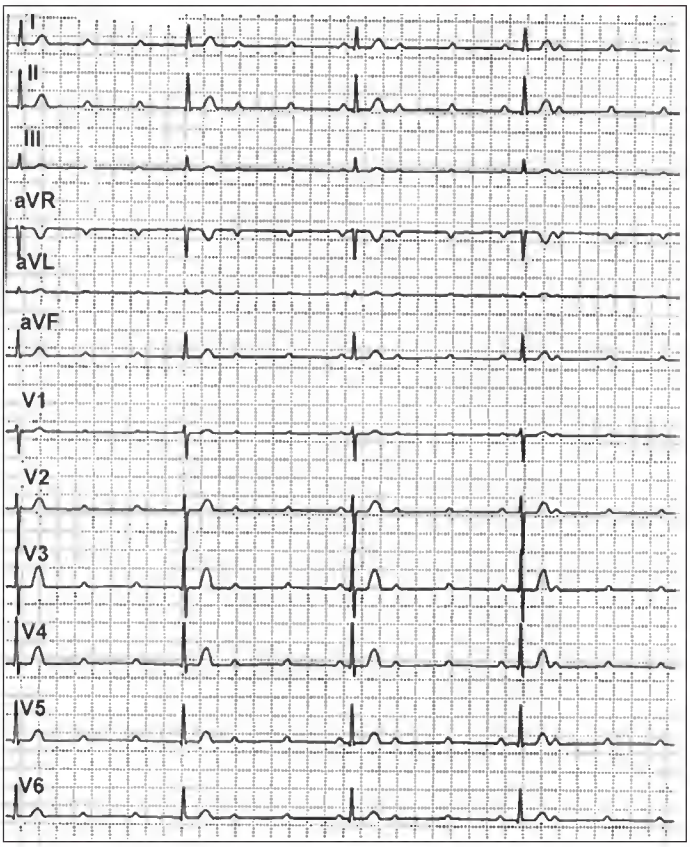

Figure 9A: Complete AV block. Narrow QRS escape rhythm.

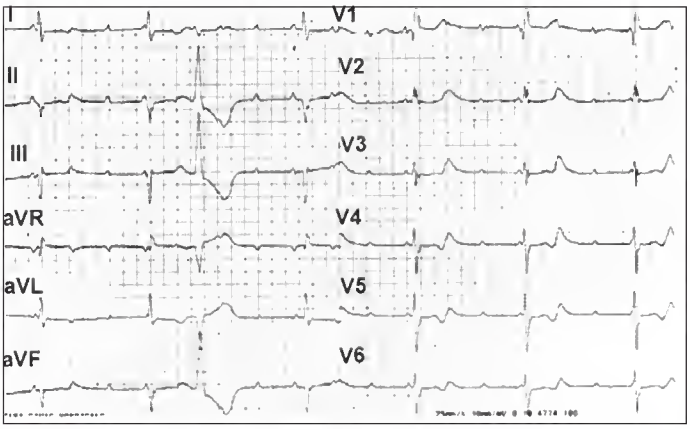

Figure 9B: Complete AV block. Wide QRS escape rhythm. One premature ventricular complex is also seen.

A narrow (normal) QRS escape rhythm is generally more stable, while a wide QRS escape rhythm carries a grave prognosis.

High-grade AV block

When 2 or more consecutive sinus P waves are blocked, it is termed as high-grade AV block.

Paroxysmal AV block

Sudden episodes of high-grade AV block when there is otherwise normal conduction is termed as paroxysmal AV block (**Figure 10**).

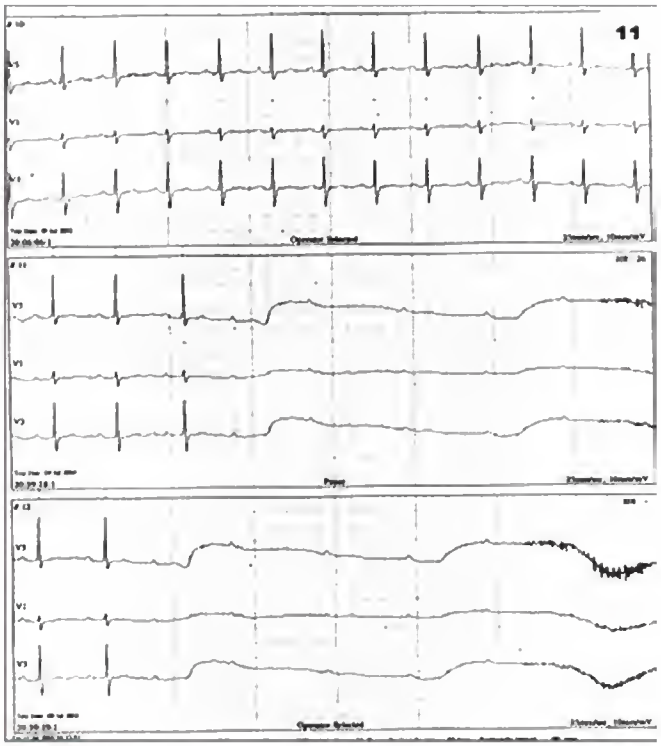

Figure 10: 24-hour Holter showing paroxysmal AV block. Likely to be vagally-mediated since there is sinus slowing along with asystole.

AV Dissociation

This is a descriptive term for a phenomenon and not a disease entity by itself. Hence, AV dissociation is not synonymous with AV block. AV dissociation connotes that the atria and ventricles are activated by separate pacemakers. This is seen in complete AV block, many cases of ventricular tachycardias, and severe sinus bradycardia (isorhythmic AV dissociation) (**Figure 11**).

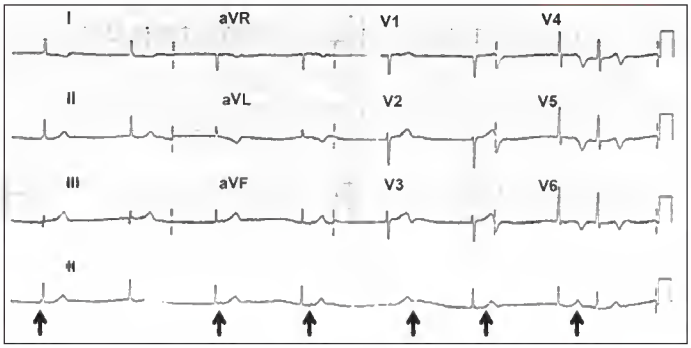

Figure 11: Isorhythmic AV dissociation. Sinus bradycardia; competing junctional escape rhythm. The sinus P is occasionally conducted. Arrows denote sinus P waves.

TREATMENT

Bradycardia is a common finding in general practice, and the clinical presentation may range from an incidental finding in asymptomatic patients to life-threatening heart block.

For the management of patients with bradycardia, it is crucial that the symptoms be recognised as related to a low ventricular rate. The suspicion of bradycardia in the differential diagnosis of haemodynamically compromised patients must usually be followed by immediate ECG recording and interpretation. A careful clinical evaluation is necessary and should include history taking, physical examination and

laboratory studies including tests of thyroid function as well as continuous 24-hour ECG recording. Identification of treatable, reversible causes of the bradycardia is the key for successful management. There is no reliable long-term medication for increasing the sinus rate.

Management of Sinus Node Dysfunction (SND)

In patients with known causes for sinus node dysfunction (SND), treatment should be directed towards the underlying aetiology. Theophylline and beta-agonists have been used to treat bradycardia symptomatically, but it does not prevent syncope. Permanent pacing is considered essential in all symptomatic cases of sinus node dysfunction. Atrial-based pacing is the ideal option for patients with significantly symptomatic sinus node dysfunction (**Figure 12**).

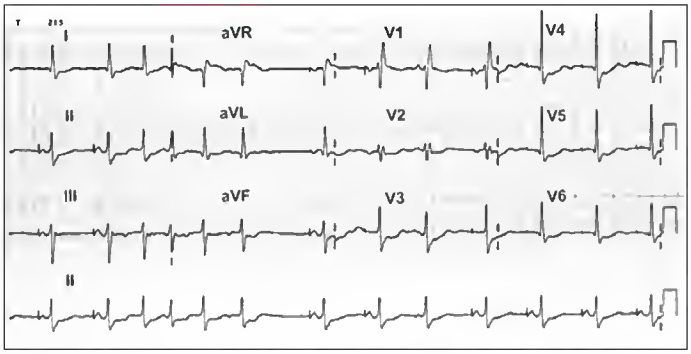

Figure 12: Atrial (AAI) pacing.

Management of Atrioventricular Conduction Disturbances

The prognosis and management of AV block depends on the level of AV block and its association with symptoms. Identification of the cause for AV conductional disturbances is important in recognising them as transient or irreversible. Drug-induced AV block can be resolved by withdrawing the causative drugs. Permanent pacing must be considered if the drugs are essential for treatment of other medical conditions. Temporary pacing is indicated in AV blocks due to conditions such as digitalis toxicity, hyperkalaemia or acute myocardial infarction till the resolution of the block. In all other cases, permanent pacing is indicated. An AV sequential pacemaker is preferable for AV block (**Figure 13**).

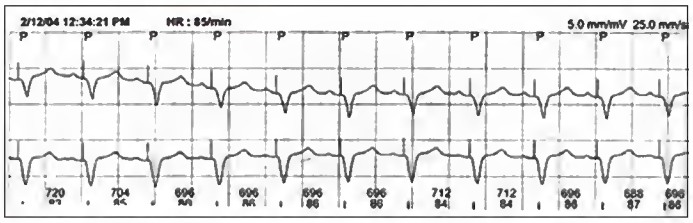

Figure 13: AV sequential pacing (atrial sensed, ventricle paced).

12.24 Tachyarrhythmias

Amit Vora

INTRODUCTION

The origin and spread of cardiac electric activity is the function of specialised cells forming the natural pacemaker sites and conduction system within the cardiac muscle. Normally, the electrical impulse is generated at the sinus node at a rate ranging from 60 to 100 per minute and propagates to activate both atria and further reach the ventricles via the atrioventricular (AV) node and His-Purkinje system. By convention any heart rate beyond 100 per minute would be defined as tachycardia. Tachycardia can be classified as shown in **Figure 1**.

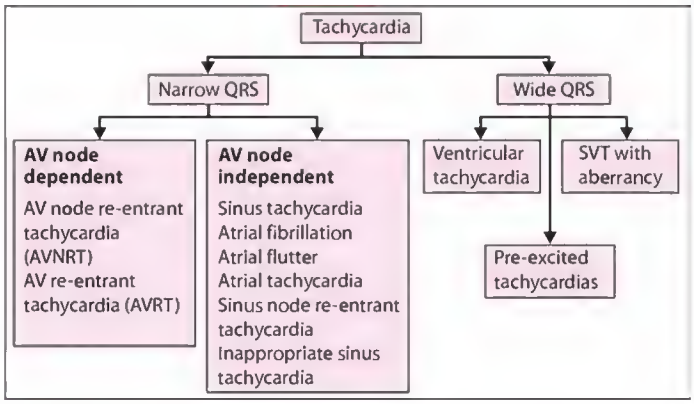

Figure 1: Classification of tachyarrhythmias.

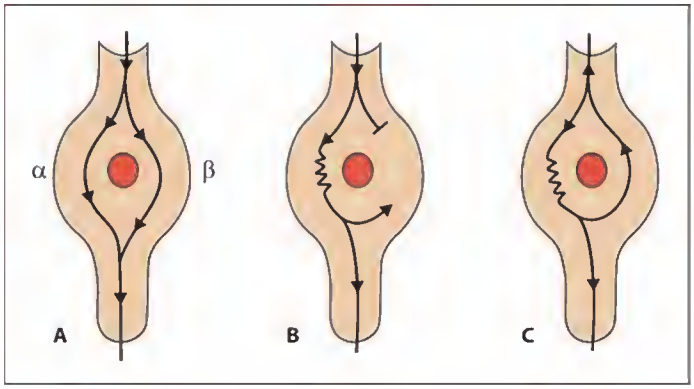
MECHANISMS OF TACHYARRHYTHMIAS

Disorders of Impulse Formation

Automaticity

Under certain conditions like ischaemia and electrolyte imbalance, the resting membrane potential of cardiac muscle cells may become less negative. This can give rise to automaticity, i.e. spontaneous phase IV depolarisations. This has been implicated in certain arrhythmias like some types of atrial tachycardia (e.g. digitalis-induced), and accelerated junctional rhythm.

Triggered activity



Triggered activity is initiated by after-depolarisations, which are oscillations in the membrane potential initiated by the preceding action potential. These may be early after-depolarisations, i.e. occurring in phase 2 or 3 of the action potential, or delayed after-depolarisations, i.e. occurring after repolarisation is complete. Early after-depolarisations have been implicated in tachycardias in congenital and acquired forms of the long QT syndrome. Delayed after-depolarisations are implicated in some digitalis-induced arrhythmias, right ventricular outflow tract tachycardia related to exercise, etc.

Disorders of Impulse Conduction

Re-entry

Under specific circumstances, the cardiac impulse may detour from its destined path and return to a previously depolarised area to re-excite it (re-enter) if it has recovered excitability. If this sequence is repetitive, a tachycardia may then result.

Re-entry requires the presence of two conducting pathways, with slow conduction in one pathway and a unidirectional block in the other, as shown in the **Figure 2**.

Figures 2A to C: (A) The electrical impulse travels through two pathways, i.e. α and β. These meet at a common exit point. (B) Since the two pathways have different refractory periods, an extra stimulus is blocked in β pathway but can conduct slowly over α pathway, and' re-enter' the β pathway retrograde. (C) This results in sustained circus movement. Tachycardia.

SUPRAVENTRICULAR TACHYCARDIA

Sinus Tachycardia

The common causes are fever, anxiety, hypovolaemia, hyperthyroidism, infection and pulmonary thromboembolism. Upright P waves in the electrocardiography (ECG) leads II, III, aVF; inverted P in aVF and transition from biphasic to upright waveform in the precordial leads help to distinguish from atrial tachycardias. Carotid sinus massage to slow the sinus rate may help to distinguish the P wave morphology. Sinus tachycardia is a marker of underlying pathophysiologic state and by itself does not warrant any treatment.

Unusually, there is persistent 'inappropriate' sinus tachycardia in the absence of any underlying cause. Paroxysmal onset of rapid sinus rates could be sinus node re-entrant tachycardia. Reassurance and beta-blockers are generally effective and only rarely does one resort to radiofrequency (RF) ablation with only a modest success.

Atrial Tachycardia

The ectopic P wave in atrial tachycardia (AT) most often precedes the QRS complex (**Figure 3**) and its morphology can suggest the site of origin of the tachycardia. Atrial tachycardia could be paroxysmal, the most common type recognised by its sudden onset and offset. The rare type is incessant or permanent. The mechanism for paroxysmal atrial tachycardia can be re-entry or triggered activity and in case of more gradual onset and offset, abnormal automaticity. While can arise from any site, there are certain common sites of origin. These are the right

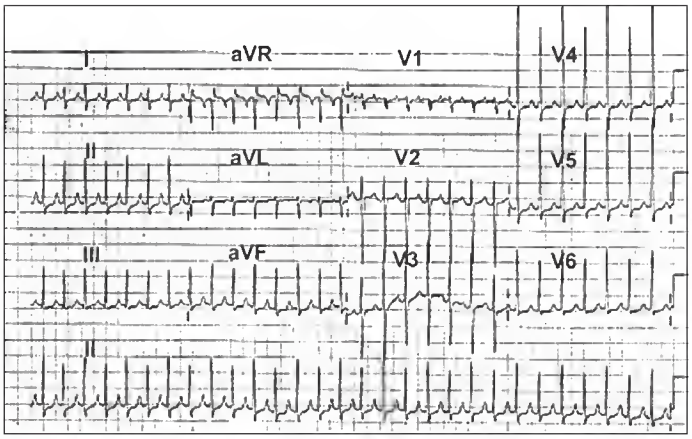


Figure 3: Atrial tachycardia. The dented T wave suggests ectopic P wave fused with it.

atrial appendage, crista terminalis, area around the coronary sinus ostium and area around the pulmonary vein orifices. In the presence of valvular disease and enlarged atria, multiple sites of origin may be present.

Incessant atrial tachycardia is a serious arrhythmia as it can result in left ventricular dysfunction, described as 'tachycardiomyopathy'. This ventricular dilatation and dysfunction is entirely reversible if sinus rhythm is restored. Amiodarone, propafenone, flecainide and quinidine are the drugs that act on the atrium and help terminate as well as prevent atrial tachycardia. For drug-resistant atrial tachycardia, ventricular rate can be controlled by drugs that depress AV nodal conduction, viz. verapamil, diltiazem, beta-blockers and digoxin. The preferred therapy for sustained or recurrent atrial tachycardia is RF ablation with a success rate of 90%. This procedure eliminates the site of origin and achieves permanent cure.

Atrial Flutter

The underlying mechanism is a macro-re-entrant circuit within the atrium. There are many varieties of atrial flutter; Type 1 or common or typical type is identified by inverted flutter waves in the inferior leads with characteristic 'saw-tooth' appearance (**Figure 4**). In these patients, there is abnormal slow conduction of electrical impulse in the isthmus region (area between the tricuspid annulus, inferior vena cava and coronary sinus). This leads to macro-re-entrant circuit within the right atrium in a counter-clockwise direction, i.e. superiorly along the septum and

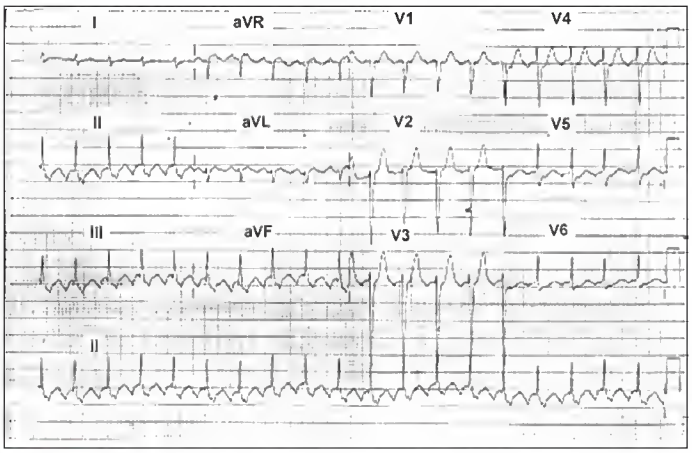

Figure 4: Typical atrial flutter with 2:1 AV conduction. Note the classic saw-tooth pattern of the flutter waves.

downwards from the sino-atrial node region along the crista towards the isthmus. Type 2 or atypical atrial flutter is due to a reverse circuit, i.e. clockwise with positive flutter waves in inferior leads. Left atrial flutter, often seen with mitral valve disease is rapid and atypical in its morphologic characteristics. The ventricular rate during atrial flutter is usually slower than the atrial rate, due to physiologic block of some of the atrial impulses in the AV node. The drug treatment is similar to that of AT. Electrical cardioversion with 100 to 200 J may be necessary in patients with haemodynamic compromise or uncontrolled rapid ventricular rates. Both the typical and atypical right atrial flutter can be cured by RF ablation along the isthmus. The left atrial flutter or multiple re-entrant circuits are less amenable to RF ablation.

Atrial Fibrillation

Multiple, simultaneous re-entrant circuits and rotor waves in both atria are responsible for initiating and sustaining atrial fibrillation (AF). The common causes are valvular heart disease, corpulmonale, cardiomyopathy, hyperthyroidism and atrial septal defect. Occasionally, lone AF is seen without any obvious cause. The atria are activated 400 to 500 times a minute. The fibrillatory waves may be fine or coarse on the ECG (**Figure 5**). Like atrial flutter, the ventricular rate in AF depends upon the AV nodal conduction. The pulse is irregular in rhythm and volume. Currently, AF is classified as new onset, paroxysmal (spontaneously terminating), persistent (can be terminated pharmacologically or by cardioversion) and permanent (cannot be terminated).

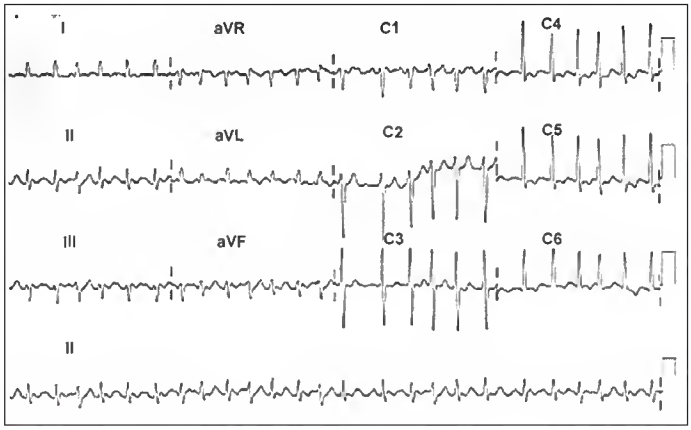

Figure 5: Atrial fibrillation with rapid ventricular rate.

The pharmacologic treatment involves ventricular rate control or restoring and maintaining sinus rhythm. Rate control approach is reasonable for first episode of AF, left atrial size greater than 6 cm, advanced age, pulmonary/thyroid disease and haemodynamically unrelieved valvular heart disease.

Importantly, the underlying cardiac or pulmonary cause needs to be tackled. A combination of amiodarone/sotalol and electrical cardioversion (200 to 360 J) is often effective. Rarely, drug-resistant AF with rapid ventricular rate resulting in tachycardiomyopathy can be effectively treated by RF ablation of the AV node and a permanent pacemaker implantation to provide a steady, controlled ventricular rate. Surgical maze procedure especially for patients undergoing valve surgery can be attempted to restore sinus rhythm. RF ablation as a cure in patients with paroxysmal AF and no structural heart disease has become a possibility in experienced centres.

Various patients with AF require anticoagulation according to their risk profile (**Table 1**).

Table 1: Guidelines for Anticoagulation in Patients with Atrial Fibrillation

Risk	Risk Factors	Anticoagulation
High risk	Prior stroke, TIA, embolism Rheumatic valvular heart disease Prosthetic valve	Definitely indicated if any of the risk factors are present
Moderate risk	Age >75 years Hypertension Diabetes mellitus LVEF ≥ 35%	Indicated if more than one risk factor are present
Low risk	Age 65-75 years Female gender Coronary artery disease Thyrotoxicosis	Not indicated

TIA = Transient ischaemic attack; LVEF= Left ventricular ejection fraction.

Atrioventricular Nodal Re-Entrant Tachycardia

This is the commonest type of paroxysmal supraventricular tachycardia (SVT). The age of onset is usually between 30 and 50 years and it is more common in women. The basis for this arrhythmia is dual pathways around the AV node, referred as slow and fast pathways. In these patients, an APB can activate the re-entrant circuit producing the typical slow-fast AV nodal re-entrant tachycardia (AVNRT) (**Figure 6**). Due to simultaneous activation of the atria and ventricles during AVNRT, the right atrial contraction produces back pressure on the jugular veins, described as the frog sign. Acute termination may be spontaneous or by vagal manoeuvres like carotid sinus massage, but often intravenous medication (diltiazem, verapamil or adenosine) is needed. For recurrent episodes the preferred drugs are verapamil, diltiazem or beta-blockers. However, the treatment of choice is RF ablation. The slow pathway is selectively ablated leaving the normal fast pathway conduction intact. With RF ablation, 99% of patients with AVNRT can be permanently and safely cured.

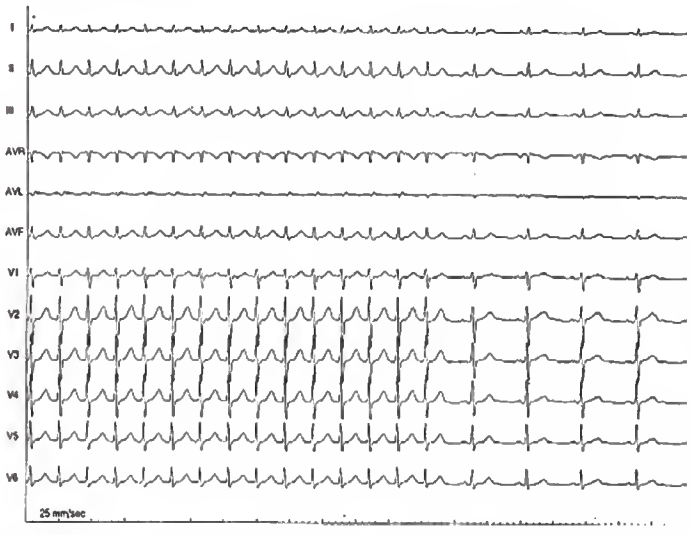

Figure 6: A 12-lead ECG of AVNRT. The P wave is buried within the QRS and only distorting the terminal portion as suggested by a pseudo S wave in inferior leads and pseudo R in lead V_1.

Atrioventricular Re-Entrant Tachycardia

AV re-entrant tachycardia (AVRT) is mediated by an accessory pathway which joins the atrium and ventricle (other than the AVN) and is a breach in continuity of the fibrous ring of the AV annulus. This has been described as the Kent bundle and responsible for the Wolff-Parkinson-White (WPW) syndrome and AVRT.

Accessory pathways are present in 0.2% of people. It is estimated that 50% of these people will experience tachycardia at some stage in life, generally starting in the second or third decade. This amounts to approximately 2 million patients in India. These accessory pathways may manifest in the ECG if they are capable of conducting antegrade. Such overt pathways lead to WPW syndrome. Majority of these pathways are 'concealed', since they can conduct only retrograde (from ventricle to atrium) and hence cannot be diagnosed from the sinus rhythm ECG. In either case, these pathways can give rise to macro-re-entrant tachycardias. Most of these tachycardias are 'orthodromic', the impulse going down the AV node and up the accessory pathway. The ECG at such time would show a narrow QRS tachycardia (**Figure 7**). The accessory pathways may conduct antegrade during tachycardia resulting in a wide QRS (pre-excited) tachycardia. This is described as anti-dromic tachycardia. AF in these patients can potentially be lethal as the ventricular rate can be faster than 300 per minute leading to ventricular fibrillation. Orthodromic tachycardias can be terminated similar to AVNRT. For pre-excited tachycardias, intravenous flecainide, amiodarone or electrical cardioversion are the alternatives. RF ablation is again the preferred choice as the success rate is as high as 98%. It is almost a mandatory recommendation for patients presenting with AF and rapid conduction over the accessory pathway.

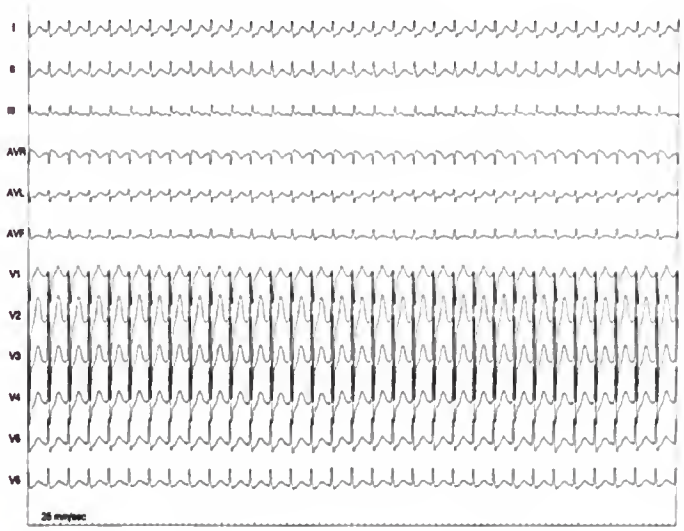

Figure 7: Narrow QRS, regular tachycardia. RP shorter than PR with ST depression in leads I and aVL and discordant ST deviation in leads aVL and aVR suggestive of orthodromic AVRT.

Various form of paroxysmal SVTs can be differentiated depending upon the RP interval and concordance of ST segment, as summarised in **Figure 8**.

Usually, SVT presents on ECG as a narrow QRS tachycardia. Occasionally, there is a wide QRS tachycardia due to bundle branch block during SVT. This can be differentiated from VT as shown subsequently (**Table 2**).

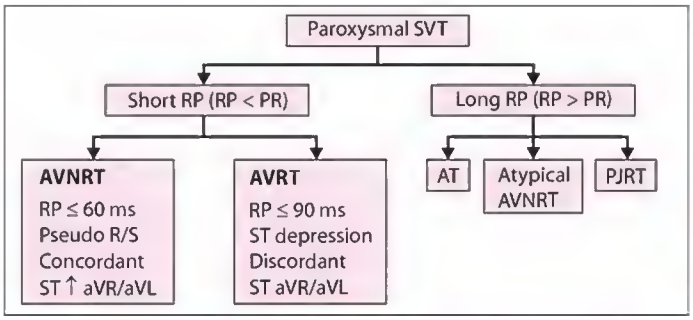

Figure 8: ECG identification of types of paroxysmal supraventricular tachycardia.

Table 2: VT *versus* SVT with Aberrancy

Ventricular tachycardia	SVT with Aberrancy
VA dissociation and fusion – present 50%	Typical bundle branch block pattern
Prolonged intrinsicoid deflection	Concordance of QRS axis and BBB morphology
Discordance between QRS axis and BBB morphology (LBBB with RAD)	
Known structural heart disease	

Simple clinical tools like carotid sinus massage can help in diagnosis of tachycardia as shown in **Table 3**.

Table 3: Effect of Carotid Sinus Massage on Tachycardia

Tachycardia	Effect
Paroxysmal supraventricular tachycardia—AVNRT or AVRT	Termination of tachycardia
AT/A flutter/A fibrillation	AV block; arrhythmia continues, more P'/F/f waves than QRS
Ventricular tachycardia	Tachycardia continues, VA block
Pre-excited tachycardia	Termination

Summary of management of paroxysmal supraventricular tachycardia is given in **Table 4**.

Table 4: Management of Paroxysmal Supraventricular tachycardia

Acute termination
- Vagal manoeuvres
- Intravenous Adenosine: 6 to 12 mg or 0.1 to 0.3 mg/kg (rapid bolus)
- Intravenous Verapamil/diltiazem: 5 to 15 mg or 0.1 to 0.2 mg/kg (over 1 to 2 min)

Long-term treatment
- Verapamil
- Beta-blockers
- Flecainide/Propafenone

Permanent cure
- Radiofrequency ablation

VENTRICULAR TACHYARRHYTHMIAS

Vast majority (90%) of the wide QRS tachycardia are ventricular tachycardia (VT). Identifying VT as either being mono-morphic or polymorphic is crucial to determine the prognosis and treatment. From a clinician's view-point, the next important step in VT management is to identify the underlying structural/electrical heart disease as shown in **Table 5**.

Monomorphic VT

This is usually regular with the rate varying from 150 min to 300/min (**Figure 9**). The QRS morphology is similar from complex to complex in a given lead in monomorphic VT. Constant variation in morphology of QRS is described as polymorphic. The monomorphic nature must be characterised on a 12-lead ECG, since on a single monitor lead a polymorphic VT may falsely appear monomorphic.

Table 5: Ventricular Arrhythmias: Clinical Scenario

Structural heart disease
- Ischaemic heart disease
- Dilated cardiomyopathy
- Hypertrophic cardiomyopathy
- Arrhythmogenic right ventricular cardiomyopathy

Idiopathic VT (in normal heart)
- Right ventricular outflow tract VT
- Fascicular VT
- Others

Primarily electrical disease
- Long QT and torsades
- Brugada syndrome
- Idiopathic VF

Specific VT
- Bundle branch re-entrant VT
- Bi-directional VT

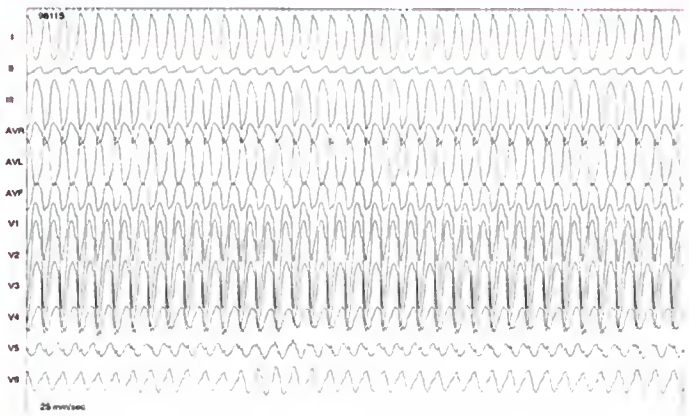

Figure 9: Rapid, monomorphic ventricular tachycardia.

Infarct Scar

This is the commonest setting of monomorphic VT. Re-entry circuits form in the islands of viable myocardium embedded in fibrous tissue. Commonly, such VT is seen to start a few months to years after a myocardial infarction (MI). The patient may be very stable during VT or there may be haemodynamic collapse, depending on the underlying ventricular function. Rarely is acute ischaemia a precipitating factor. Emergency management requires intravenous procainamide or amiodarone, since lignocaine is effective in less than 30% of these patients. If haemodynamically unstable, electrical cardioversion with 100-360 J is advisable. Implantable cardioverter defibrillator (ICD) is the treatment of choice in patients with past ischaemic heart disease and VT. ICD is the device like pacemakers implanted subcutaneously under the clavicle with electrodes in the right atrium and ventricle. The device detects VT/VF and delivers either overdrive pacing or shock and restores sinus rhythm (**Figure 10**). Beta-blockers often in combination with amiodarone are used when ICD is not feasible. Alternatively, sotalol can be tried.

Cardiomyopathy

Both dilated cardiomyopathy as well as hypertrophic cardiomyopathy may cause monomorphic VT. Re-entry or

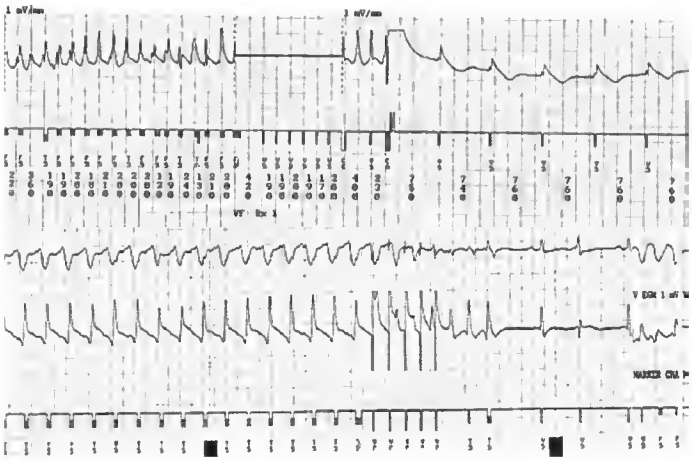

Figure 10: Electrograms from the implantable cardioverter defibrillator. Top panel shows detection of VF and successful treatment with shock. Bottom panel shows successful overdrive pacing to terminate VT.

automaticity around areas of fibrosis is the usual cause. The management is essentially similar to that for infarct scar VT.

Treatment Plan for Sustained Monomorphic Ventricular Tachyarrhythmias

Anti-arrhythmic drugs:-

Intravenous procainamide 10 to 14 mg/kg bolus (< 50 mg/min) and 1 to 4 mg/min as maintenance;

Intravenous amiodarone 150 mg over 10 minutes, 1 mg/min for 6 hours and then 0.5 mg/min over 18 hours

Over-drive pacing

Electric cardioversion

Arrhythmogenic Right Ventricular Cardiomyopathy

Young adults presenting with VT showing a left bundle branch block like morphology. It is often misdiagnosed as idiopathic VT. In 30% of cases, it is familial. The ECG in sinus rhythm is usually abnormal, showing T inversions and sometimes the classical epsilon wave in lead V_1 (**Figure 11**). The right ventricular disease may be subtle and hence missed at echocardiography. A signal averaged ECG helps in identifying abnormal late potentials and magnetic resonance imaging is often diagnostic with right ventricular wall thinning and fatty replacement of myocardium. Treatment options are sotalol, amiodarone, beta-blockers and

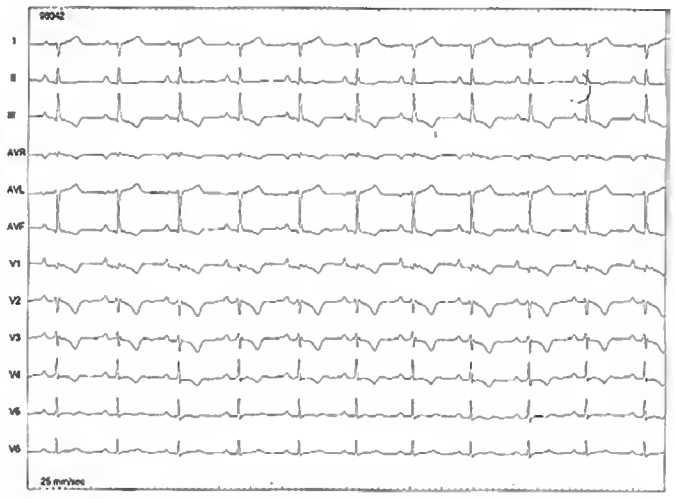

Figure 11: Twelve-lead ECG of a patient with ARVC, showing classic epsilon waves in lead V1 and T wave inversion in precordial leads.

verapamil. With life-threatening VT, an implantable defibrillator is advisable.

Idiopathic Ventricular Tachycardia

Often VT is seen in healthy young adults who have no structural heart disease. Two patterns are common, one arising from the right ventricular outflow tract and the other from the left ventricular posterior fascicle. The right ventricular outflow tract VT shows a LBBB-like morphology and a vertical QRS axis and is either repetitive, ill-sustained or could be sustained (**Figure 12**). It is exercise-induced and responds well to beta-blockers. The idiopathic left VT shows a RBBB-like morphology with left or north-west QRS axis deviation (**Figure 13**). It is relatively narrow as it arises from the left posterior fascicle. Acute termination with adenosine or verapamil is possible. Hence, idiopathic left VT is often misdiagnosed as SVT. Both the idiopathic VTs have a natural history very similar to SVTs (benign outcome) and can be permanently cured by RF ablation. There are many other locations of idiopathic VT now described, especially the left ventricular outflow tract VT.

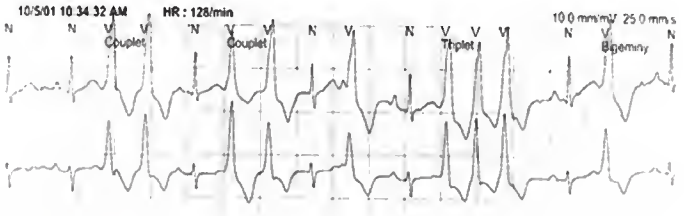

Figure 12: Right ventricular outflow tract (RVOT) VT. Holter strip show repetitive form and the bottom 12-lead ECG show sustained VT.

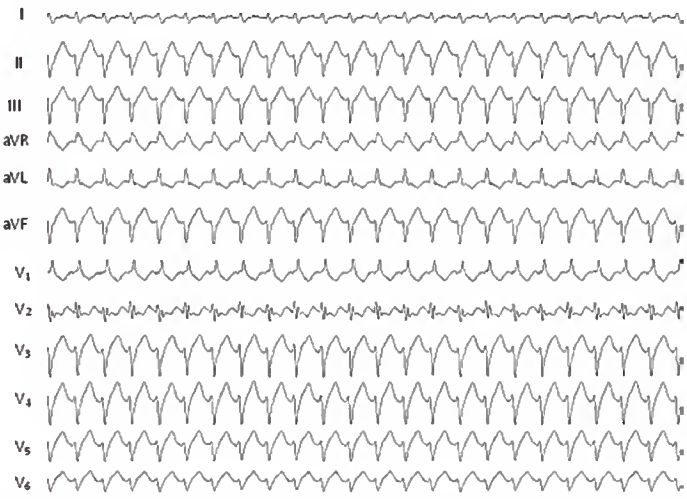

Figure 13: Twelve-lead ECG of idiopathic left ventricular tachycardia (ILVT). Note the relatively narrow QRS with RBBB-like morphology and left-axis deviation.

Polymorphic VT

This is a life-threatening arrhythmia since it can degenerate into ventricular fibrillation (VF). The underlying abnormalities include long QT syndrome and acute ischaemia.

Long QT Syndrome

This could be either congenital or acquired. The congenital long QT syndrome is a genetic defect, whereas, the acquired form is due to hypokalaemia or potassium channel blocking cardiac or non-cardiac drugs. The characteristic arrhythmia, *torsades de pointes* (**Figure 14**) is triggered by a VPB which occurs while

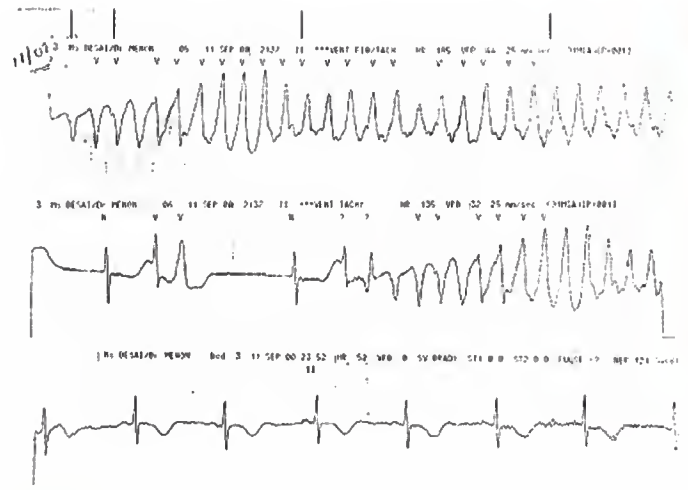

Figure 14: Torsades de pointes. Polymorphic VT in a patient with acquired long QT.

the ventricles are still depolarising. The torsades is often self-terminating, but is fatal in the event it is sustained. The commonest presentation is unexplained syncope and the ECG must be carefully assessed for QT prolongation. Beta-blockers with pacemaker are the treatment of choice for the congenital long QT syndrome. Left cervical stellate ganglionectomy and ICD implantation are other options for the resistant variety. Removal of the offending agent and correcting electrolyte imbalance is the mainstay for the acquired long QT variety. Intravenous lignocaine, phenytoin and isoprenaline are known to shorten the QT and may be useful.

Acute ischaemia

Unstable angina or MI can be complicated by polymorphic VT. Acute termination can be achieved with defibrillation (300-360 J) or intravenous lignocaine 2 mg/kg. Further management entails aggressive efforts to alleviate ischaemia. Acute coronary syndrome can often precipitate an electrical storm defined as two or more sustained VT requiring electric cardioversion within 24 hours. The principles of managing electrical storm are outlined in **Table 6**.

VENTRICULAR FIBRILLATION

The commonest setting for ventricular fibrillation (VF) is MI and structural heart disease with left ventricular systolic dysfunction. In acute MI the VF occurrence is classified as primary and secondary.

Table 6: Principles of Managing Electrical Storm

Anti-ischaemic measures
NTG, heparin, thrombolysis, revascularisation
Anti-adrenergic drugs
Heavy sedation
Beta-blockers
Anti-arrhythmic drugs
Lignocaine—no role as primary prophylaxis
Beta-blockers
Adjuvants
Intravenous magnesium
Electrical cardioversion

Primary ventricular fibrillation

It occurs within the first 24 hours of MI. Severe electrical instability triggered by ischaemia is the mechanism. If terminated by prompt defibrillation, the long-term prognosis is similar to that of uncomplicated infarction. Unless further arrhythmias occur, anti-arrhythmic drugs (except beta-blockers) are not necessary.

Secondary ventricular fibrillation

This is seen after established infarction, usually after 24 hours. Patients who develop secondary VF usually have large infarction with severe left ventricular dysfunction. Therefore, the prognosis is grim. If defibrillation is successful, lignocaine or amiodarone are advisable. Urgent efforts to stabilise and improve the ventricular function are warranted.

The last decade has seen the potential of the life-saving ICD therapy. It is now established to be beneficial in all patients with VT and abnormal hearts. Its role has been suggested for primary prophylaxis in high-risk individuals, i.e. post-MI, ejection fraction less than 0.30, wide QRS (> 120 ms), NYHA II, non-sustained VT, T wave alternant or abnormal heart rate variability and electrophysiology study inducing sustained VT. Radiofrequency ablation is used only as a salvage procedure when there are recurrent VTs requiring multiple ICD shocks.

12.25 Sudden Cardiac Death

Ashish K Thakur

DEFINITION

Sudden cardiac death (SCD) and sudden cardiac arrest (SCA) refer to a catastrophic symptom complex due to sudden cessation of cardiac output and haemodynamic collapse leading to death or non-fatal outcomes. Over the years, SCD has been traditionally used as the term encompassing all forms of this syndrome but successful resuscitation or spontaneous reversion to a cardiac rhythm compatible with circulation and life would now be classified as SCD survivor or SCA rather than SCD. The 2006 American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) defines SCA as 'sudden cessation of cardiac activity so that the victim becomes unresponsive, with no normal breathing and no signs of circulation'. If corrective measures are not taken rapidly, this condition progresses to sudden death. Cardiac arrest should be used to signify an event as described above, that is reversed, usually by CPR and/or defibrillation or cardioversion, or cardiac pacing. Sudden cardiac death should not be used to describe events that are not fatal.

EPIDEMIOLOGY

Over million people die every year of SCD across the world. Accurate data for SCD as a cause of death are difficult to obtain, and are certainly unavailable from Indian subcontinent. However, data from United States suggests up to 15 % of total deaths annually could actually be due to SCD. SCD is twice as more common in men than women and its incidence of SCD rises with age, coronary artery disease (CAD), ventricular dysfunction and structural heart disease. Majority (up to two-thirds) of SCD/SCA occurs in the setting of CAD where it may be the initial mode of presentation in about 20% patients. About half of all mortality in acute myocardial infarction could be due to SCD, occurring before hospital admission. Various forms of structural heart diseases are known to increase SCD risk and some continue to be identified.

AETIOPATHOGENESIS

The most common mechanism of SCD is haemodynamic collapse due to ventricular fibrillation (VF) (**Figure 1**) or sustained ventricular tachycardia (VT) (**Figure 2**). The initial symptoms leading up to the event are generally very infrequent or inconspicuous, unless in the setting of acute coronary syndrome (ACS) with typical cardiac sounding chest pain. The cardiac arrest leads to quick unconsciousness and collapse due to cerebral hypoperfusion, respiratory arrest and depending on the specific

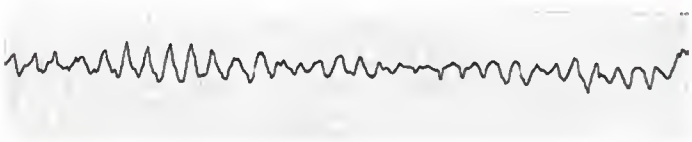

Figure 1: ECG strip showing ventricular fibrillation.

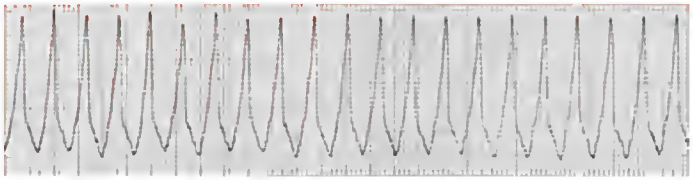

Figure 2: ECG strip showing ventricular tachycardia.

clinical scenario, death might follow if resuscitation is not successful or is not attempted or unavailable. As mentioned, CAD causes up to two-thirds of SCD which occurs most commonly in the setting of ACS than stable angina patients. Various causes of SCD are listed in **Table 1**. A minority (about 10%) of SCD is caused by dilated cardiomyopathy and heart failure (ventricular dysfunction), hypertrophic cardiomyopathy and other structural heart abnormalities. Arrhythmogenic right ventricular dysplasia (ARVD) is a condition associated with fibrosis of the right ventricle best diagnosed by cardiac MRI and is now an established cause of SCD.

Table 1: Causes of Sudden Cardiac Death (SCD)/Sudden Cardiac Arrest (SCA)

SCD with coronary disease
Acute coronary syndromes
Stable angina
Coronary embolism
Non-atherogenic CAD (arteritis, dissection, congenital coronary anomalies and coronary spasm)
SCD with structurally abnormal heart
Dilated cardiomyopathy
Hypertrophic cardiomyopathy
Valvular heart disease (mitral valve prolapse)
Congenital heart disease
Arrhythmogenic right ventricular dysplasia (ARVD)
Myocarditis
Cardiac tamponade
Cardiac rupture
Aortic dissection
SCD with no structural heart disease
Prolonged QT syndrome
Brugada syndrome
WPW (pre-excitation) syndrome
Catecholaminergic VT/VF
Familial SCD
Chest wall trauma (commotio cordis)
Non-cardiac causes of SCD
Pulmonary embolism
Central airway obstruction
Haemorrhagic stroke
Drowning

SCD can also occur in a structurally normal heart in about 10% cases, especially in young individuals, mainly due to genetic or acquired predisposition to electrophysiological abnormalities causing life-threatening ventricular arrhythmias. Prolonged QT

syndrome is well known to predispose to life-threatening ventricular arrhythmias (*torsades de pointes*). A minority of ventricular pre-excitation (WPW syndrome) patients could have VF due to antegrade conduction via the accessory pathway if they went into atrial fibrillation.

Brugada syndrome is known to significantly increase the risk of SCD. This condition is diagnosed by typical ECG findings (right bundle branch block and ST elevation in right precordial leads) and electrophysiological testing. Some rather fascinating and recently identified conditions with high SCD risk include catecholaminergic VT/VF (heightened sympathetic surge leading to arrhythmias). Evidence also suggests that the whole symptom complex of SCD is actually a very complex process, often triggered by various factors like stress, plaque rupture causing ACS, electrolyte abnormalities (low potassium/magnesium) and some pro-arrhythmic drugs. Identifying otherwise healthy individuals at high-risk for SCD may be very difficult. In general, traditional cardiovascular risk factors also tend to enhance the SCD risk. In addition, family history of SCD is a very important risk marker, increasing it by twice at most. Non-cardiac conditions presenting as SCD include pulmonary embolism, aspiration, drowning and other major respiratory emergencies.

PROGNOSIS

It is important to discuss this at this stage before dealing with the management aspects of this SCD/SCA. Being a life-threatening emergency, it occurs mostly out-of-hospital and is not witnessed. The risk of recurrence may be as high as 50% in 12 months time. The response time to effective resuscitation largely determines the clinical outcomes. Understandably the prognosis is much better for in-hospital SCD. It may sometimes be quite difficult to establish whether it is true SCD or 'non-cardiac SCD'.

Current evidence in the published literature indicates that about 25% to 40% of witnessed VF is likely to survive until hospital discharge. This is better if the underlying cardiac rhythm is VT, where survival may be up to 65% to 70%. However, only about 30% of the out-of-hospital SCD have successful resuscitation and eventually just about 10% survive to discharge. Many of these patients have significant neurological problems due to anoxic brain injury. The poor outcomes for out-of-hospital SCD can be predicted from factors like advanced age, prolonged resuscitation, haemodynamic support, heart failure, renal impairment, and persistent neurological dysfunction. Interestingly, majority of in-hospital deaths for SCD survivors are due to non-cardiac causes like pneumonia, sepsis, multi-organ failure and neurological problems.

MANAGEMENT

As mentioned before, the outcome following SCD depends upon numerous factors including the underlying rhythm and the rapidity of resuscitation. Management of a SCD scenario initially comprises of aggressive resuscitation as per protocols and, if successful, to find and treat any reversible factors, like coronary disease amenable to revascularisation by angioplasty or bypass surgery. This should be followed by strategies for secondary prevention (re-occurrence of SCD event). On the contrary, primary prevention strategy is to be adopted for people with high risk of SCD.

Commonly performed cardiac tests in SCD survivors include echocardiogram and coronary angiogram. Cardiac MRI and electrophysiological testing are further and highly valuable tools to rule out any structural heart disease and abnormal electrical pathways, respectively.

SECONDARY PREVENTION

Device therapy with implantable cardioverter defibrillator (ICD) is the treatment of choice for majority of SCD survivors after careful consideration. Various criteria and guidance have been proposed, and the 2006 UK National Institute of Clinical Excellence (NICE) for the use of ICD for secondary prevention is summarised in **Table 2**. It is very important to remember that the ICD itself just treats the dysrhythmia rather than preventing it. Further, some of these difficult clinical scenarios may need electrophysiological testing with a view towards ablative therapy. Patients with propensity for recurrent arrhythmias also require 'top up' medical therapy with beta-blockers or class III anti-arrhythmic agents (e.g. amiodarone). The drugs are much less efficacious and should be considered only for their adjunctive role or where ICD implantation is deemed inappropriate (much reduced life expectancy otherwise, terminal cancer, significant co-morbidities).

PRIMARY PREVENTION

This is a very interesting area due to various subsets of patients/people who may be classified as being at high-risk of having SCD Primary prevention is aimed at preventing the occurrence of first SCD event in high-risk patients. This includes careful and thorough assessment, which comprises of detailed cardiac evaluation to exclude any structural heart disease, patient and family screening where necessary and tests like echocardiogram, coronary angiogram, cardiac MRI and electrophysiological testing. Genetic tests may also be necessary to identify patients carrying the high-risk genes and they could be offered prophylactic treatment. The three most important groups for primary prevention include at-risk post-myocardial infarction patients, high-risk cardiomyopathy (including hypertrophic cardiomyopathy), and patients with Brugada syndrome, Long QT syndrome, Pre-excitation (WPW syndrome) and familial SCD. These patients, after careful assessment, should receive an ICD. The 2006 UK-NICE guidance for ICD for primary prevention of SCD is listed in **Table 3**. Adjunctive medical therapy may be necessary, as explained before.

Table 2: 2006 UK National Institute of Clinical Excellence Guidance for Implantable Cardioverter Defibrillators (ICDs) for Secondary Prevention (Defined as the Prevention of an Additional Life-Threatening Event in Survivors of Sudden Cardiac Events or in Patients with Recurrent Unstable Rhythms)

Patients who present, in the absence of a treatable cause, with one of the following:

a. Having survived a cardiac arrest due to either VT or VF.
b. Spontaneous sustained VT causing syncope or significant haemodynamic compromise.
c. Sustained VT without syncope or cardiac arrest, and who have an associated reduction in ejection fraction (LVEF of less than 35%) (no worse than class III of the New York Heart Association functional classification of heart failure).

Table 3: 2006 UK National Institute of Clinical Excellence Guidance for Implantable Cardioverter Defibrillators (ICDs) for Primary Prevention (Defined as Prevention of a First Life-Threatening Arrhythmic Event)

Patients who have:

1. A history of previous (more than 4 weeks) myocardial infarction (MI) and:
   either
   left ventricular dysfunction with an LVEF of less than 35% (no worse than class III of the New York Heart Association functional classification of heart failure)
   and
   non-sustained VT on Holter (24-hour ECG) monitoring
   and
   inducible VT on electrophysiological (EP) testing
   or
   left ventricular dysfunction with an LVEF of less than 30% (no worse than class III of the New York Heart Association functional classification of heart failure)
   and
   QRS duration of equal to or more than 120 milliseconds
2. A familial cardiac condition with a high-risk of sudden death, including long QT syndrome, hypertrophic cardiomyopathy, Brugada syndrome or arrhythmogenic right ventricular-dysplasia (ARVD), or have undergone surgical repair of congenital heart disease.

In patients with previous MI, the highest risk patients are the ones with significantly impaired ventricular systolic function with or without ventricular ectopy. The heart failure patients may or may not have ischaemic heart disease, and a subset of them benefit from prophylactic ICD implantation. A lot of these patients now receive combined device therapy comprising of cardiac re-synchronisation (for heart failure) and ICD (for SCD prevention), which is called CRT-D. In addition to device therapy, conventional secondary prevention treatment with beta-blockers and ACE-inhibitors or angiotensin receptor blockers also reduce the SCD incidence, especially in post-MI patients.

COMMUNITY

There may be many patients at high-risk of SCD but how to identify them? This issue is difficult and currently just a 'tip of the iceberg', with only a handful being diagnosed and treated successfully. With its proven benefits, many countries are putting in a lot of efforts into primary prevention of SCD and the need to identify the high-risk patient is vital to this. The various ways to do this in the community include assessment of family history, vague symptoms (many have dizzy spells, unexplained collapses), ECG screening, etc. The role of general practitioners is invaluable to suspect and refer these cases to tertiary centres. Many cases require genetic screening and there are now established clinical genetics services in many countries. Information about familial conditions predisposing to SCD is widely available on the internet, including support groups for patients and families, who need on-going counselling and specialist input.

CONCLUSIONS

SCD is often a fatal clinical condition with a dramatic presentation, often associated with CRD. Many conditions with structural heart disease predispose to SCD. There are now many known conditions with normal structural heart and high-risk for SCD/SCA due to electrical abnormalities. Over the years, the prognosis for in-hospital SCD has improved but it still remains very poor for out of hospital events. Advances in diagnostic technologies like electrophysiology, cardiac MRI and genetic testing have helped to find out the susceptible patients. Treatment of SCD is mainly based on device therapy with ICD for secondary/primary prevention along with adjunctive drug and/or electrophysiological options where necessary.

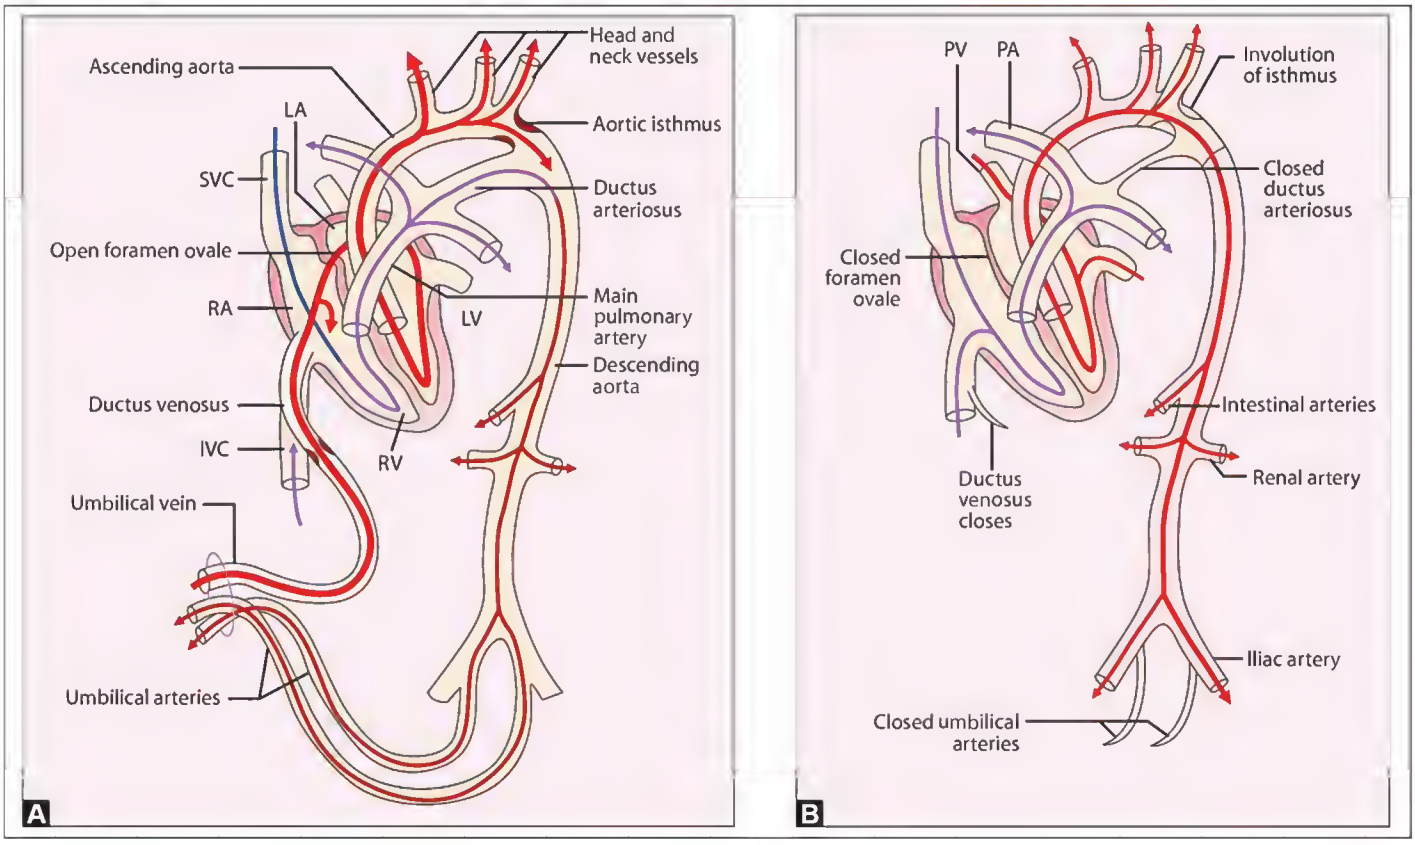
12.26 Congenital Heart Disease

Sunita Maheshwari

The estimated incidence of congenital heart disease (CHD) is 1%, i.e. 1 out of 100 children have some form of CHD, either major or minor. In India, it is possible that the incidence may be higher due to deficiency of folic acid, consanguinity, etc. Pre-conceptual folic acid (i.e. taken 3 months before pregnancy) has been documented to reduce the incidence of heart disease, so all women planning a pregnancy should be advised to start folic acid.

The majority of congenital heart diseases (CHDs) occur as isolated defects and are not associated with other diseases. However, these can also be a part of various genetic and chromosomal syndromes such as Down's syndrome (AV canal), Turner's syndrome (coarctation), Marfan's syndrome (aortic root dilation, mitral valve prolapse), Noonan's syndrome (pulmonary stenosis), and DiGeorge's syndrome (tetralogy of Fallot and other conotruncal anomalies).



No known cause can be identified for most congenital heart defects. Drugs such as retinoic acid for acne, alcohol, and infections (such as rubella) during pregnancy can contribute to some congenital heart problems.

The clinical diagnosis of cardiac lesions in children requires not just clinical skills but a high index of suspicion and a systematic diagnostic approach.

As several lesions are now detected early, the main questions are whether to intervene or not and if yes, then when? This chapter will focus on some key issues, e.g. operability and clinical diagnosis with emphasis on some of the major lesions.

THE FOETAL CIRCULATION

Understanding the foetal circulation helps clarify how some forms of CHD occur (**Figures 1A and B**). The foetus has only a

Figures 1A and B: Changes in the circulation at birth. (A) In the foetus, oxygenated blood comes through the umbilical vein where it enters the inferior vena cava (IVC) via the ductus venosus (red). The oxygenated blood streams from the right atrium (RA) through the open foramen ovale to the left atrium (LA) and via the left ventricle (LV) into the aorta. Venous blood from the superior vena cava (SVC) (blue) crosses under the main blood stream into the RA and then, partly mixed with oxygenated blood (purple), into the right ventricle (RV) and pulmonary artery (PA). The pulmonary vasculature (PV) has a high resistance and so little blood passes to the lungs; most blood passes through the ductus arteriosus to the descending aorta. The aortic isthmus is a constriction in the aorta that lies in the aortic arch before the junction with the ductus arteriosus and limits the flow of oxygen-rich blood to the descending aorta. This configuration means that less oxygen-rich blood is supplied to organ systems that take up their function mainly after birth, e.g. the kidneys and intestinal tract. (B) At birth, the lungs expand with air and PV resistance falls, so that blood now flows to the lungs and back to the LA. The left atrial pressure rises above right atrial pressure and the flap valve of the foramen ovale closes. The umbilical arteries and the ductus venosus close. In the next few days, the ductus arteriosus closes under the influence of hormonal changes (particularly prostaglandins) and the aortic isthmus expands.

small flow of blood through the lungs, as it does not breathe in utero. The foetal circulation allows oxygenated blood from the placenta to pass directly to the left-side of the heart through the foramen ovale without having to flow through the lungs.

Congenital defects may arise if the changes from foetal circulation to the extra uterine circulation are not properly completed. Atrial septal defects (ASDs) occur at the site of the foramen ovale. A patent ductus arteriosus may remain if it fails to close after birth. Failure of the aorta to develop at the point of the aortic isthmus and where the ductus arteriosus attaches can lead to narrowing or coarctation of the aorta (COA).

In foetal development, the heart develops as a single tube which folds back on itself and then divides into two separate circulations. Failure of septation can lead to some forms of ASDs and ventricular septal defects (VSDs). Failure of alignment of the great vessels with the ventricles contributes to transposition of the great arteries, tetralogy of Fallot and truncus arteriosus.

ACYANOTIC HEART DISEASES

Atrial Septal Defect

Atrial septal defect (ASD) is one of the most common congenital heart defect and occurs twice as frequently in females. Frequently missed in childhood, this lesion causes problems of pulmonary hypertension (PH) after adulthood is reached. ASD, typically, is symptomatic in childhood poor weight gain, frequent respiratory infections and rarely congestive heart failure (CHF) have been ascribed to it. In general, however if a child is in cardiac failure and the diagnosis is an ASD, a detailed evaluation for some other anomaly (e.g. partial or total anomalous pulmonary venous return), mitral involvement valve should be performed.

Types of atrial septal defect

Four types of ASDs or interatrial communications exist: ostium primum, ostium secundum, sinus venosus and coronary sinus defects (**Figures 2A and B**). Most are ostium secundum defects involving the fossa ovalis that in utero was the foramen ovale. Ostium primum defects result from a defect in atrioventricular septum and are associated with cleft mitral valve.

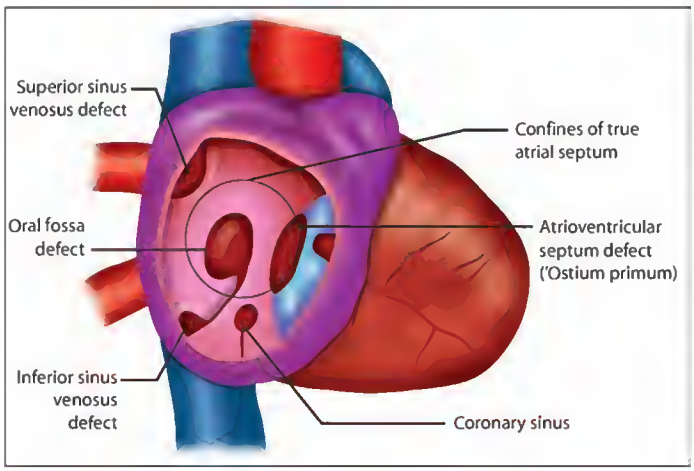


Figure 2A: Various types of atrial septal defects.

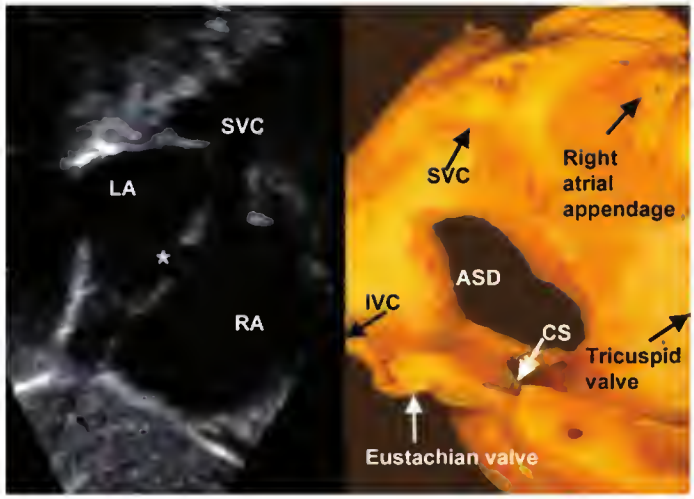

Figure 2B: Morphology of atrial septal defect (ASD).

ASD = Atrial septal defect; S = Coronory sinus; IVC = Inferior vena cava; SVC = Superior vena cava; RA = Rightatrium; LA = Left atrium.

Clinical evaluation

A wide split second heart sound is present. The ECG invariably shows some variant of the rsR' pattern in lead V1, consistent with right ventricular volume overload. In sinus venosus defects, a superior P wave axis occurs. Echocardiography-transthoracic or in doubtful cases, transoesophageal echo, can confirm the diagnosis (**Figure 3**). It demonstrates the location of the ASD-primum, secundum or sinus venosus as well as right heart volume overload and a non-invasive assessment of pulmonary artery pressure (PAP).

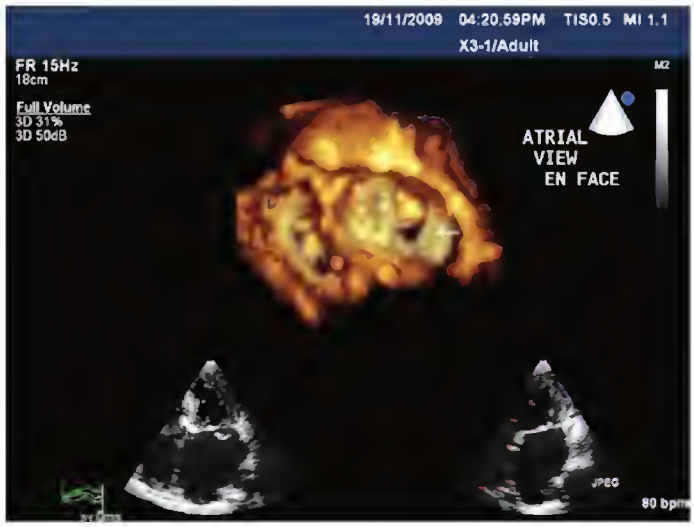

Figure 3: A three-dimensional echocardiographic en face view of atrial septal defect.

Management

As a result of increased flow into the pulmonary circulation, there is right ventricular volume load and a gradual increase in pulmonary vascular damage and resistance, which typically occurs in the 2nd and 3rd decade of life. Although the right ventricular volume overload is well-tolerated for many years there is eventual RV failure. Additionally, PH has been noted in 13% of Indian patients less than 10 years of age. Based on this data, and to avoid the deleterious effect of longer periods of RV volume overload, the optimal age for closure of ASD is around 4 to 5 years of age.

ASD can either be closed surgically by an open-heart procedure or non-surgically in the cardiac catheterisation laboratory using devices. An ostium secundum ASD with septal rim on either side is amenable to device closure (**Figure 4**). However, at present, sinus venosus and ostium primum defects need

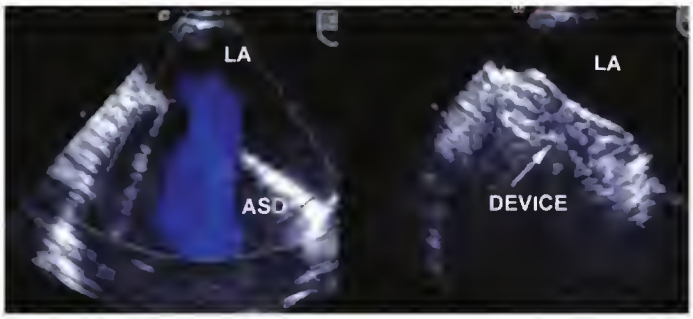

Figure 4: The left image is a transoesophageal echocardiogram of ostium secundum ASD with colour flow before device closure, whereas the right-side shows post-release of an Amplatzer device.

surgery. Now-a-days, minimal access surgery to avoid a long thoracotomy scar can also be performed via a short sternal incision or a lateral thoracotomy.

Ventricular Septal Defects

VSDs are among the commonest cardiac lesions in children. In the classification by Soto *et al*, the ventricular septum is considered to have four components: an inlet septum separating the tricuspid and mitral valves; a trabecular septum, which extends from the attachments of the tricuspid leaflets outward to the apex; the smooth-walled outlet or infundibular septum; and the membranous septum (**Figures 5A and B**). Physiologically, these are classified as large (PAP equals left ventricular pressure), moderate (PAP < LV pressure) and small (normal pulmonary artery pressures). Symptoms and natural history, to a large extent, depend on the pulmonary vascular resistance (PVR).

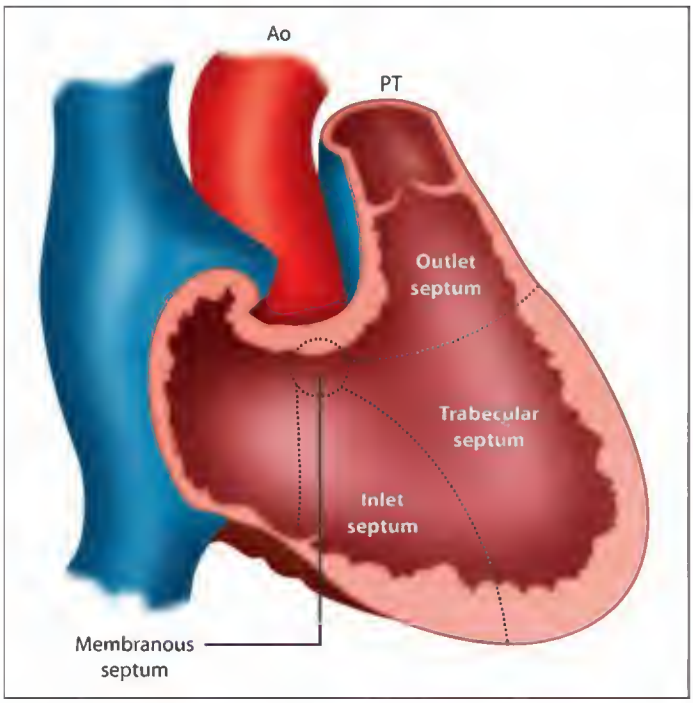

Figure 5A: Four components of the ventricular septum.

Ao = Aorta; PT=Pulmonary trunk.

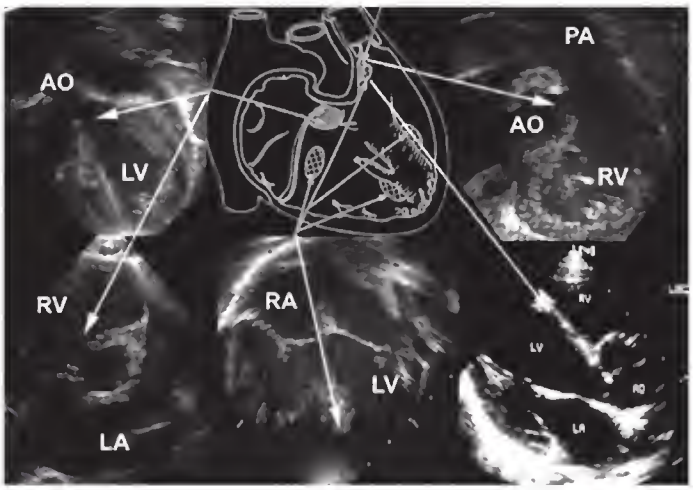

Figure 5B: Montage of the different types of ventricular septal defects. The central diagram outlines the location of the various types of defects as seen from the right ventricle. The two left images show a perimembranous ventricular septal defect. The bottom middle echocardiogram is a muscular apical defect. The upper right image is a right anterior oblique view in a doubly committed ventricular septal defect. The lower right is a short-axis view showing an outlet ventricular septal defect with prolapse of the right coronary cusp.

AO=Aorta; LV=Left ventricle; PA=Pulmonary artery; RA=Right atrium; RV=Right ventricle.

Congenital VSD occurs as a result of incomplete separation of ventricles. Embryologically, the interventricular septum has a membranous and a muscular portion, and the latter is further divided into inflow, trabecular and outflow portions. Most congenital defects are perimembranous, i.e. at junction of membranous and muscular portion.

Large VSD, severe pulmonary hypertension and low PVR

These VSDs, initially present with tachypnoea, sweating due to increased sympathetic activity, poor feeding, and failure to thrive in an infant. On examination, there is evidence of over circulation and pulmonary hypertension: respiratory distress, an active praecordium, a short systolic ejection murmur, a loud second heart sound, a mid diastolic rumble from increased flow across the mitral valve, hepatomegaly and radiographic evidence of cardiomegaly and plethora. A moderate VSD (**Figure 6**) showing turbulence while a large VSD (**Figure 7**) showing no turbulence.

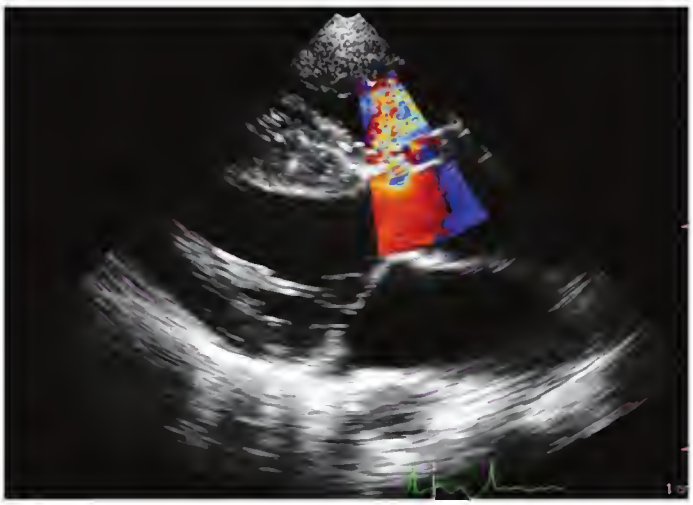

Figure 6: Parasternal long axis view demonstrating turbulence through perimembranous VSD.

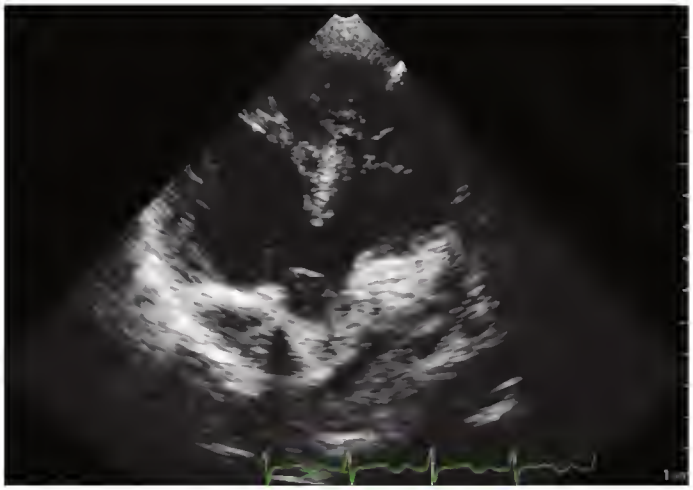

Figure 7: Four-chamber view demonstrating large inlet VSD.

Large VSD, severe pulmonary hypertension and high PVR

Once the pulmonary resistance increases, the pulmonary blood flow reduces and the symptoms regress. At this point, as there is no evidence of CHF, caretakers feel reassured. This is the danger period as intervention gets delayed. Once the pulmonary resistance becomes higher than the systemic resistance, the flow across the VSD changes from right to left leading to cyanosis. On examination, the praecordium is typically quiet with no significant murmurs (as the LV and RV pressures are equal in large VSDs, there are typically no murmurs across a large VSD; as the pulmonary flow decreases, the pulmonary ejection murmur also disappears), a banging S2 and radiographic evidence of a normal sized heart with distal pruning. Once Eisenmenger syndrome develops, it is too late for intervention.

When an infant is seen with a large VSD, there is a chance that it will get smaller with time, but studies differ in respect to probability. A patient with a large VSD seen at 1 month has an 80% chance of closing; whereas a 6-month-old with a large defect has less than a 50% chance of spontaneous closure.

Management

Infants with large VSD typically develop signs of CHF at 6 to 8 weeks of life when the pulmonary vascular resistance is low and the physiological anaemia is at its *nadir*. Therapy includes digoxin, diuretics, and after-load reducing agents. Additionally, treating anaemia is helpful as anaemia can aggravate the failure. If there is heart failure in spite of medications and/or failure to thrive, early surgical closure at 3 to 4 months of life is warranted. If a baby is doing well but has a large VSD, this defect should still be closed early, i.e. by 5 to 6 months, as an occasional patient will develop irreversible PH by 6 to 12 months of age.

Moderate VSD

This is a pressure restrictive defect and the PAPs are protected. Therefore, there is no risk of developing Eisenmenger syndrome.

If there is moderate cardiomegaly and plethora, and the child is otherwise asymptomatic, one can watch for 2 to 4 years. If the VSD does not get smaller, surgical closure is advised to prevent the long-term problems of LV dysfunction secondary to volume over load.

Small VSD

Less than 10 years of age: The consensus is to leave it alone and follow-up for any development of aortic regurgitation (AR).

More than 10 years of age: The issue of surgically closing small holes at this age is controversial. Advocates of closure quote the risk of endocarditis. Conservatives use the argument that it still may close, the only ill effect is endocarditis, which is treatable, and why take the small but present risk of surgery. Most cardiologists would agree that the risk of open-heart surgery is greater than the risk of endocarditis, so leave well enough alone.

The only exception to this is in the presence of aortic regurgitation (AR). In about 5% of VSD, and especially in the supracristal variety, the aortic valve cusp prolapses into the VSD as a result of a Venturi effect resulting in AR. Once this occurs, it is progressive over the following 5 to 10 years. Therefore, the development of AR detected either by echo or by finding a new diastolic murmur on examination is an indication for closure of a small VSD. The indication and timing of VSD closure are summarised in **Table 1**.

Table 1: Timing of Closure of Ventricular Septal Defects

The timing of closure of VSDs is dependent on the size and the symptoms of the defect
Large VSD
Persistent CHF, failure to thrive – close by 3 to 4 months of age
No CHF but pulmonary artery hypertension (PAH): surgery by 5 to 6 months
Moderate VSD
Wait until age 2 to 4 years, earlier, if failure to thrive
Small VSD
If aortic regurgitation develops or previous episode of endocarditis, early surgery is warranted

Patent Ductus Arteriosus

Clinical evaluation

The clinical presentation of a patent ductus arteriosus (PDA), like other left to right shunts, depends on its size and the pulmonary vascular resistance (PVR). In large PDA, the presentation is similar to a large VSD with signs of over-circulation, absence of a significant murmur, a loud S2 and radiographic evidence of cardiomegaly and plethora. Bounding pulses are a clue to a large PDA or aorto-pulmonary window (APW) being the cause of the heart failure. The ECG demonstrating a large continuous flow into the pulmonary artery from the aorta clinches the diagnosis (**Figure 8**). Patients

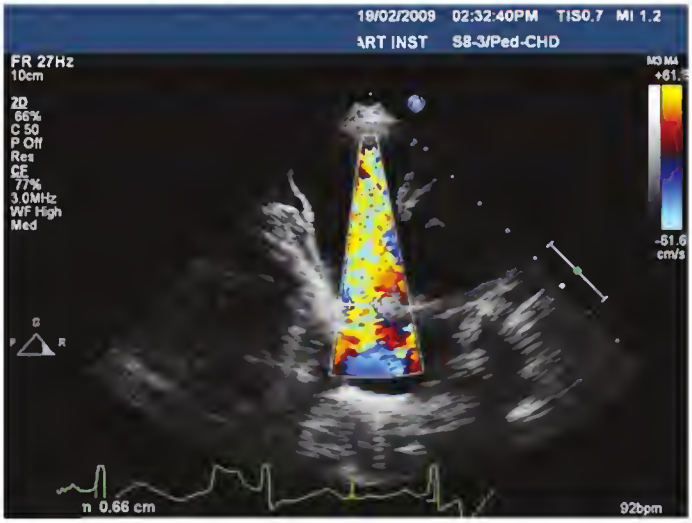

Figure 8: Ductal view on transthoracic echocardiography demonstrating patent ductus arteriosus.

with smaller PDA have the classic continuous Gibson's machinery murmur heard best at the infraclavicular area or the left upper sternal border. As the aortic pressure is higher than the PAP in both systole and diastole this results in a continuous murmur. Patients with large PDA with substantial PH may develop differential cyanosis (pink fingers, blue toes). Continuous murmur will be absent in these cases.

Management

With small PDA, the main risk is endarteritis. However, with larger ducts, there can be a significant volume load on the left heart. For both these reasons, PDA need to be closed. Closure of small PDA is done to prevent subacute bacterial endocarditis (SBE).

If the clinical examination suggests a PDA but there is no evidence on the echocardiogram, one needs to keep in mind the diagnosis of APW. This is a connection between the aorta and the main pulmonary artery and leads to pulmonary over-circulation and hypertension and clinical findings similar to a large VSD or PDA.

The methods used for closure of a PDA include surgical ligation or division via a lateral thoracotomy or non-surgical closure via the deployment of coils or devices across the PDA.

Coarctation of the Aorta

Coarctation of the Aorta (CoA), a narrowing of the arch, occurs in 6% to 8% of patients with CHD. Untreated, coarctation has a poor natural history. In Campbell's classic study, the mean age of death was 34 years. The most common causes of death were heart failure (26%), aortic rupture (21%), endocarditis (18%), and intracranial haemorrhage (12%). Early therapy has several advantages, one being the lower incidence of chronic hypertension. The prevalence of hypertension was 6% in patients who underwent coarctation repair at less than 5 years of age, compared to 30% to 50% in those whose coarctation was repaired at an older age. For all these reasons, early diagnosis and therapy is imperative.

Clinical evaluation

The clinical presentation of CoA is variable. In newborns, the patent ductus arteriosus supports the distal circulation. The RV pumps to the descending aorta via the PDA. As a result, neonates present with signs of right heart failure. Once the PDA closes, the baby has no flow to the lower body and goes into shock.

In older children, the diagnosis may be more subtle – intermittent claudication, upper limb hypertension or the finding of diminished femoral pulses. The best way to never miss a coarctation is to palpate the femoral or dorsalis pedis pulse at every visit.

The ECG may show left ventricular hypertrophy and the radiography can demonstrate the classic rib notching (from development of collaterals) in older children. Echocardiography is diagnostic and demonstrates the narrowing of the arch and the pressure gradient across the CoA (**Figure 9**).

Management

Once diagnosed, CoA is treated either surgically or non-surgically. In newborns and young infants, surgery is the best option as the recurrence rate with angioplasty is high. In older infants and children, balloon angioplasty can be performed with a high success rate and reasonable degree of safety. In older children with near adult sized aortas, the availability of stents has increased

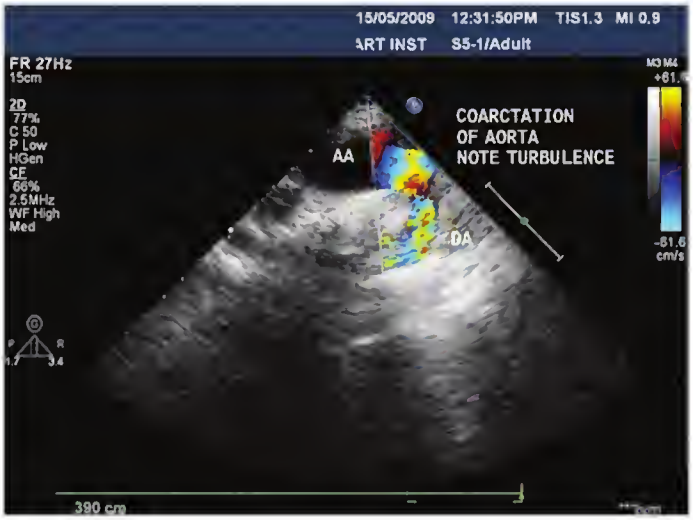

Figure 9: Echocardiography demonstrating the narrowing of the arch and the pressure gradient across the CoA.

the success rate of non-surgical procedures. (Stents are made of stainless steel and can be deployed at the site of coarctation to permanently relieve the obstruction.)

Congenital aortic stenosis and pulmonary stenosis have been discussed in the chapter of Valvular Heart Disease (Chapter 14 of this section).

CYANOTIC HEART DISEASE

Tetralogy of Fallot

In cyanotic heart disease, by far, tetralogy of Fallot (TOF) remains the most common diagnosis. TOF was described over 100 years ago by a French physician, Etienne-Louis Arthur Fallot as a condition consisting of pulmonary arterial stenosis, an interventricular septal communication, deviation of aorta to the right, and concentric hypertrophy of the RV. This lesion still bears his name (**Figure 10**).

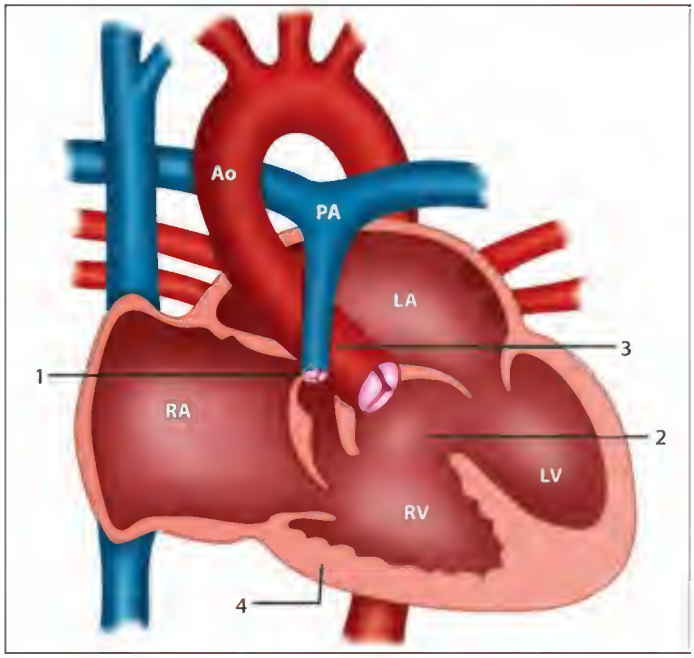

Figure 10: Diagrammatic representation of tetralogy of Fallot.

1=Pulmonary stenosis; 2=Ventricular septal defect; 3=Overriding aorta; 4=Right ventricle hypertrophy.

Ao = Aorta; LA = Left atrium; LV = Left ventricle; PA = Pulmonary artery; RA = Right atrium; RV = Right ventricle.

Clinical Evaluation

The main symptom of cyanosis is related to the degree of pulmonary stenosis; the more the stenosis the more the right to left shunt, the less the pulmonary blood flow and the more the cyanosis. Hypoxic spells occur in infancy, typically in the early mornings and are characterised by tachypnoea, increasing cyanosis and at times, syncope.

Physical examination varies from no murmur during a spell to a systolic ejection murmur to continuous murmurs due to collaterals. The classical ECG findings are right axis deviation and RVH with a radiography demonstrating low pulmonary blood flow and the 'boot shaped' heart. Cardiac catheterisation is no longer routinely indicated. Cardiac computed tomography (CT) or catheterisation is performed if there is a question regarding distal pulmonary arteries or coronary arteries.

Management

Medical management is limited to treating spells, preventing dehydration and fever which can precipitate spells, treating iron deficiency and advising endocarditis prophylaxis. Beta-blockers are used as a bridge to delay surgical intervention.

When to surgically intervene in TOF has always been a contentious issue. In our country, the approach has been to do a complete correction (i.e. closing the VSD and opening the RVOT with or without a transannular patch) by the age of 6 to 18 months, depending on the centre. Waiting until '10 kg' is no longer required and surgical repair can be done as early as is indicated, for instance in the United States – total TOF correction is done soon after birth. In patients with small pulmonary arteries or with a coronary artery crossing the right ventricular outflow tract, a Blalock Taussig (BT shunt) can be performed as a first stage.

Transposition Complexes

The key anatomical feature that characterises this group of diagnoses is ventriculoarterial discordance. This is most commonly seen in the context of AV concordance, also known as complete transposition or d-TGA (dextro-TGA). Congenitally corrected TGA or l-TGA (levo-TGA) is combination of ventriculoarterial discordance with AV discordance (**Figure 11**).

Transposition of the Great Arteries (d-TGA)

In d-TGA, the right ventricle gives rise to the aorta and the LV to the pulmonary artery. This leads to deoxygenated blood going to the body and oxygenated blood returning to the lungs. If there is inadequate mixing (i.e. via an ASD, VSD, PDA), the baby presents with increasing cyanosis leading to acidosis and, eventually, death.

Clinical evaluation

Classically it presents in male children with cyanosis, a single second heart sound and no murmur. The radiograph may show the 'egg on side' appearance, and the diagnosis is confirmed on echocardiography wherein the LV gives rise to the PA and the RV connects to the aorta.

Management

Cardiac catheterisation is no longer indicated unless a balloon atrial septostomy needs to be performed to increase mixing. A non-invasive alternative is prostaglandin (PGE1) which can help open the PDA and help with mixing, thus alleviating cyanosis. The dose needs to be titrated and reduced if hypotension or apnoea occurs.

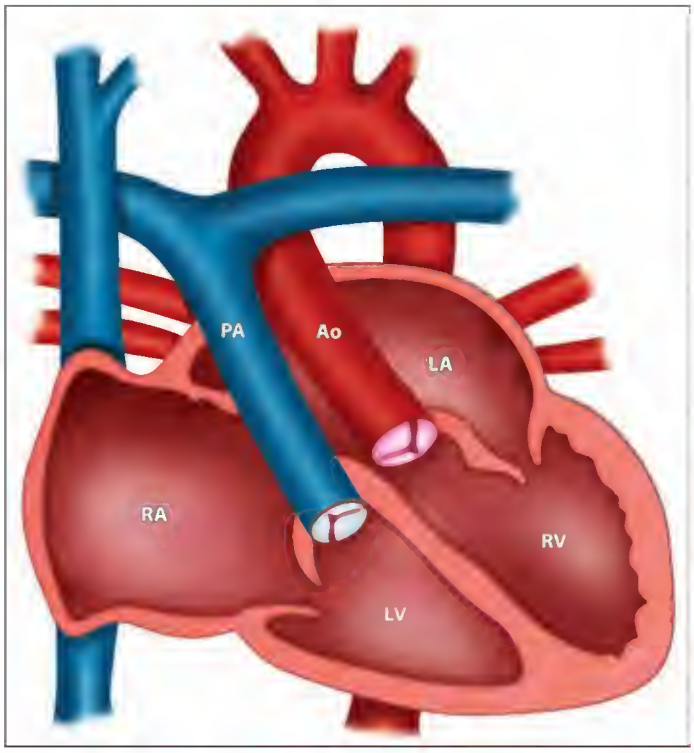

Figure 11: Diagrammatic representation of congenitally corrected transposition of the great arteries.

Ao = Aorta; LA = Left atrium; LV = Left ventricle; PA = Pulmonary artery; RA = Right atrium; RV = Right ventricle.

The ideal operation is an arterial switch operation where the RV is connected back to the PA and the LV is connected back to the aorta leading to a 'normal heart'. Early diagnosis and treatment of d-TGA is essential for the following reason: The LV pumps to the pulmonary artery which is a low pressure artery. Within 4 weeks, the LV undergoes 'disuse atrophy' and it regresses. At this point if an arterial switch is done then the LV is unable to generate enough pressure to pump to the body and it fails. Thus, an arterial switch should ideally be done in the first 4 weeks of life.

Total Anomalous Pulmonary Venous Connection (TAPVC)

Instead of the pulmonary veins connecting normally to the LA, they connect to the RA. An obligatory ASD then allows right to left shunting to maintain left heart output.

Clinical evaluation

Any obstruction along the pathway leads to significant cyanosis, acidosis, low cardiac output, pulmonary venous congestion, a small heart on radiograph and eventual early death. In non-obstructed TAPVC, the presentation is similar to an ASD with a systolic ejection murmur and a widely split S2. Clinically, one can differentiate between the two with an oxygen saturation probe which will reveal a lower oxygen saturation in TAPVC.

Management

Echocardiography is diagnostic and early surgical correction is indicated; this is one of the true paediatric cardiac surgical emergencies.

Truncus Arteriosus

In this lesion, the pulmonary arteries arise from the ascending aorta and typically are at high pressure. This is one of the causes of babies presenting with heart failure and cyanosis, other lesions being single ventricle, TGA-VSD, TAPVC, etc.

Clinical evaluation

These babies are present with CHF and bounding pulses (due to rapid run off into the pulmonary arteries). On examination, these may have a high-pitched early diastolic murmur from truncal regurgitation, in addition to the single S2 and systolic murmurs.

Management

The only remedy is surgical correction where the pulmonary arteries (PA) are connected back to the RV with or without a homograft. Re-operation may be needed in 2 instances: (1) if a homograft is placed, which the baby outgrows with growth thus requiring a new, larger homograft, and (2) pulmonary valve replacement, in some cases. Families need to be counselled that re-operation may be needed over time.

Tricuspid Atresia and Other Forms of Single Ventricle

Babies with single ventricle can present in two ways: (1) with cyanosis if pulmonary stenosis is the main issue and (2) heart failure and pulmonary overflow if there is no pulmonary stenosis. In single ventricle situations, the fundamental issue is that one chamber is doing the work of two chambers. The goal, therefore, of treatment is to connect the superior vena caval blood (Glenn shunt) to the pulmonary arteries to reduce the load on the single ventricle. In order to do this, the PAP must be low. So, in babies with pulmonary stenosis, a Glenn shunt can be done by 6 to 9 months of age. In babies with high flow situations, CHF and high PAP, a pulmonary artery banding needs to be done at 1 month in order to reduce PA pressure to a level where a Glenn shunt can be done later. The Fontan operation, wherein the inferior vena cava is connected to the pulmonary artery, relieves cyanosis completely but it has its own long-term issues. Its routine use, therefore, has been called into question. In single ventricle situations, prognosis is variable but not as dismal as previously thought.

Ebstein's Anomaly

Ebstein's anomaly refers to a downward displacement of tricuspid valve tissue into the RV. Thus, a portion of the RV acts like the atrium. This atrialised RV contracts poorly and interferes with right ventricular filling.

Dyspnoea, fatigue and palpitation are the usual symptoms. Cyanosis is present due to right to left shunt at the atrial level. A systolic murmur of tricuspid regurgitation is heard at the lower left sternal border. The first and second heart sounds are widely split and third and fourth heart sounds may be heard. Thus, multiple scratchy quality heart sounds is an important feature of Ebstein's anomaly.

Box-like globular cardiac configuration is seen on chest radiography which closely resembles a large pericardial effusion. ECG shows tall and peaked P waves. The diagnosis is confirmed by echocardiography (**Figure 12**).

Patients who are symptomatic should undergo a tricuspid valve repair in which marsupialisation of the atrialised RV is undertaken with realignment of the tricuspid cusps to the tricuspid annulus. This procedure is preferred over operations in which the tricuspid valve is replaced with a prosthetic valve.

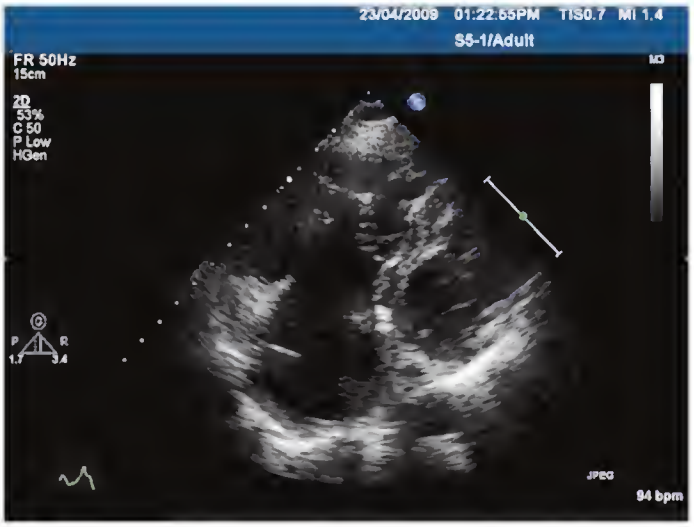

Figure 12: Chamber view demonstrating apical displacement of septal leaflet of tricuspid valve in Ebstein's anomaly.

IMAGING IN CONGENITAL HEART DISEASE

When it comes to the preferred choice of imaging for CHD in children, echocardiography has no match. Optimum windows, zero radiation and easy availability of the expertise make echocardiography, 'the investigation of choice'. However, CT is an extremely helpful complementary imaging modality in the evaluation of CHD. Poor acoustic windows and poor depiction of extracardiac vascular structures are the major limitations of echocardiography, both of which can be successfully overcome with the use of cross-sectional CT imaging. Short acquisition times and, thereby, decreased requirement for sedation leads to CT definitely scoring over magnetic resonance imaging (MRI) in children.

Cardiac CT and MRI are being increasingly utilised to assess pulmonary artery anatomy (e.g. in TOF), arch anomalies (e.g. complex coarctations, interrupted aortic arch), pulmonary veins (e.g. TAPVC where pulmonary venous drainage is unclear), vascular rings and slings, etc.

ASSESSING OPERABILITY IN CHD

The issue of operability arises often for clinicians involved in the care of children with heart disease. In infants less than 6 months of age one can generally make an assumption that the children are operable as irreversible pulmonary vascular obstructive disease (PVOD) is unusual at that age. In older infants, and particularly in older children or adults, the question of how much and how reversible the PVOD is often arises.

A key concept is that in all large left to right (L-R) post-tricuspid shunts (i.e. VSD, PDA, atrioventricular canal (AV canal), APW, etc.) the systemic, i.e. aortic pressure is directly transmitted to the pulmonary artery. Therefore, in large shunts there is severe pulmonary artery hypertension (PAH) right at birth. As time progresses, the high flow and high pressure cause an elevation in pulmonary vascular resistance (PVR). It is this change in PVR that determines symptoms and operability.

For a variable period of time after PVR starts to increase, changes in lung vasculature may still be reversible following correction of the defect, i.e. the patient may still be operable. However, once irreversible PVOD is established, closure of the defect may

actually worsen the natural history and hasten mortality as a result of right heart failure.

Fundamental Concept

If the PVR is low, the shunt will be L-R and the patient will exhibit signs of pulmonary overcirculation. A patient with low PVR is always operable.

If the PVR is high, the shunt will become R-L and there will be signs of cyanosis without overcirculation. A patient with high PVR may be inoperable.

Using this concept one can come to a conclusion of operability looking for features of pulmonary overcirculation. A child with low PVR, i.e. who is operable has the following clinical features (**Table 2**).

Table 2: Clinical Features Favouring Surgery Based on Pulmonary Vascular Resistance

Symptoms of heart failure, e.g. failure to thrive, sweating, etc.
Tachycardia
Tachypnoea
An active hyperdynamic praecordium
A loud P2 along with a systolic ejection murmur of high flow (across the pulmonary valve in a VSD and across the aortic valve in a PDA/APW)
Potentially a mid diastolic rumble related to increased flow across the mitral valve
Evidence of LV volume load on ECG
Cardiomegaly and pulmonary plethora on CXR
An echo showing primarily a left to right shunt and a dilated LA/LV. In aorto-pulmonary window, reversal of flow in the aortic arch/descending aorta is a powerful predictor of operability as it suggests that the PVR is lower than the systemic vascular resistance (SVR)

On the other hand, a patient who is inoperable will have no clinical features of pulmonary over-circulation (**Table 3**).

Borderline Operability

In certain situations the clinical features are borderline. A patient with a quiet praecordium, no flow murmur, an oxygen saturation of 90% but mild cardiomegaly on CXR and equal sized ventricles with a bidirectional shunt on echo poses an operability diagnostic dilemma and a therapeutic challenge. In such cases,

Table 3: Criteria Showing High Pulmonary Vascular Resistance and Inoperable Defects

A quiet praecordium
Absence of a systolic ejection flow murmur in the presence of a loud banging P2
Evidence of cyanosis or an oxygen saturation less than 85% to 90%. (In a PDA the lower limb saturation would be measured)
Right ventricular hypertrophy on ECG
Absence of cardiomegaly or plethora on CXR with peripheral pruning
Primarily right to left shunting on the echo with right heart dilation

a cardiac catheterisation may add value in terms of a decision. Traditionally, a calculated PVR of less than 8 RU with oxygen/nitric oxide or other pulmonary vasodilators is considered evidence of operability. Although 100% oxygen has been conventionally used to assess the degree of 'reversibility', the role of oxygen in outcome prediction remains questionable. A recent multicentre haemodynamic study of patients with CHD and PH concluded that the reliability of pre-operative haemodynamic cath lab evaluation of operability was limited despite the use of vasodilators.

In a large PDA balloon occlusion of the duct can be performed. The demonstration of a substantial fall, especially of the PA diastolic pressure, suggests operability. However 100% correlation between this and operability has not been noted in all studies.

In conclusion, CHD is a diverse group of lesions with varying presentations. Early and accurate diagnosis along with timely intervention is the key to long-term good outcomes.

12.27 Heart in Systemic Diseases

Aspi R Billimoria

The heart is involved in many systemic disorders. In most of these conditions, other manifestations like joint involvement or CNS affection may predominate and the cardiac involvement is often considered as a 'complication'. In a few patients, especially those with thyroid disease, cardiac manifestations may be the presenting complaints and may even precede other systemic manifestations.

HEART IN ENDOCRINE DISORDERS

Thyroid Disorders

Both thyroxine (T_4) and triiodothyronine (T_3) have a direct stimulatory effect on the myocardium.

Hyperthyroidism

Excess thyroid hormone has a direct effect on the heart but many of the clinical manifestations are due to increased beta-adrenergic stimulation. The increased basal metabolism leads to increased oxygen demand, resulting in tachycardia and increased cardiac output. The positive inotropic action of the hormone increases the force of contraction which, if untreated, results in high-output failure.

Signs and symptoms

Apart from signs of hyperthyroidism like ocular signs and goitre, the patient may complain of palpitations, dyspnoea or angina. The pulse is rapid and of high volume (due to the high-output state) and may be irregular if atrial fibrillation is present. Systolic hypertension is invariably present. A loud first heart sound and a third heart sound may be present with a systolic murmur in the left parasternal region. The hyperdynamic heart may cause rubbing of the normal pericardium against the pleura, resulting in a scratchy sound, the Means-Lerman scratch. In advanced untreated cases, there may be signs of cardiac failure.

Investigations

The commonest electrocardiographic changes are sinus tachycardia or atrial fibrillation (which may be at first paroxysmal and then permanent). The P wave may be notched and the PR interval may be prolonged. About 15% of patients have a right bundle branch block.

Treatment

Cardiac manifestations generally do not respond to conventional cardiac drugs without specific anti-thyroid treatment. Beta-blockers are useful as they slow the heart rate and suppress beta-adrenergic activity. Digitalis and diuretics are useful in treating cardiac failure.

Hypothyroidism

The heart becomes pale and flabby and dilates. Histopathology reveals swelling of the myofibrils, loss of striations and interstitial fibrosis. There is increased capillary fragility which leads to leakage of fluids into the interstitial spaces, resulting in pericardial effusion.

Signs and symptoms

There is bradycardia and the pulse is of low volume. The blood pressure is usually low but in a few cases there may be hypertension. The heart size is enlarged and the heart sounds may sound distant. A pericardial rub may be heard. Severe cardiac failure may be present. A few patients may complain of angina or suffer myocardial infarction due to secondary hyperlipidaemia.

Investigations

The electrocardiogram characteristically reveals sinus bradycardia, low voltage and flat T-waves. The QT interval may be prolonged. Changes of pericardial effusion may be seen. Chest X-ray reveals an enlarged heart and signs of pericardial effusion. Pericardial effusion can be confirmed by echo-cardiogram.

Treatment

The cardiac manifestations do not respond to conventional therapy unless hormone replacement therapy is instituted. It is advisable to start with a low dose of thyroid hormone in elderly patients and those with angina, as tachycardia may exacerbate myocardial ischaemia.

Adrenal Disorders

Hyperaldosteronism

Hypersecretion of aldosterone results in hypertension, hypokalaemia and metabolic acidosis. The diagnosis is suspected when the patient has diastolic hypertension and low serum potassium. Treatment is aimed at removal of the mineralocorticoid-producing tumour but in patients who are at poor risk for surgery, spironolactone in high doses (up to 200 mg/day) may be given.

Cushing's syndrome

The cardiac manifestations are usually those of hypertension and ischaemic heart disease due to hyperlipidaemia. The treatment is that of the primary disease.

Adrenal insufficiency

Decreased secretion of glucocorticoids results in marked hypotension which worsens on standing. The electrocardiogram reveals sinus bradycardia, flat or inverted T-waves and generalised low voltage. The treatment is by replacement therapy with corticosteroids.

Phaeochromocytoma

This is a catecholamine-producing tumour which causes severe adrenergic stimulation, resulting in hypertension and tachycardia. The catecholamine release and its manifestations are usually episodic, though, hypertension may be permanent

in a few cases. The heart may develop a cardiomyopathy-like picture in chronic cases.

Electrocardiography reveals left ventricular hypertrophy, T-wave inversion, sinus tachycardia and occasionally, paroxysmal atrial tachycardia.

The adrenergic activity should be blocked initially with alpha-adrenergic blockers like phenoxybenzamine or prazosin. Later on, beta-blockers or calcium-channel blockers may be added. Treatment is by surgical excision of the tumour.

Pituitary Gland Disorders

Acromegaly

The cardiovascular manifestations include hypertension, ischaemic heart disease and congestive heart failure. The heart size is markedly enlarged, out of proportion to the rest of the splanchnomegaly. The hypertension responds well to conventional therapy.

HEART IN ANAEMIA

Chronic severe anaemia (haematocrit < 25%) leads to a high-output state. Since the oxygen-carrying capacity of the RBCs is reduced, accumulation of metabolites occurs in the tissues and causes peripheral vasodilatation leading to reflex tachycardia and hyperkinetic circulatory state. Chronic anaemia leads to work hypertrophy of the heart and finally to its dilatation and cardiac failure.

Signs and Symptoms

The commonest symptoms are fatigue, dyspnoea on exertion, anginal pains and swelling of the ankles.

Physical examination reveals tachycardia and collapsing pulse, and pistol-shot sound and Duroziez's murmur may be audible over the femoral artery. The heart may be clinically enlarged and the apex beat hyperdynamic. There may be loud heart sounds and a systolic 'haemic' murmur at either the base or the apex of the heart. Mid-diastolic murmurs across the mitral and tricuspid valves may be heard and are due to increased flow. If the ventricles dilate, murmurs of tricuspid and mitral regurgitation may be heard. Dilatation of the great vessels may cause murmurs of aortic and pulmonary regurgitation. There may be signs of congestive cardiac failure.

Investigations

Electrocardiogram reveals tachycardia and flattened or inverted T waves. X-ray chest may show a normal or dilated heart. The haemogram reveals the underlying anaemia.

Treatment

The treatment is that of anaemia and, if possible, it's underlying cause. Severe anaemia may require blood transfusions. Transfusion of whole blood may overload the circulation; in these cases packed cells may be transfused after intravenous frusemide injection. Digoxin is not useful in treating cardiac failure due to anaemia, though diuretics may help in reducing the oedema.

HEART IN MALNUTRITION AND VITAMIN DEFICIENCY

Protein-Calorie Malnutrition

This is seen mainly in children either as marasmus or kwashiorkor and is due to deficiency of protein intake. Kwashiorkor may also be seen in adults. The heart becomes thin-walled and flabby and there is atrophy of the muscle fibres. Clinically, the patient has hypotension, low pulse pressure and low cardiac output. Generalised signs of malnutrition are seen.

Beriberi

Beriberi is due to thiamine (vitamin B1) deficiency and is either of the dry or wet variety. The heart is involved in wet beriberi. It may occur due to deficient intake in patients eating polished rice, or in alcoholics and in diabetes. It may also form part of generalised hypovitaminosis.

Thiamine helps in the oxidation of pyruvic acid to lactic acid and deficiency leads to pyruvate and lactate accumulation. This results in peripheral vasodilatation and reflex tachycardia, a hyperkinetic circulatory state. Renal retention of sodium and water leads to increased blood volume. Chronic beriberi may result in congestive cardiac failure.

Signs and symptoms

The patient complains of severe dyspnoea on exertion and swelling of the legs, along with the classical signs of dermatitis and peripheral neuropathy. On examination, there is tachycardia, wide pulse pressure and signs of cardiac failure, with pericardial or pleural effusion. Auscultation may reveal a third heart sound and apical systolic murmur.

Investigations

Electrocardiogram shows sinus tachycardia, low-voltage QRS complex and T-waves, and prolongation of the QT interval. Chest X-ray will show an enlarged cardiac shadow and signs of pericardial or pleural effusion.

Diagnosis

The diagnosis is made clinically by the presence of hyperkinetic circulatory state, skin changes and peripheral neuropathy. Laboratory analysis will reveal increased blood pyruvate and lactate levels.

Treatment

Patients do not respond well to conventional cardiac therapy. Thiamine given in doses of 100 mg daily, either intravenous or intramuscular, brings about dramatic improvement in a few days. Concurrent treatment with digoxin, diuretics and a low-sodium diet is also advisable.

HEART IN COLLAGEN DISEASES

Systemic Lupus Erythematosus

The heart is involved in 50% to 60% of cases of SLE. There are three modes of involvement.

Pericarditis is the commonest lesion. Exudative pericardial effusion occasionally may cause cardiac tamponade. Rarely there may be constrictive pericarditis.

Endocarditis takes the form of Libman-Sacks verrucous vegetations, which are formed of degenerated valve tissue and may be as large as 3 mm. Usually, they do not cause any valvular malfunction.

Myocarditis is present on histopathology at autopsy which reveals fibrinoid necrosis and changes of angiopathy.

Polyarteritis Nodosa

This disease is characterised by necrotising inflammation of the blood vessels, also involving those of the heart. The coronary arteries are involved and angina pectoris and myocardial infarction may result. Hypertension, due to renal artery involvement, is very common and may lead to congestive heart failure. Atrial flutter and fibrillation are also observed in some cases.

Scleroderma

This disease is characterised by vasculitis, but the process is slow and results in scarring and fibrosis, leading to obliteration of small vessel lumen. Obliteration of pulmonary vessels leads to the development of pulmonary hypertension. Coronary artery involvement is common and leads to precipitation of anginal attacks and myocardial infarction. Myocardial involvement due to fibrosis results in congestive cardiac failure. Atrio-ventricular conduction defects are also observed, as is pericarditis. Cardiac dilatation may produce regurgitation murmurs.

Rheumatoid Arthritis

All the cardiac tissues are involved. Valvular involvement is due to rheumatoid granulomas, and the commonest valves affected are the aortic and the mitral, with regurgitation as the end result. Myocarditis, due to granulomas, may precipitate left ventricular failure. Pericarditis resembling tuberculosis is quite common and may occur in as many as 50% of cases. About 20% of the cases may have coronary arteritis.

Reiter's Disease

The heart is involved usually only in the acute stages of the disease when pericarditis and atrio-ventricular conduction defects may occur. Auscultation may reveal apical systolic murmur and occasionally aortic and mitral regurgitation.

SYPHILITIC HEART DISEASE

Syphilitic Aortitis and Aortic Regurgitation

Syphilis most commonly involves the ascending aorta, probably because it has a richer lymphatic supply. Fibrous tissue replaces normal aortic wall tissue, leading to weakening of the walls and aneurysm formation. The aneurysm is usually fusiform in shape. The aorta assumes a 'tree bark' appearance due to wrinkling of the intima. If the infection and inflammation extend into the root of the aorta, it may cause dilatation of the aortic annulus and result in aortic regurgitation. The latter is characterised by a loud second sound ('*bruit de tambour*') and an early diastolic regurgitation murmur which is better heard on the right sternal border, owing to the dilated aorta. The EDM of rheumatic aortic regurgitation is better heard in the left third intercostal space (Erb's area).

Coronary Ostial Narrowing

This results in angina pectoris. However, it differs from the angina caused by atherosclerosis in the following manner: attacks come on at rest, anginal pain lasts for a longer period of time, and angina is not relieved by sublingual nitrates.

Syphilitic Myocarditis

This is not commonly seen now. Gumma formation was common in earlier times and resulted in atrio-ventricular conduction blocks.

Treatment

All patients with cardiovascular syphilis should be given antibiotic therapy to check further progress of the disease. Surgery is indicated for aneurysm and aortic regurgitation. Coronary ostial narrowing may be treated by endarterectomy or bypass grafting.

HYPERKINETIC CIRCULATORY STATES

Hyperkinetic circulatory states comprise conditions where the resting cardiac output is increased to more than 6 litres/minute. The principal contributing factor is lowered peripheral vascular resistance (afterload) leading to increased venous return. This may be the result of peripheral vasodilatation or of peripheral shunting as in arteriovenous fistulae. The cardiac output rises due to an increase in heart rate, stroke volume or both. Usually, the patients cope with the problem well and do not develop cardiac failure. However, in patients in whom the problem develops acutely, cardiac failure may result. Causes of hyperkinetic circulatory states are given in **Table 1**.

Table 1: Causes of Hyperkinetic Circulatory States

- **Physiological**
  - After a hot bath
  - Vigorous exercise
  - Pregnancy
- **Pathological**
  - Chronic high-output states
    - Thyrotoxicosis
    - Chronic severe anaemia
    - Beriberi
    - High fever
    - Paget's disease of bones
    - Systemic arteriovenous fistulae
    - Hyperkinetic heart syndrome
    - Hepatic diseases
  - Acute high-output states
    - Severe anaemia and thyrotoxicosis that worsen suddenly
    - Acquired arteriovenous fistulae

Paget's Disease of Bones

This is characterised by a process of rapid bone formation and resorption at various sites, with increased vascularity of the affected bones. However, this is not the cause of the high-output state, which is believed to be due to increased blood flow in the cutaneous vessels overlying the affected bones, in order to dissipate the heat produced because of increased metabolism of the bones.

There are no specific findings in the cardiovascular system. Metastatic calcification of the valve rings and conduction tissues may occur, resulting in atrioventricular blocks. There is no specific treatment for the high-output state, except that for Paget's disease itself.

Arteriovenous Fistulae

They produce high-output states only if they are large in size. Clinical findings reveal a high-volume pulse and mild tachycardia. Pressure over the fistula may slow the heart rate (Nicaladoni-Branham's sign). If the fistula is superficial, the skin over it may be warmer and auscultation usually reveals a 'machinery' murmur. Auscultation of the heart may reveal third and fourth heart sounds. These fistulae may be congenital or acquired.

Congenital fistulae may be single or multiple and may vary in size from that of a strawberry birthmark to huge, ugly swellings

that disfigure the limbs. They are more common in the lower limbs. The affected limb may be swollen and enlarged. Hereditary haemorrhagic telangiectasia is a congenital condition in which arteriovenous fistulae may occur. These often involve the liver and lungs. The liver may be enlarged and palpable and a bruit may be heard over it.

Acquired fistulae usually occur after gunshot and stab wounds and are commonly found in the thighs. Due to the increased blood flow, the affected limb increases in size. Other types of acquired fistulae are shunts that are surgically made for haemodialysis, those occurring in Wilms' tumour and, rarely, by rupture of an aortic aneurysm into the inferior vena cava.

Diagnosis

The skin changes over the fistula, the enlarged limb and the continuous murmur are pathognomonic. The electrocardiogram may be either normal or may reveal mild left ventricular enlargement. Chest roentgenograms reveal either a normal sized or a slightly enlarged heart. To localise the site of the fistula, angiograms may be necessary.

Treatment

Small fistulae may be left alone, especially if they do not cause cosmetic embarrassment. Surgical excision yields excellent results; this may, however, not be possible in all patients, especially those having multiple or very large fistulae.

Hyperkinetic Heart Syndrome

This syndrome usually occurs in young men; they have a high-output state without any detectable cause. They complain of palpitations and atypical chest pain. Examination shows a high pulse pressures and third and fourth heart sounds; in some patients, systolic murmurs are heard. The exact cause of the syndrome is not known.

Treatment with beta-adrenoreceptor blockers yields excellent results.

Hepatic Diseases

Hepatocellular failure leads to vasodilatation resulting in high-output states. There may also be arterio-venous fistulae in the lungs. The exact cause is not known. These may be due to hypoxia or diminished deactivation of vasodilator substances and oestrogens in the liver.

12.28 Disorders of the Myocardium

KK Talwar, Pawan Poddar

Disorders of the myocardium are an important and heterogeneous group of diseases. The term 'cardiomyopathy' was first used in 1957 and is defined by World Health Organization as 'a disease of the myocardium associated with cardiac dysfunction'. Various classifications for cardiomyopathies have been proposed. American Heart Association has divided cardiomyopathies into 2 groups: primary cardiomyopathies (solely or predominantly confined to heart muscle); and secondary cardiomyopathies (pathological myocardial involvement as part of generalised systemic disorders) (**Figure 1**).

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy (DCM), the most common form of cardiomyopathy, is characterised by ventricular dilatation and impaired contraction of left or both ventricles leading to systolic dysfunction. It is more common in males and between the ages of 20 and 50 years. The 5-year survival after diagnosis is 50%.

Aetiology

Dilated cardiomyopathy can occur in an idiopathic form or secondary to other cardiac or systemic diseases (**Table 1**). Idiopathic form may represent sequelae of remote episodes of viral myocarditis. Autoimmunity has also been implicated as the underlying mechanism in idiopathic DCM. About 25% to 35% of cases of DCM are familial. A large number of genes have been implicated. Modes of inheritance include autosomal dominant (AD) with incomplete penetrance, autosomal recessive (AR) and X-linked.

Clinical Presentation

Clinical picture is dominated by symptoms of left ventricular failure. Some patients remain asymptomatic for years. Others present with symptoms of fatigue and weakness due to diminished cardiac output. Elevated left ventricular (LV) filling pressures result in symptoms of exertional dyspnoea, paroxysmal nocturnal dyspnoea and orthopnoea. Clinical course is punctuated by thromboembolism and atrial or ventricular arrhythmias. Chest pain may result from underlying coronary artery disease (CAD) or pulmonary embolism. Features of right heart failure may develop in late stages of the disease.

Physical findings include tachycardia, low arterial pressure and cool extremities secondary to low cardiac output. Jugular venous pressure (JVP) may be elevated with prominent 'a' and 'v' waves. Dependent oedema, ascites and hepatomegaly indicate right heart involvement. Cardiovascular examination reveals marked cardiomegaly with palpable third heart sound. Auscultatory findings include soft S1, prominent S3 and pansystolic murmurs of mitral and tricuspid regurgitation.

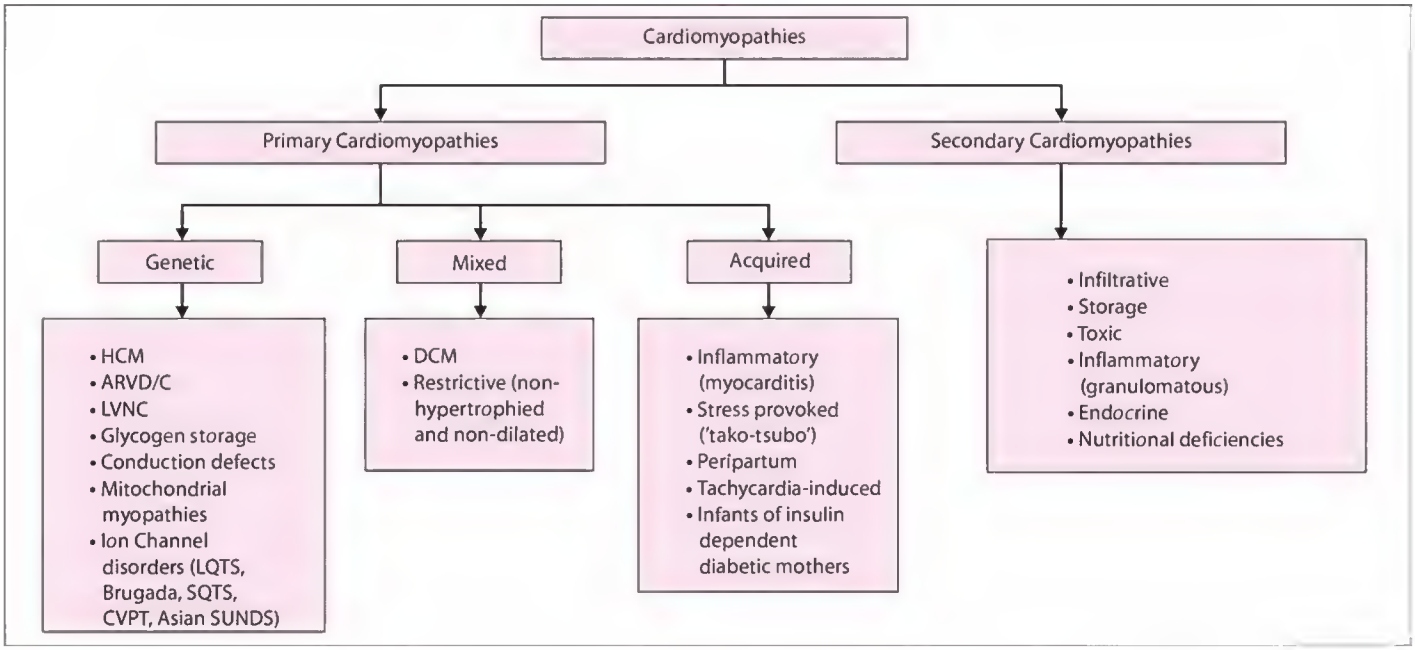

Figure 1: American Heart Association (AHA) classification of cardiomyopathies.

HCM = Hypertrophic cordiomyopothy; DCM = Diloted cardiomyopothy; ARVD/C = Arrhythmogenic right ventriculor dysplosio/cardiomyopothy; LVNC = Left ventriculor noncompoction; LQTS = Long-QT syndrome; SQTS = Short-QT syndrome; CVPT = Catecholominergic polymorphic ventriculor tochycordia; SUNDS = Sudden unexploined nocturnol deoth syndrome.

Pulmonary venous congestion produces tachypnoea and rales over bilateral basal lung fields.

	Cocaine
	Phenothiazines
	Heavy metals: cobalt, lead, mercury

Investigations

Electrocardiographic findings are non-specific. They include isolated T-wave changes, septal Q-waves, prolonged atrioventricular conduction, bundle branch blocks, and atrial or ventricular arrhythmias. Echocardiography is the main stay of diagnosis and reveals dilatation of left ventricle and other chambers with globally diminished systolic function (**Figure 2**). It may identify mural thrombi, quantify mitral and tricuspid regurgitation and assess severity of pulmonary hypertension. Echocardiography excludes secondary causes like valvular heart disease. Thallium myocardial perfusion imaging or coronary angiography is required to definitely exclude CAD. Endomyocardial biopsy (EMB) is done in selected cases to rule out myocarditis, infiltrative disorders like amyloidosis, sarcoidosis, haemochromatosis and storage disorders. Detection of viral antigen in EMB specimen may help to plan anti-viral therapy.

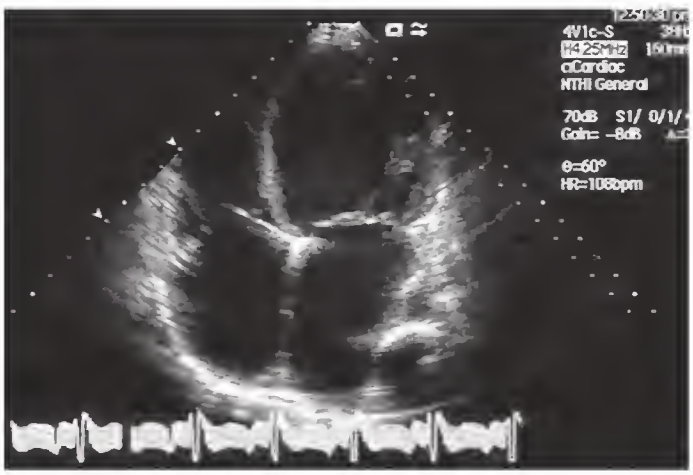

Figure 2: 2D echocardiographic image (apical 4-chamber view) showing dilatation of all four cardiac chambers in a patient with DCM.

Pathology

Grossly, there is cardiomegaly with increase in myocardial mass and marked chamber dilatation (**Figure 3**). Mural thrombi are seen frequently at various stages of organisation.

Figure 3: Gross photograph showing left-side of the heart with dilated cavity, endocardial sclerosis and mural thrombus in DCM.

Microscopic findings are non-specific and consist of myocyte hypertrophy, myocyte atrophy and interstitial fibrosis. Characteristic histologic findings in certain secondary forms of DCM include lymphocytic infiltration in myocarditis, granulomas in sarcoidosis and intramyocellular iron deposition in haemochromatosis.

Treatment

Treatment is directed to control heart failure symptoms. Diuretics, β-blockers, angiotensin converting enzyme inhibitors (ACEIs)/angiotensin receptor blockers (ARBs) and digoxin form the mainstay of treatment. Diuretics and digoxin provide symptomatic relief whereas β-blockers, ACEIs/ARBs and spironolactone improve survival as well. Therapy with β-blockers and ACEIs/ARBs should be initiated in lowest dose and then gradually up-titrated to maximum tolerated dose. Counselling regarding the natural history of the disease and the need for long-term treatment goes a long way in ensuring compliance to medications. Salt and fluid intake is restricted. All patients with prior ventricular fibrillation/sustained ventricular tachycardia should be offered implantable cardioverter defibrillator (ICD). Implantation of ICD also improves survival in patients with left ventricular ejection fraction less than 30%. In patients with left bundle branch block (LBBB) with wide QRS (>120 ms) and left ventricular ejection fraction (LVEF) ≤35%, who remain symptomatic despite maximum medical therapy, cardiac resynchronisation therapy (CRT) using

biventricular pacing improves survival, functional status, exercise tolerance and ejection fraction. Patients who have progressed to end-stage disease are candidates for heart transplantation. Anticoagulation is indicated in patients with mural thrombus and prior thromboembolism. Arrhythmias should be aggressively treated. In patients with atrial fibrillation, amiodarone is an effective drug and may restore normal sinus rhythm in some.

MYOCARDITIS

Myocarditis is defined as a disease process characterised by non-ischaemic inflammatory cellular infiltration of the myocardium with or without associated myocyte necrosis (Dallas criteria).

Aetiology

The most common underlying aetiology of myocarditis is common viral infections (coxsackie virus A and B, echovirus, adenovirus, poliovirus, parvovirus B-19, influenza virus, HIV and others). Less commonly, myocarditis results from other infections (bacterial, fungal, parasitic or rickettsial), toxic or hypersensitive drug reactions, collagen vascular disorders, snake/insect bites, radiation injury or electric shock.

Pathogenesis

Myocyte injury may result from direct cytopathic effect of inciting agent, cell-mediated cytotoxicity or autoantibody-mediated damage.

Clinical Presentation

Clinical presentation of myocarditis is variable and includes asymptomatic presentation with ECG abnormalities, sub-acute presentation with symptoms and signs of heart failure and ventricular dilatation (resembling DCM), and fulminant presentation with severe LV dysfunction without chamber dilatation. Symptoms may include dyspnoea, orthopnoea, chest pain, cough, fatigue, palpitations and syncope. A viral prodrome with fever, myalgia, and respiratory or gastrointestinal symptoms may precede the development of cardiac symptoms. Atrial and ventricular arrhythmias are common. Conduction blocks, including complete heart block, may be seen. Acute coronary syndrome remains an important differential diagnosis.

Investigations

Electrocardiography shows tachycardia with non-specific ST-segment and T-wave abnormalities, occasionally mimicking acute myocardial infarction. Cardiac biomarkers like troponins and CK-MB are elevated. Echocardiography reveals globally decreased ventricular function with chamber dilatation. However, in fulminant myocarditis, ventricular cavity may be small with increased wall thickness. Contrast-enhanced magnetic resonance imaging (MRI) reveals delayed gadolinium enhancement of the myocardium in T2-weighted images and suggests myocarditis. Coronary angiography is done to rule out CAD. Endomyocardial biopsy is the gold standard for diagnosis of myocarditis but has limited sensitivity and specificity. It is indicated in patients with unexplained rapidly progressive heart failure of less than 2 weeks duration refractory to conventional treatment and in those with unexplained heart failure associated with life-threatening ventricular arrhythmias or conduction system disease. Detection of viral antigen in EMB specimen confirms a viral aetiology.

Pathology

Gross

During the active phase, the gross appearance of the heart is variable as the myocardial involvement may be focal, patchy or diffuse. The myocardium is often mottled with pale foci and hyperaemic-haemorrhagic areas. Mural thrombi may be present, especially in dilated hearts.

Histopathology

There is interstitial mononuclear inflammatory infiltrate predominantly lymphocytic, with damage to adjacent myocytes (**Figure 4**). This may be focal, multifocal or diffuse. The nature of myocarditis can be confirmed by immuno-histochemical and molecular work-up. The most common viral cause of myocarditis is coxsackie virus B as confirmed by molecular analysis. Lately, parvovirus is emerging as an important cause of viral myocarditis.

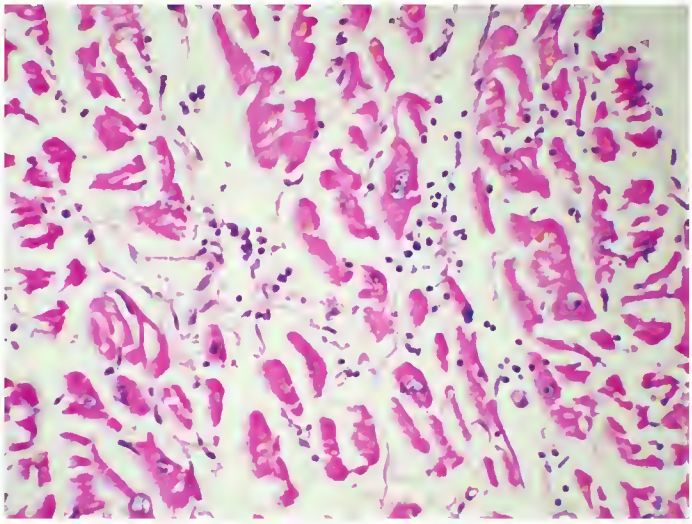

Figure 4: Microphotograph showing myocarditis with lymphocytic infiltrate and myocyte necrosis (H and E X 280).

Treatment

Treatment is supportive with diuretics, ACEIs and β-blockers. In patients who worsen on medical therapy, mechanical circulatory assist devices may be used as a bridge for transplantation or recovery. About 40% of patients recover uneventfully with supportive treatment. Antiviral therapy is being evaluated in patients with positive viral antigen in EMB specimen and immunosuppressive therapy in patients with negative viral antigen.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is a primary genetic cardiac disorder resulting from mutation in genes encoding sarcomeric proteins. The hallmark of HCM is left (± right) ventricular hypertrophy in the absence of chronic pressure or volume overload. HCM has intrigued clinicians and researchers for decades due to its heterogenous expression, unique pathophysiology and variable clinical presentation. It is known by various other names like hypertrophic obstructive cardiomyopathy (HOCM), idiopathic hypertrophic subaortic stenosis (IHSS), and asymmetric septal hypertrophy (ASH). Hypertrophic cardiomyopathy is the most common inherited cardiovascular disorder with a prevalence of 0.2% (or 1 in 500) in the general population.

The HCM phenotype usually manifests during adolescence with marked increase in wall thickness accompanying adolescent growth spurt. Differentiating HCM from physiological hypertrophy in 'athlete's heart' is important for clinical implications (**Table 2**). Apical HCM (wall thickening confined to the left ventricular apex) is a morphological variant characterised by spade-shaped ventricular cavity (**Figure 5**) and giant symmetrical T wave inversions in lateral precordial leads on ECG (**Figure 6**). This variant has a benign course and good prognosis.

Table 2: Differentiating Hypertrophic Cardiomyopathy from Athlete's Heart

	HCM	Athlete's Heart
Family history of HCM	+	–
Marked LVH or unusual patterns of hypertrophy	+	–
LV cavity dilatation	–	+
LA enlargement	+	–
Abnormal ECG patterns	+	–
Abnormal LV filling pattern on pulse Doppler interrogation of mitral inflow velocities	+	–
Female gender	+	–
Thickness with deconditioning	–	+

Aetiology: Genetics

Hypertrophic cardiomyopathy is inherited as an autosomal dominant trait with positive family history in over 60% of cases. The remainder of the cases arise from *de novo* mutations in known or as yet unknown genes or may include other causes of LV hypertrophy like Fabry's disease and glycogen storage disorders. More than 450 mutations in 13 sarcomeric genes have been implicated.

Pathophysiology

Diastolic dysfunction

Diastolic dysfunction is seen in 80% of patients and manifests as dyspnoea and exercise intolerance. This is related to LV

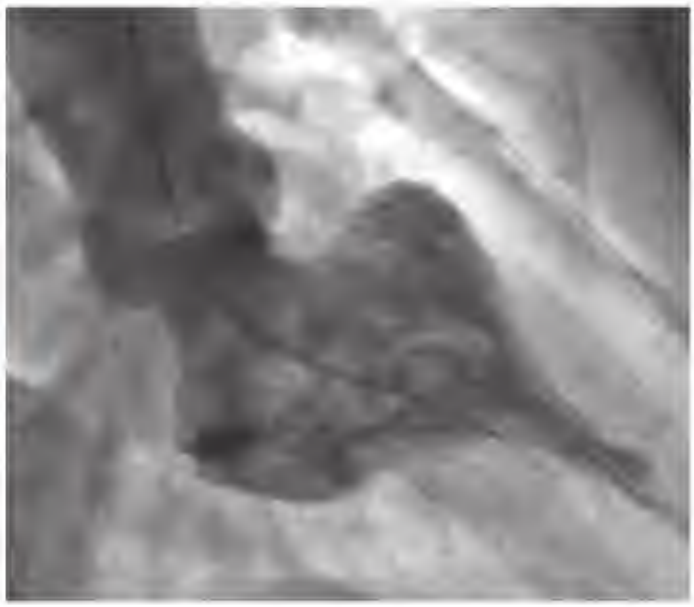

Figure 5: Left ventriculogram at end diastole showing 'spade-shaped ventricular cavity' in a patient with apical HCM.

hypertrophy, interstitial fibrosis, myocardial ischaemia and abnormal calcium influx. Systolic function is normal or increased in HCM.

Left ventricular outflow tract obstruction

Left ventricular outflow tract obstruction (defined as gradient ≥30 mm) in HCM is dynamic and varies with changes in preload, afterload and contractility (**Table 3**). It is seen at rest in 25% of individuals and that at rest or on provocation in 70%. It is produced by systolic anterior motion (SAM) of the mitral valve and mid-systolic contact with hypertrophied septum and is an independent predictor of heart failure and cardiovascular deaths.

Myocardial ischaemia

Myocardial ischaemia in HCM results from multiple mechanisms —reduced arteriolar density, myocardial hypertrophy, micro-

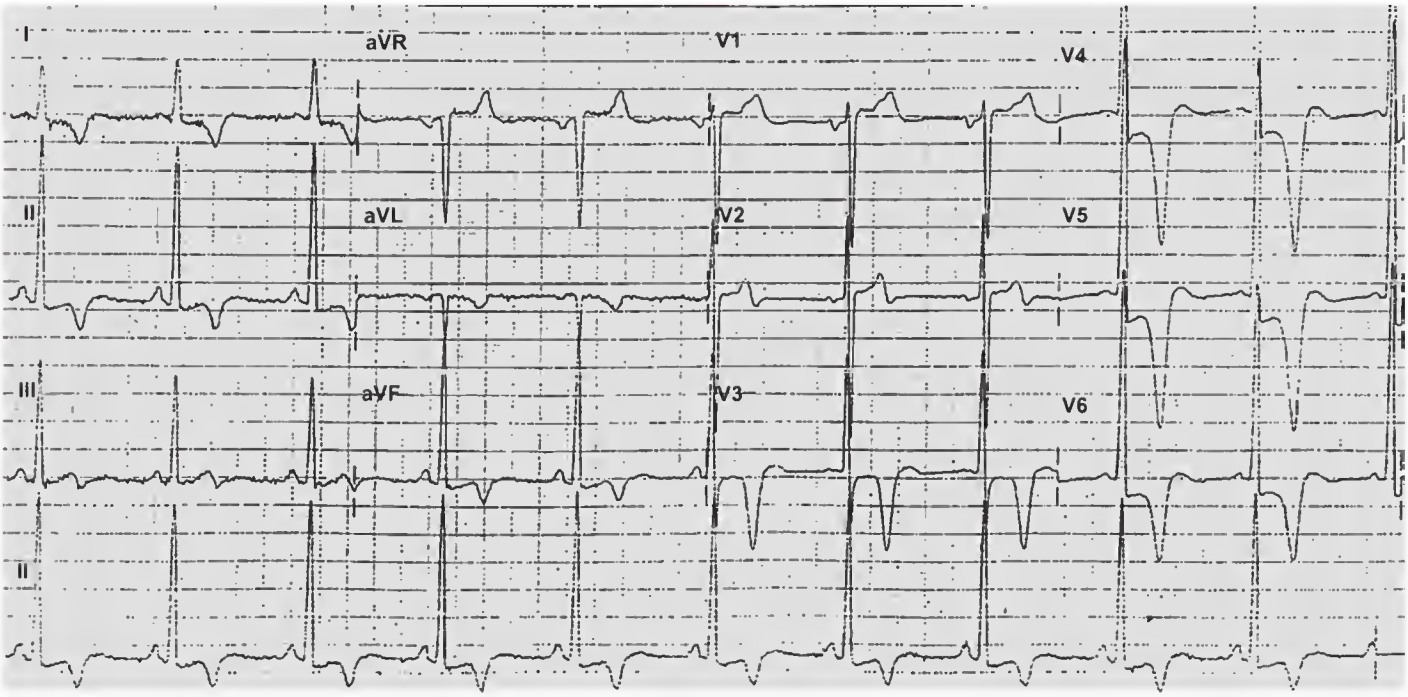

Figure 6: ECG of a patient with apical HCM showing giant T wave inversions (defined as ≥5 mm in limb leads and ≥10 mm in chest leads) with tall R waves.

vascular dysfunction, left ventricular outflow tract obstruction (LVOTO) and diastolic dysfunction.

Table 3: Effect of Changes in Preload, Afterload and Myocardial Contractility on LVOT Gradient and HCM Murmur

Manoeuvres increasing LVOT Gradient and Intensity of Murmur	Manoeuvres Decreasing LVOT Gradient and Intensity of Murmur
I **Decreased preload**	I **Increased preload**
Valsalva manoeuvre	IV fluids
Standing	Supine position
Nitrates	II **Increased afterload**
II **Decreased afterload**	Squatting
ACEIs/ARBs	Isometric handgrip
Amyl nitrite/Nitroglycerine	
III **Increased myocardial contractility**	
Premature ventricular contractions	
Exercise	

Natural History

Natural history of HCM is variable. Some patients remain asymptomatic throughout life, whereas in others, clinical course is marked by occurrence of symptoms of heart failure, atrial arrhythmias or sudden cardiac death (SCD). Symptoms may develop at any age. Hypertrophic cardiomyopathy related mortality in the community is about 1% per year in adults and 2% per year in children. Three per cent of patients develop end-stage disease characterised by wall-thinning and systolic dysfunction mimicking dilated cardiomyopathy.

Clinical Presentation

Most common presenting symptoms in affected patients include dyspnoea on exertion, angina, fatigue, presyncope or syncope and palpitations. Syncope may result from sudden reduction in cardiac output secondary to atrial or ventricular arrhythmias or significant LVOTO. Physical examination in patients without obstruction may just reveal brisk carotid upstroke and a left-sided fourth heart sound. In patients with LVOTO physical examination demonstrates a prominent 'a' wave in jugular venous waveform, bifid carotid pulse with brisk upstroke and a secondary shoulder, double or triple apical impulse, reversed splitting of second heart sound and a dynamic ejection systolic murmur at the left lower sternal border and apex. Ejection systolic murmur varies in intensity with the magnitude of LVOTO (**Table 3**). Pansystolic murmur (PSM) of mitral regurgitation is heard at the apex in some patients with obstruction.

Investigation

Electrocardiographic abnormalities are seen in 90% to 95% of patients with HCM which include LV hypertrophy, left atrial enlargement, ST segment and T wave abnormality, prominent Q-waves and diminished R-waves in lateral precordial leads. Periodic ambulatory Holter monitoring detects atrial or ventricular arrhythmias and helps risk stratify patients for SCD. Failure of blood pressure to increase during cardiopulmonary exercise testing identifies a subset with increased risk for SCD.

Echocardiography is the 'gold standard' for diagnosis of HCM and for screening asymptomatic relatives. Classical 2D echocardiography findings include asymmetrical septal hypertrophy (**Figures 7 and 8**), small LV cavity, LA enlargement and SAM of anterior mitral leaflet. Doppler echocardiography can assess diastolic dysfunction, measure left ventricular outflow tract (LVOT) pressure gradient and quantify mitral regurgitation. Since LVOT gradient is dynamic, Doppler assessment should be done both at rest and after provocative manoeuvres like Valsalva and exercise. Magnetic resonance imaging (MRI) is useful when hypertrophy is confined to unusual areas like apex or anterolateral free wall, which are difficult to image adequately with echocardiography.

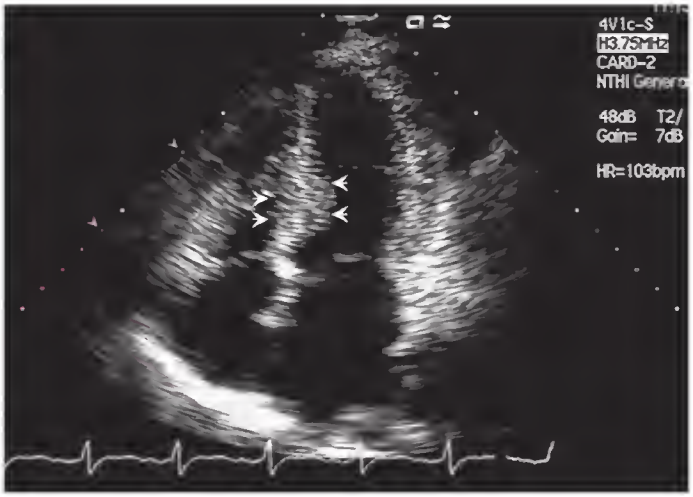

Figure 7: 2D echocardiographic image (apical 4-chamber view) showing hypertrophied basal septum (arrows) in a patient with HCM.

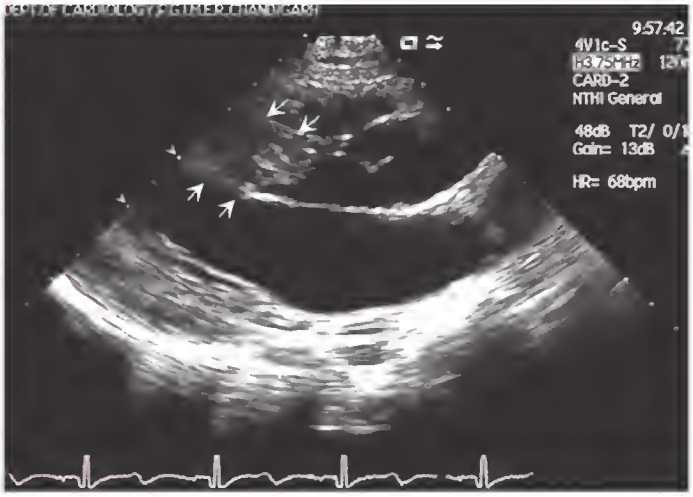

Figure 8: 2D echocardiographic image (parasternal long-axis view) showing hypertrophied basal septum (arrows) in a patient with HCM.

Cardiac catheterisation is indicated in patients with chest pain and atherosclerotic risk factors to exclude epicardial coronary artery disease. It can quantify LVOT gradient at rest or with provocation in patients with LVOTO (**Figure 9**).

Pathology

Grossly the heart is overweight and bulky with regional or concentric left ventricular hypertrophy. Myocardial hypertrophy is strikingly variable in extent and distribution. Asymmetric patterns of hypertrophy are more common, often confined to basal anterior septum, but occasionally to posterior septum, anterolateral free wall or apex. In some patients, disease involves both the ventricles or is confined only to the right ventricle. The magnitude of hypertrophy may vary from minimal to marked (wall thickness up to 60 mm), even in patients with similar genotypes. Mitral valve is elongated and enlarged in two-thirds

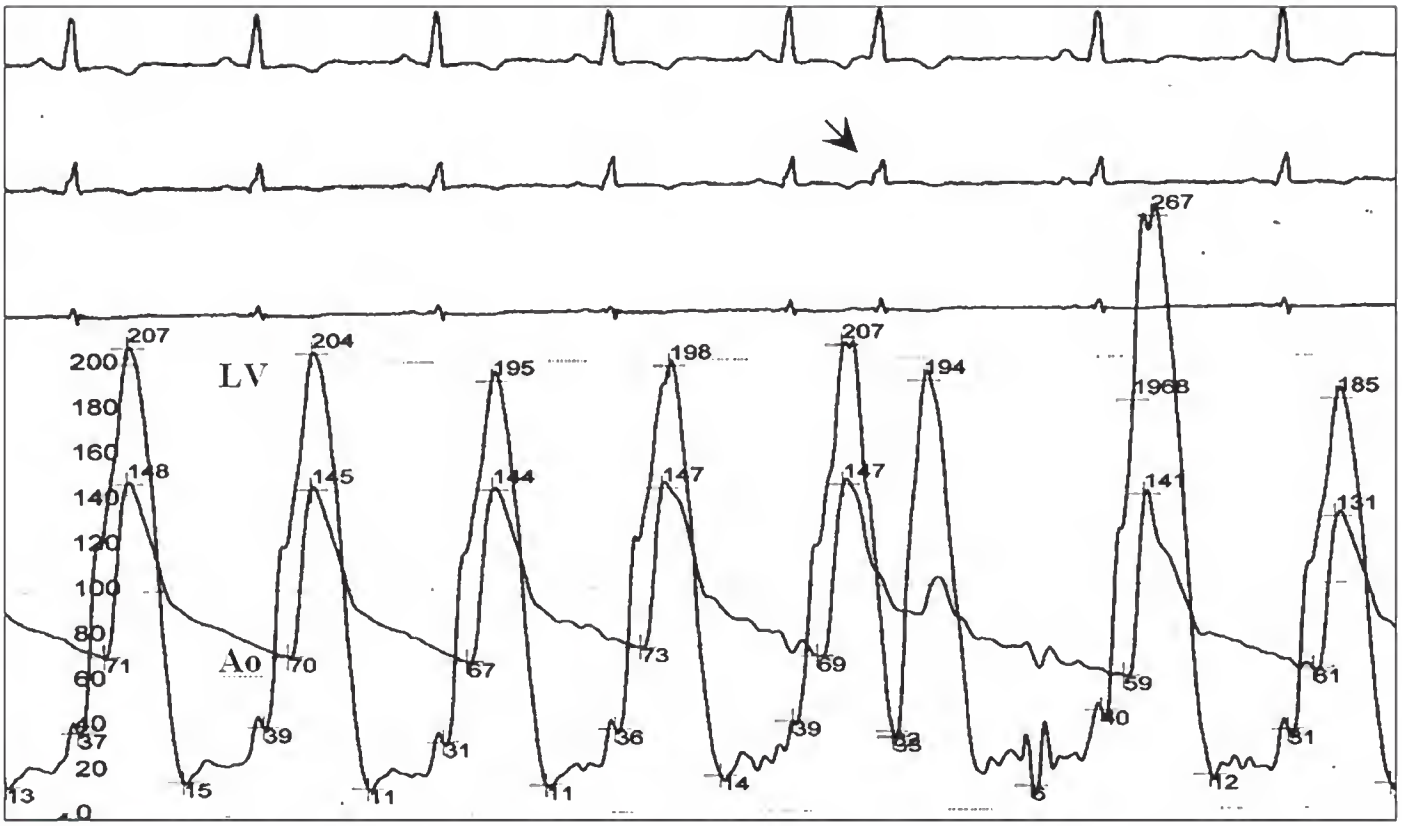

Figure 9: Simultaneous LV and aortic (Ao) pressure tracings in a patient with obstructive HCM showing marked increase in LV-aortic pressure gradient and decrease in pulse pressure following a premature ventricular contraction—the Brockenbrough Braunwald phenomenon.

of patients. This along with basal anterior septal hypertrophy narrows the left ventricular outflow tract and contributes to left ventricular outflow tract obstruction. The subepicardial coronary arteries are usually normal.

Myocyte disarray with myocardial hypertrophy is appreciable at light microscopy. The myocytes display bizarre forms with herringbone pattern. Myocyte disarray is characteristic and occupies at least 20% of one or more tissue blocks. The interstitial arteries are thickened with smooth muscle proliferation.

Risk Stratification and Sudden Cardiac Death

Sudden cardiac death in HCM is most common in adolescents and young adults and has a predilection for early morning hours. Hypertrophic cardiomyopathy is the most common cause of SCD in competitive athletes. Major underlying mechanism of SCD in these patients is ventricular tachyarrhythmias. Several risk factors for SCD have been identified (**Table 4**). The incidence of SCD is 1% per year in patients with ≤1 risk factors and 3% per year in patients with ≥2 risk factors.

Table 4: Risk Factors for SCD in HCM

Proven Risk Factors
Aborted cardiac arrest
Spontaneous sustained ventricular tachycardia
Family history of premature SCD
Unexplained syncope
LV wall thickness ≥30 mm
Multiple repetitive non-sustained VT on Holter monitoring
Abnormal BP response to exercise

Treatment

Affected individuals should be counselled to avoid strenuous exercise and competitive sports. Symptomatic patients with LVOTO are first managed medically. Medical therapy consists of β-blockers, calcium channel blockers and disopyramide. β-blockers are used as first-line agents. They improve disabling symptoms and limit the latent outflow gradient provoked during exercise when sympathetic tone is high by virtue of their negative ionotropic and chronotropic effects. β-blockers lessen LV contractility and myocardial oxygen demand and possibly reduce microvascular myocardial ischaemia. β-blockers are less effective in patients with obstruction under basal condition. Disopyramide is an important agent in such patients. It decreases both resting and provocable gradients but has anticholinergic side effects which should be watched for. It should be avoided in patients with benign prostatic hypertrophy and glaucoma. Disopyramide can result in fast ventricular response if patient develops atrial fibrillation (AF) and should always be used with β-blockers. Angiotensin converting enzyme inhibitors increase outflow tract obstruction and should be avoided. Patients with obstructive HCM who remain symptomatic despite medical therapy can be treated with surgical myomectomy or alcohol septal ablation. In alcohol septal ablation, selective injection of 1 to 2 mL of absolute alcohol in first septal branch of left anterior descending artery causes infarction and necrosis of hypertrophied part of the septum and relieves outflow obstruction. Elderly patients with obstructive HCM or patients with mid-cavitary obstruction may benefit from dual chamber pacing with short AV delay. Patients with ≥1 major risk factors for SCD should be offered ICD. Prospective screening of family members of affected individuals should be done with yearly 12-lead ECG and echocardiography

beginning at 12 years of age and continued up to 18 to 21 years of age and thereafter every five years.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy (RCM), a less common form of cardiomyopathy, is characterised by increased ventricular stiffness that results in impaired diastolic filling of the ventricle. The systolic function remains normal in early stages of the disease process. The ventricular wall thickness is either normal or increased depending on the underlying aetiologies.

Aetiology

Restrictive cardiomyopathy can occur in an idiopathic form or as part of specific disorders (**Table 5**). Idiopathic RCM is most common (50% of all cases) and can be familial with autosomal dominant mode of inheritance. Among the specific forms of RCM, amyloidosis is the most common outside the tropics. Endomyocardial fibrosis (EMF) is particularly common in the tropics.

Table 5: Secondary Causes of Restrictive Cardiomyopathy

Amyloidosis
Endomyocardial fibrosis
Sarcoidosis
Storage disorders: Haemachromatosis, Fabry's disease, Glycogen storage disorder
Drugs: Anthracyclines, Serotonin, Methysergide
Others
Gaucher's disease
Scleroderma
Hurler's syndrome
Hunter's syndrome
Pseudoxanthoma elasticum
Hyper-eosinophilic syndrome
Carcinoid heart disease
Metastatic cancer
Radiotherapy

Clinical Presentation

Patients with RCM can present with symptoms and signs of right or left ventricular failure. Right-sided symptoms and signs predominate in most patients. Left-sided involvement gives rise to dyspnoea on exertion, paroxysmal nocturnal dyspnoea and orthopnoea. Thromboembolic complications are common. Conduction blocks are common in amyloidosis and sarcoidosis whereas atrial fibrillation (AF) is seen in idiopathic form.

Physical examination reveals tachycardia. JVP is elevated with rapid 'x' and 'y' descents. Kussmaul's sign is present in some patients. Hepatomegaly, peripheral oedema and ascites are often present. Cardiovascular findings include third and fourth heart sounds and pansystolic murmurs of mitral and/or tricuspid regurgitation. Cardiomegaly is characteristically absent. It is important to accurately differentiate RCM from constrictive pericarditis (**Table 6**) which can present with similar findings but can be cured surgically.

Investigations

Electrocardiography shows non-specific ST- and T-wave abnormalities. There may be evidence of left ventricular hypertrophy, AF or conduction abnormalities. In amyloidosis, ECG may reveal low voltage in limb leads and normal or increased voltage in precordial leads. Chest X-ray may show evidence of atrial enlargement with pulmonary venous congestion. Cardiac size is within normal limits. Echocardiography reveals normal-sized ventricles with biatrial enlargement and evidence of atrioventricular valve regurgitation (**Figure 10**). Ventricular walls may be thickened in patients with infiltrative disorders and may show characteristic granular and sparkling appearance and thickened interatrial septum in amyloidosis (**Figure 10**). Doppler echocardiography reveals characteristic restrictive pattern of mitral inflow velocity (**Figure 11**). Cardiac catheterisation shows characteristic 'dip and plateau' configuration in ventricular pressure tracing. Endomyocardial biopsy may reveal specific causes of RCM like amyloidosis, sarcoidosis and storage disorders. CT chest for pericardial thickness and calcification should be done in every case to rule out constrictive pericarditis.

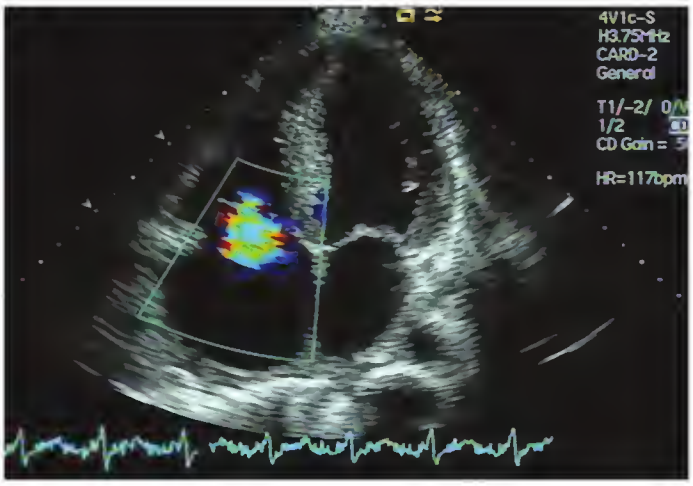

Figure 10: 2D echocardiographic image (apical 4-chamber view) showing dilatation of both the atria with normal-sized ventricles and mild tricuspid regurgitation in a patient with amyloidosis. Note the granular and sparkling appearance of interventricular septum.

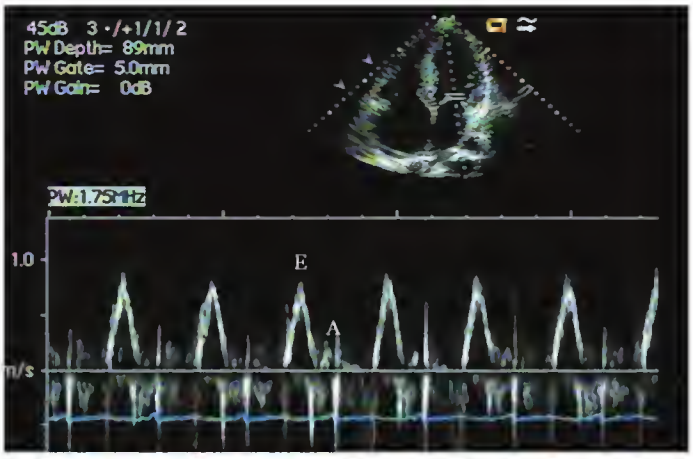

Figure 11: Pulse wave Doppler interrogation of mitral inflow velocities showing restrictive LV filling pattern (E > A) in a patient with RCM.

Pathology

Based on pathological involvement, RCM can be divided into two groups—with predominant endocardial involvement, or myocardial involvement. Conditions causing predominant endocardial involvement include EMF, Loeffler's endocarditis, carcinoid heart disease, metastatic cancers, radiation and drugs. Conditions with predominant myocardial involvement include idiopathic RCM, infiltrative disorders (amyloidosis, sarcoidosis) and storage disorders (haemachromatosis, Fabry's disease).

Table 6: Differentiating Restrictive Cardiomyopathy from Constrictive Pericarditis

	Restrictive Cardiomyopathy	Constrictive Pericarditis
Physical Examination		
JVP	Kussmaul's sign may be present	Kussmaul's sign usually present
Pulsus paradoxus	Absent	Present in one-third of cases
Apical impulse	Prominent	Usually not palpable
S2	Loud with narrow splitting	Wide split
S3	Present	Absent
Pericardial knock	Absent	Present
Murmur of MR/TR	Common	Uncommon
Electrocardiography	Conduction blocks common	Conduction blocks uncommon
Chest X-ray	No cardiomegaly; no pericardial calcification; signs of pulmonary venous congestion present	Pericardial calcification may be seen
2D-Echocardiography		
Posterior wall flattening in mid/late diastole	Absent	Present
Septal bounce	Absent	Present
Atrial enlargement	Marked	Mild
Pericardial thickness	Normal (<2 mm)	Increased
Doppler Echocardiography		
Significant respiratory variation in mitral (>25%) and tricuspid inflow velocities (>40%)	Absent	Present
Hepatic-vein diastolic flow reversal	More in inspiration	More in expiration
MR/TR	Common/Moderate-to-severe	Uncommon/Mild
Catheterisation		
Difference between LVEDP and RVEDP	>5 mm Hg	≤5 mm Hg
RV systolic pressure (RVSP)	>50 mm Hg	<50 mm Hg
RVEDP/RVSP	<one-third	>one-third
Endomyocardial Biopsy	Abnormal; may reveal aetiological diagnosis	Usually normal
CT/MRI	Pericardium usually normal	Pericardium is thickened

Characteristic gross examination findings in EMF and Loeffler's endocarditis include diffuse mural thrombi in ventricles obliterating the apices. In amyloidosis, the heart appears tan, firm and rubbery (**Figure 12**).

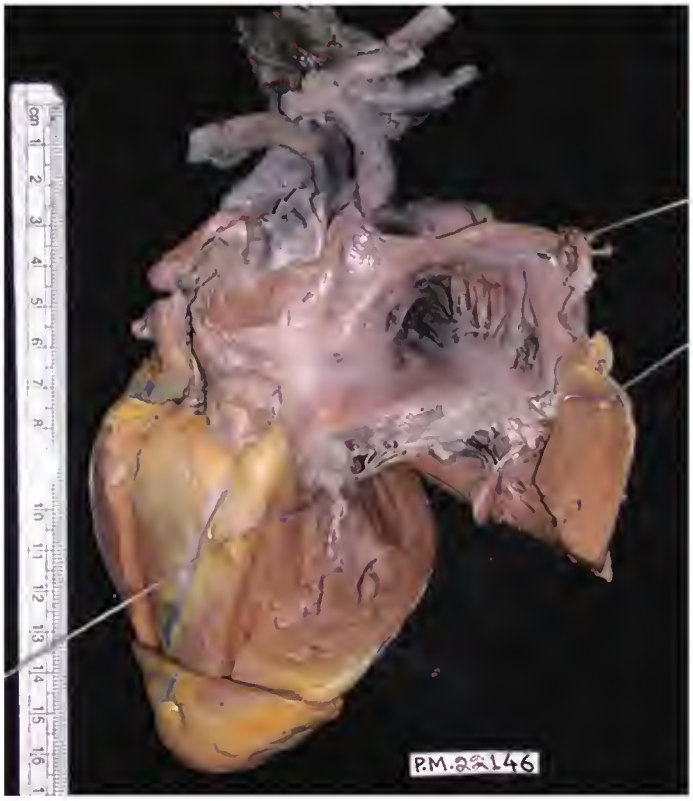

Figure 12: Gross photograph showing normal-sized left ventricle with tan, firm and rubbery myocardium and dilated left atrium in a patient with amyloidosis.

Microscopically, Loeffler's endocarditis is characterised by eosinophilic necrotising myocarditis. Amyloid deposits appear as hyaline eosinophilic material surrounding myocytes in the interstitium. This material is congophilic and gives apple green birefringence on polarised light (**Figure 13**).

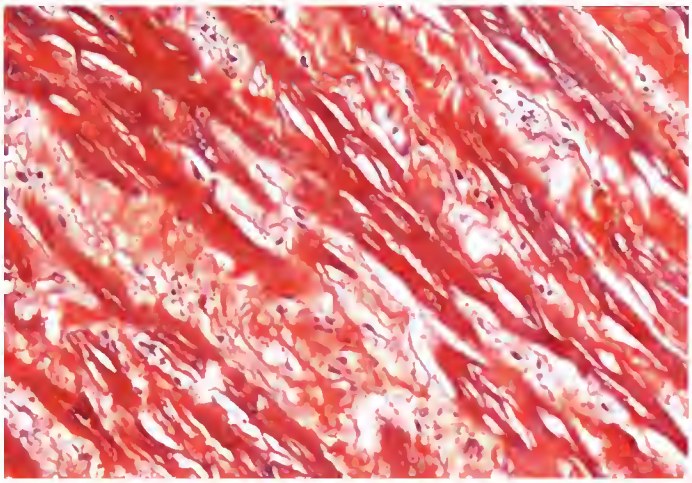

Figure 13: Microphotograph showing amyloid material deposited in the interstitium and myocytes (Congo Red X 140).

Treatment

Diuretics are used to treat pulmonary and systemic venous congestion. Atrial fibrillation is poorly tolerated due to loss of atrial contribution to ventricular filling and rapid ventricular response. Attempt should be made to maintain sinus rhythm by electrical cardioversion or anti-arrhythmic drugs. Digoxin should be used with caution in patients with amyloidosis due to its arrhythmogenic potential. Patients with AF, valvular

regurgitation and low ejection fraction are at increased risk of thromboembolism. They should be treated with oral anticoagulation. Patients with conduction blocks may require pacemaker implantation. ICD is indicated in patients with sustained ventricular arrhythmias.

Therapies for secondary forms of RCM are tailored to the underlying aetiologies—chemotherapy and autologous stem cell transplantation for amyloidosis, enzyme replacement therapy for Fabry's disease, iron chelation for haemachromatosis and immunosuppressive therapy for sarcoidosis.

Prognosis

Prognosis in RCM is variable depending on the underlying aetiology. RCM secondary to amyloidosis has poor prognosis with a median survival of less than two years. Idiopathic RCM has intermediate prognosis with five years survival of 64%.

Endomyocardial Fibrosis

Endomyocardial fibrosis (EMF) is characterised by fibrotic thickening of the endocardium and obliteration of right, left or both the ventriclular cavities. The disease has predilection for involvement of apices and inflow portion of the ventricles resulting in atrioventricular (AV) valve regurgitation. Right ventricular involvement is most common followed by left ventricular and biventricular involvement. Endomyocardial fibrosis is common in Brazil, Uganda, Nigeria, Ivory Coast and Kerala in Southern India. Several hypotheses have been proposed to explain the aetiology of EMF. They include hyper-eosinophilia, excessive consumption of plantains rich in serotonin, excessive consumption of cassava tubers which are rich in vitamin D, or a diet rich in thorium and deficient in magnesium (geochemical hypothesis). Endomyocardial fibrosis differs from other forms of RCM by the presence of marked cardiac enlargement due to AV valve regurgitation. Echocardiography reveals aneurysmal atria and small ventricles with apical fibrosis and cavitary obliteration. Intra-atrial thrombi and AV valve regurgitation are common findings. Endo-cardiectomy ± AV valve repair or replacement is the surgical treatment of choice in patients with advanced disease. Mild cases are treated conservatively with diuretics and digoxin.

OTHER SPECIFIC FORMS OF CARDIOMYOPATHY

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is characterised by development of left ventricular systolic dysfunction and symptoms of heart failure between the last month of pregnancy and the first five months postpartum. Incidence rates vary from 1 in 1,485 to 1 in 15,000 live births. Proposed aetiopathogenesis include myocarditis, abnormal immune response to pregnancy, nutritional deficiencies, abnormal prolactin levels and maladaptive response to the haemodynamic stresses of pregnancy. Peripartum cardiomyopathy is more common with advanced maternal age, multiparous state, multiple gestation, obesity, black race and pre-eclampsia. Clinical presentation and treatment are similar to that in DCM. Dopamine agonist, bromocriptine has shown encouraging results in pilot studies. Mortality is 25% to 50%. Fifty per cent of patients experience resolution of symptoms with normalisation of chamber dimensions and systolic function. Patients with persistent LV systolic dysfunction are at increased risk of death in subsequent pregnancy and should be advised to avoid pregnancy.

Alcoholic Cardiomyopathy

Long-term alcohol consumption is an important cause of dilated cardiomyopathy accounting for 3.8% of all cases. Alcohol is a myocardial toxin which causes myocyte apoptosis and changes in many aspects of myocyte function ultimately leading to chamber enlargement and systolic dysfunction. Asymptomatic alcoholic cardiomyopathy is seen in patients consuming >90 g of alcohol a day for >5 years. Patients who continue to drink develop symptoms of heart failure. Treatment includes standard heart failure therapy and abstinence from alcohol. Prognosis of alcoholic cardiomyopathy patients with abstinence is similar to idiopathic DCM whereas patients who continue to drink fare worse.

Arrhythmogenic Right Ventricular Dysplasia

Arrhythmogenic right ventricular dysplasia or cardiomyopathy (ARVD/C) is a familial cardiomyopathy, mainly affecting the right ventricle (RV). Most common mode of inheritance is autosomal dominant. It is characterised by fibrofatty replacement of the myocardium. The disease typically affects inflow, apical, and outflow portions of the RV ('triangle of dysplasia'). Sudden cardiac death due to arrhythmias originating from right ventricle is the most common mode of presentation. Progressive right heart failure develops in late stages of the disease. Echocardiography and MRI form the main stay of diagnosis. Fatty replacement of RV myocardium can be reliably detected by MRI. Therapeutic options in patients with ARVD/C include β-blockers, anti-arrhythmic drugs, or an ICD. Patients with progressive right or biventricular systolic dysfunction are treated with standard therapy for heart failure.

Tako-Tsubo Cardiomyopathy

Tako-tsubo cardiomyopathy is characterised by transient apical ballooning of left ventricle and masquerades as an acute coronary syndrome. Ninety per cent of cases involve post-menopausal women. In majority of cases, symptoms are precipitated by physical or emotional stress. Catecholaminergic surge is incriminated in the pathophysiology of the disease. Presentation is with chest pain and dyspnoea, ST-segment elevation on ECG and elevated cardiac enzymes. Echocardio-graphy shows akinetic/hypokinetic apical portion of LV with hyper contractile basal regions. The shape of LV resembles an octopus pot ('tako-tsubo'). Coronary angiography reveals normal coronaries. Treatment is supportive and prognosis is good.

12.29 Diseases of the Pericardium

Sanjay Tyagi, Amit Mittal

INTRODUCTION

The pericardium is a fibrous sac surrounding the heart, the thicker, outer parietal pericardium and an inner, thinner visceral layer. The two layers are separated by small amount of pericardial fluid (25 to 50 mL) produced by the visceral pericardium. It is an ultrafiltrate of the plasma and is resorbed by the lymphatics. The pericardium prevents friction between the heart and surrounding structures, acts as a mechanical and immunological barrier, and limits distention of the heart thereby maintaining a relatively fixed maximal heart volume.

Only the lower two-third of the parietal pericardium is sensitive to pain, the pain sensation being carried by the phrenic nerves. Inflammation of the pericardial layers is usually caused by infection (viral, bacterial, etc.), but can also have a non-infectious aetiology. Chronic inflammation with fibrosis and calcification can lead to a rigid, thickened and calcified pericardium, with progression to pericardial constriction. The most common forms of pericardial diseases include acute and recurrent pericarditis, isolated pericardial effusion with or without cardiac tamponade, and constrictive pericarditis.

PERICARDITIS

Pericarditis is inflammation of the pericardium with or without an associated pericardial effusion.

It can be of three types:

1. Acute (dry or effusive) pericarditis
2. Recurrent pericarditis
3. Chronic (effusive, adhesive, or constrictive)—lasting three months or more.

Aetiology

Pericarditis has a vast array of causes that can be separated into infectious and non-infectious categories. While in west idiopathic causes account for a greater number of cases, with viral infections being the most frequent cause; in the developing countries, tuberculosis accounts for 60% to 80% of the acute pericarditis (dry or effusive). Non-infectious pericarditis can be subdivided into immunoreactive, neoplastic, traumatic and metabolic causes. Some of the common causes are listed in **Table 1**.

ACUTE PERICARDITIS

Acute pericarditis may be either dry or effusive. Bread and butter pericarditis is another name given to dry pericarditis because of the typical appearance when the two layers are separated. Effusive pericarditis involves presence of fluid in excess of 50 mL in the pericardial cavity. Pericardial effusion may be transudate (hydropericardium), exudate, pyopericardium or haemopericardium, or a combination of these.

Clinical Features

Symptoms

Most patients with acute pericarditis experience sharp retrosternal chest pain, but in some cases it may be asymptomatic. Pericardial pain is usually worse with inspiration and when supine, and is relieved by sitting forward. Typically, the pain is referred to the scapular ridge, presumably due to irritation of the phrenic nerves, which pass adjacent to the pericardium. Dyspnoea can occur with acute pericarditis but is common with large pericardial effusions. Patient may experience constitutional symptoms like fever, bodyache, malaise, joint pain, and anorexia.

Signs

Inspection of the praecordium is normal but on palpation pericardial rub may be felt in left parasternal area and apex of the heart. The characteristic sign of acute pericarditis is the 'pericardial rub' heard on auscultation. It is a high-pitched, to-and fro-scratchy sound, heard both in systole and diastole. It is best audible in the third, fourth and fifth left intercostal spaces near the sternal edge, though the location may change with the position of the patient. It is better heard when the patient sits up, leans forward and is heard louder if the diaphragm of stethoscope is pressed harder to the chest wall. Sometimes only the systolic or the diastolic component may be heard and so the rub can be mistaken for a murmur.

Table 1: Aetiology of Pericarditis

Idiopathic or non-specific pericarditis	
Infections	Bacterial, tuberculous, viral (coxsackie, influenza, HIV, etc.), fungal, rickettsial, mycoplasma, leptospiral, listeria, parasitic and others
Vasculitis and connective tissue disease	Rheumatoid arthritis, rheumatic fever, systemic lupus erythematosus, scleroderma, giant-cell arteritis, polymyositis (dermatomyositis), Behçet's syndrome, familial Mediterranean fever and others
Diseases in adjacent structures	Myocardial infarction, aortic dissection, pneumonia, pulmonary embolism, empyema
Metabolic disorders	Uraemia, dialysis-related, myxoedema
Neoplastic disorders	Primary: Mesothelioma, sarcoma, fibroma, lipoma and others Secondary (metastatic or direct spread): Lung carcinoma, lymphoma, carcinoid and others
Trauma	Direct: Pericardial perforation (penetrating injury) and cardiac injury (cardiac surgery, percutaneous procedures) Indirect: Radiation, non-penetrating chest injury
Association with other syndromes	Post-myocardial and pericardial injury syndromes, inflammatory bowel disease, Loffler syndrome, Stevens-Johnson syndrome, giant-cell arteritis, hypereosinophilic syndromes, acute pancreatitis, others

The pericardial rub arises from the inflamed visceral and parietal layers of the pericardium rubbing together but most patients with acute pericarditis (including those with audible rubs) have at least a small pericardial effusion. The pericardial friction rub can be differentiated from a pleural rub, which is absent during held respiration, whereas the pericardial rub is unaffected.

Diagnosis

The diagnosis of acute pericarditis is based on three simple criteria—typical pericardial chest pain, pericardial friction rub and typical electrocardiographic changes. The echocardiographic finding of pericardial effusion, which is not an accepted diagnostic feature, is justified considering that it is a confirmatory finding when present (**Table 2**).

Investigations

Patients with acute pericarditis usually have evidence of systemic inflammation, i.e. leucocytosis, elevated erythrocyte sedimentation rate, and increased C-reactive protein. Troponin levels may also be elevated in acute pericarditis due to some involvement of the myocardium by the inflammatory process.

Electrocardiography

Early in the course of acute pericarditis, the ECG typically shows diffuse ST elevation in association with PR-segment depression (**Figure 1**). The ST elevation is usually present in all leads except for aVR, but in post-myocardial infarction pericarditis the changes may be more localised. Classically, the ECG changes of acute pericarditis evolve through 4 progressive stages shown in **Table 2**.

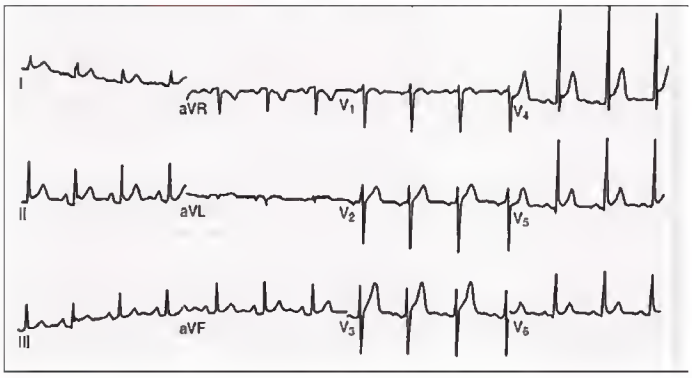

Figure 1: ECG in acute pericarditis. Diffuse ST segment elevation with PR segment depression.

Table 2: Diagnostic Pathway in Acute Pericarditis

Diagnostic Measure	Characteristic Findings
Auscultation	Pericardial rub
ECG	Stage I, diffuse ST segment elevation and PR segment depression
	Stage II, normalisation of the ST and PR segments
	Stage III, widespread T wave inversions
	Stage IV, normalisation of the T waves
Echocardiography	Pericardial effusion
Blood Analysis	Raised ESR, CRP, LDH, leucocytes (inflammation markers)
	Troponin I, CK-MB (markers of myocardial involvement)
Chest X-ray	Ranging from normal to 'water bottle' shape
	Performed primarily to reveal pulmonary or mediastinal pathology

Echocardiograhy

Echocardiography usually demonstrates at least a small pericardial effusion or it may be normal.

Prognosis

Prognosis depends on the aetiology of acute pericarditis. Acute benign or idiopathic forms have an excellent prognosis, while the uraemic pericarditis is usually a harbinger of death. Pericarditis due to rheumatic fever also has a good prognosis.

Treatment

Treatment for pericarditis should be targeted towards the specific aetiology but most cases are idiopathic or viral, so an empirical therapy is required. Empirical therapy in form of NSAIDs or aspirin is the first-line approach and mainstay of treatment. Anti-tubercular and antibiotic treatment should be instituted whenever required along with supportive therapy in the form of salicylates and corticosteroids to bring about early relief and to prevent formation of adhesions. Symptomatic treatment for the relief of fever and pain may be provided with analgesics. Rest and avoidance of physical activity are useful adjunctive non-pharmacologic measures that should be adopted until active disease is no longer evident, especially in case of rheumatic pericarditis.

PERICARDIAL EFFUSION

Pericardial effusion occurs when fluid accumulates in the intrapericardial space. It can occur with or without evidence of inflammation and pericarditis. Idiopathic aetiology is less common in patients with isolated pericardial effusion (**Table 3**).

Pathology

Under normal conditions, the space between the parietal and visceral pericardium contains only a small amount of fluid, usually up to 50 mL or less. In pericardial effusion, the quantity may vary from 200 mL to well over a litre. The fluid may be an exudate or a transudate or may contain blood, pus or chyle.

Clinical Features

Symptoms

They are essentially the same as those of acute pericarditis, but the dyspnoea may be more marked. Dyspnoea is thought to be due to compression of the lungs and bronchi and also due to encroachment on the intrathoracic space. Leaning forward may relieve this dyspnoea. This is because the fluid then gravitates forwards and downwards, exerting lesser pressure on the lungs and bronchi. If the effusion is large and produces sufficient pressure on the bronchi and oesophagus, it may result in a dry hacking cough, hoarseness of the voice and difficulty in swallowing.

Signs

On inspection, a cyanotic tinge may be observed in large effusions. Examination of the heart reveals the apex beat to be either weakly palpable or it may not be palpable at all. Bulging of the praecordium and the xiphisternum may be seen. There are very few or no palpable precordial pulsations.

Percussion of the heart reveals an increase in the area of the cardiac dullness especially on the left-side. Percussion of the back reveals an area of dullness in the left infrascapular region with bronchial breathing and aegophony (Ewart's sign). This is due to a compression of the base of the left lung. On auscultation, the heart sounds are muffled. A pericardial rub may be occasionally heard, though it tends to disappear with the accumulation of fluid (**Table 3**).

Table 3: Pericardial Effusion: Salient Features

Silent praecordium
Tachycardia
Ewart's sign
Muffled heart sounds

CARDIAC TAMPONADE

Cardiac tamponade is a medical emergency and its diagnosis is of major clinical importance. It has been described as 'an impaired diastolic filling of the ventricles due to raised intrapericardial pressure as a result of fluid accumulation in the intrapericardial space'.

Aetiology

Pericardial disease of almost any aetiology can produce cardiac tamponade by effusion accumulation and increased intrapericardial pressure. The most common causes are idiopathic, malignancy, tuberculosis, radiation, myxoedema, post-cardiotomy and lupus.

Haemodynamics

Cardiac tamponade occurs when fluid accumulation in the intrapericardial space is sufficient to raise the pressure surrounding the heart to the point where cardiac filling is altered. Ultimately, compression of the heart by a pressurised pericardial effusion results in markedly elevated venous pressures and impaired cardiac output producing shock. Because of its lower pressures, the right heart is most vulnerable to compression by a pericardial effusion, and abnormal right heart filling is the earliest sign of a haemodynamically significant pericardial effusion.

The increased pericardial pressure in cardiac tamponade accentuates the interdependence of the cardiac chambers as the total cardiac volume is limited by the pericardial effusion. The volume in any cardiac chamber can only increase when there is an equal decrease in the volume in other chambers. Because the total intrapericardial volume is fixed by the effusion, the increased inspiratory right ventricular filling crowds the left ventricle and impairs its filling (**Figure 2A**). Thus, in tamponade, left heart filling occurs preferentially during expiration when there is less filling of the right heart. The small normal respiratory variation in left ventricular stroke volume and systolic arterial pressure is markedly accentuated in cardiac tamponade, resulting in the clinical finding of 'paradoxical pulse'. Owing to decreased cardiac output a compensatory tachycardia ensues. Eventually, the systemic pressure falls (**Figure 2B**).

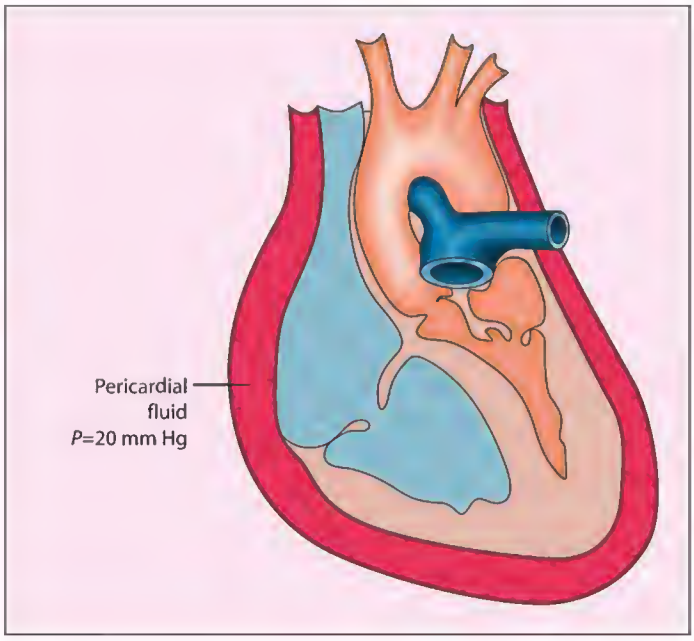

Figure 2A: Schematic illustration of leftward septal shift with encroachment of left ventricular volume during inspiration in cardiac tamponade.

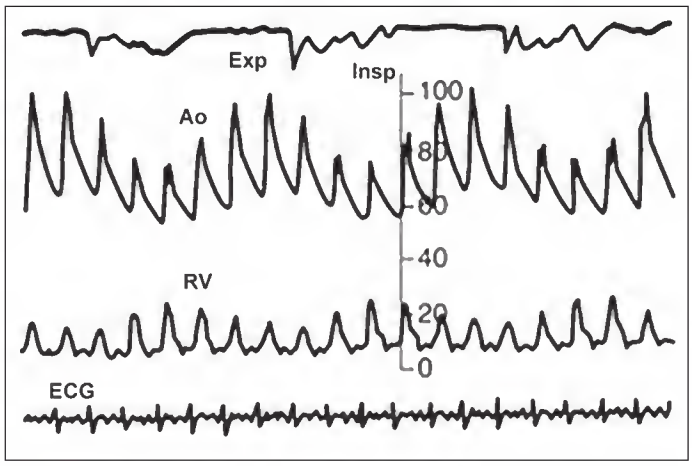

Figure 2B: Respiration marker and aortic and right ventricular pressure tracings in cardiac tamponade. A paradoxical pulse and marked, 180-degree, out-of-phase respiratory variation exists in right- and left-sided pressures.

Clinical Features

Symptoms

Cardiac tamponade is a treatable cause of cardiogenic shock that can be rapidly fatal if unrecognised. Patients with impending or early tamponade are usually anxious and may complain of dyspnoea and chest pain. Other symptoms include cough, fatigue and presyncope. With progression, patient presents with shock, altered mental status and pulseless electrical activity.

Signs

Cyanosis may be present and the patient usually sits up and leans forward or may assume a knee-chest position. Cardiac tamponade is suspected in a patient who runs a rapid downhill course and exhibits the tetrad of rising venous pressure, fall in arterial pressure, small quiet heart and tachycardia.

The increased venous pressure is usually apparent as jugular venous distension. The X-descent is typically the dominant jugular venous wave with little or no Y-descent. The heart sounds are classically soft or muffled; especially if there is a large pericardial effusion. The hallmark of cardiac tamponade is a paradoxical pulse. A paradoxical arterial pulse with a diminution in the volume during deep inspiration is quite characteristic of large effusions. This may be further corroborated by the use of a sphygmomanometre, i.e. reduction of >10 mm Hg in systolic pressure during inspiration.

Investigations for Pericardial Effusion and Cardiac Tamponade

General investigations for pericardial effusion and cardiac tamponade include routine blood counts and ESR. There may be leucocytosis and neutrophilia and the sedimentation rate may be high.

Electrocardiography

ECG can be normal or non-specific ST-T-wave changes are seen, total electrical alternans is seen in large effusions and tamponade (**Figure 3**). Bradycardia and electromechanical dissociation are diagnostic of end-stage tamponades.

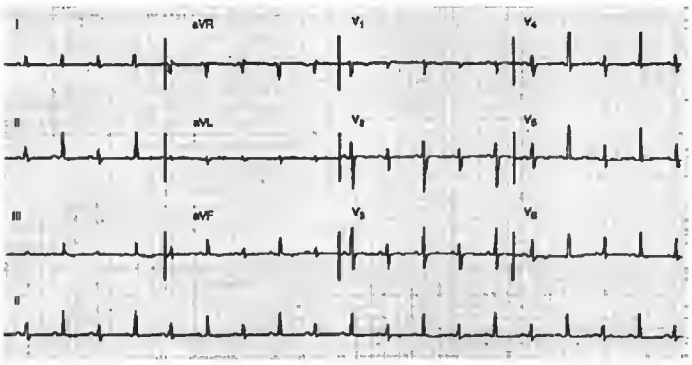

Figure 3: Total electrical alternans seen in large pericardial effusion and cardiac tamponade.

X-ray

In pericardial effusion, the cardiac silhouette will be increased in size. Enlarged cardiac silhouette with clear lungs on chest radiograph is very characteristic of large pericardial effusion (Money Bag appearance) (**Figure 4**). The individual chamber and blood vessel contours are lost.

Echocardiography

Echocardiography is an important part of the evaluation in patients with pericardial effusion and cardiac tamponade. The most important finding is the separation of the two pericardial layers by an 'echo-free' space. Small pericardial effusions are only seen posteriorly. Pericardial effusions large enough to produce cardiac tamponade are almost always circumferential (both anteriorly and posteriorly).

Figure 4: Enlarged cardiac silhouette with clear lung field in large pericardial effusion.

Echocardiography reveals the size of effusions:

1. Small (echo-free space in diastole <10 mm)
2. Moderate (at least >10 mm posteriorly)
3. Large (>20 mm)
4. Very large (>20 mm with compression of the heart)

In cases of gross effusion, the heart assumes a 'swinging' effect, wherein the heart seems to oscillate within the pericardial sac. Echocardiography also provides information on the significance of the pericardial effusion. In the presence of cardiac tamponade, there is diastolic collapse of the free walls of the right atrium and/or right ventricle (**Figures 5 and 6**). The collapse is exaggerated during expiration when right heart filling is reduced. Right atrial collapse is more sensitive for tamponade, but right ventricular collapse lasting more than one-third of diastole is a more specific finding for cardiac tamponade. On echo Doppler study, there can be marked reciprocal respiratory variation in mitral and tricuspid flow velocities reflecting the enhanced ventricular interdependence that is the mechanism of the paradoxical pulse.

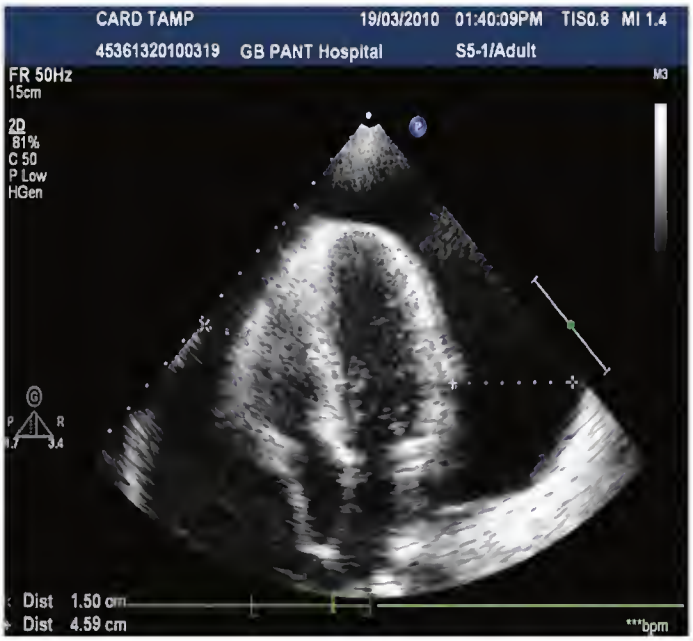

Figure 5: Echocardiography showing circumferential pericardial effusion with RA collapse (White or red arrow).

Diagnostic and Therapeutic Pericardiocentesis

Aspiration of the pericardial fluid will not only confirm the diagnosis but also help in detection of the aetiology. The aspirated fluid should be analysed and sent for bacteriological culture and sensitivity tests. If there is no haemodynamic compromise and the diagnosis can be established by other means, pericardiocentesis may not be necessary but it is generally advisable in patients with very large pericardial effusions (>20 mm on echocardiography), even in the absence of tamponade. It must be recognised that pericardiocentesis will not yield a diagnosis in most patients and, therefore, the reason for draining large effusions is to avoid potential progression to tamponade.

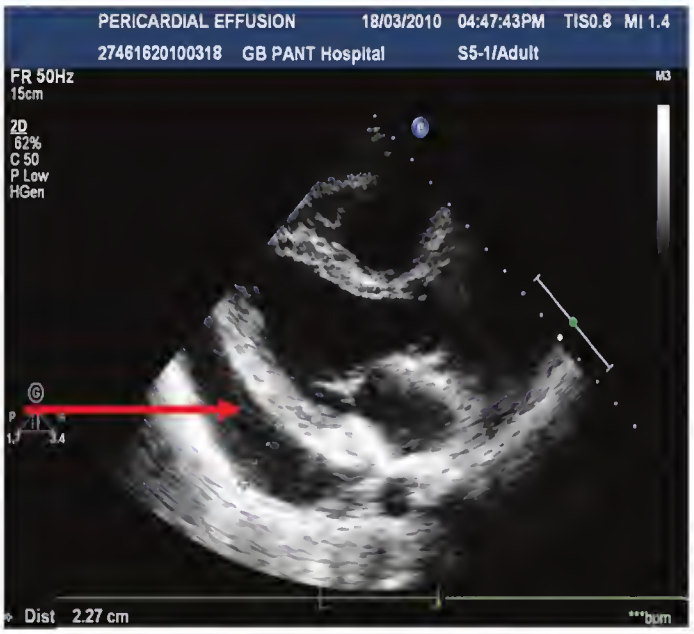

Figure 6: Echocardiography showing large posterior pericardial effusion (Red arrow).

Other Investigative Procedures

Computerised axial tomography and magnetic resonance imaging also help, especially when echocardiography does not reveal good images due to pulmonary disease.

Prognosis

This depends on the aetiological factor. Tuberculous pericardial effusion very often results in chronic constrictive pericarditis. Pericardial effusion in uraemia and neoplasms are harbingers of death. Purulent pericardial effusion, if not treated vigorously, may prove fatal.

Treatment

The treatment of pericardial effusion is two-fold; treatment of the aetiological factor and treatment of the effusion.

The treatment of cardiac tamponade is drainage of the pericardial effusion. Medical management is usually ineffective and should be used only while arrangements are being made for pericardial drainage. Fluid resuscitation may be of transient benefit if the patient is volume depleted. The use of inotropic agents is usually ineffective because there is already intense endogenous adrenergic stimulation.

PERICARDIOCENTESIS

Pericardiocentesis is the aspiration of the pericardial fluid for therapeutic as well as for diagnostic purposes. Indications for pericardiocentesis are: cardiac tamponade, diagnosis of the aetiology of pericardial effusion and introduction of drugs into the pericardial cavity (when indicated).

Procedure

Pericardiocentesis can be performed either using fluoroscopic (cardiac catheterisation laboratory) or preferably in the intensive care unit, under echocardiographic guidance. There are various sites for aspiration but the two commonest sites used are the subxiphoid and the left fifth intercostal space. The subxiphoid approach is the much preferred route, as one can aspirate fluid even in the case of small effusions. This route is extrapleural and avoids the coronary, pericardial, and internal mammary arteries. It is prudent to drain the fluid in stepped amounts of less than 1 litre at a time to avoid acute right ventricular dilatation.

The feasibility of pericardiocentesis is high (>93%) in patients with anterior effusion more than 10 mm, while the rate of success is only 58% with small, posteriorly located effusions. The most serious, but rare, complications are lacerations/perforations of the myocardium and the coronary vessels. In addition, patients can experience air embolism, pneumothorax, arrhythmias (usually bradycardia), and puncture of the peritoneal cavity or abdominal viscera.

If the fluid withdrawn is found to be purulent or there is large effusion then an indwelling pigtail catheter is left in pericardial cavity for drainage of residual or reoccurring effusion later on. Along with this, appropriate antibiotic therapy should be instituted.

SPECIAL FORMS OF PERICARDITIS

1. **Idiopathic Pericarditis**

   As the name suggests, the cause of this type of pericarditis is not known, though it is presumed to be viral. It affects all age groups and presents with fever, bodyache and chest pain. Pericardial effusion develops in about 75% of the cases.

   Treatment consists essentially of rest and analgesics. If pain is very severe and the effusion does not subside, then corticosteroids may be given. Very rarely, constrictive pericarditis may ensue.

2. **Rheumatic Pericarditis**

   This is seen in cases of acute rheumatic fever and is characterised by tachycardia, chest pain and fleeting joint pains. Usually, it is dry pericarditis ('bread and butter' pericarditis) but pericardial effusion may occur. There is complete regression with treatment and no sequelae are seen.

3. **Uraemic Pericarditis**

   Two forms of pericarditis have been described in renal failure:

   (a) Uraemic pericarditis

   Fibrinous inflammation with adhesions between the thickened pericardial membranes ('bread and butter' appearance) caused by the high degree of azotemia in advanced renal failure before dialysis is started or shortly, thereafter. This is seen usually in the terminal stages of uraemia. The pericarditis is of the dry type.

   (b) Dialysis-associated pericarditis

   Patients on maintenance haemodialysis, and occasionally with chronic peritoneal dialysis caused by inadequate dialysis and/or fluid overload.

   Most patients with uraemic pericarditis respond within 1 to 2 weeks to haemo or peritoneal dialysis, with resolution of chest pain and reduction of the pericardial effusion. To avoid intrapericardial haemorrhage, heparin-free haemodialysis should be used.

4. **Post-Infarction Pericarditis**

   Pericarditis may occur 'early' or be 'delayed' (Dressler's syndrome) after myocardial infarction. Early pericarditis occurs in the first few days of a transmural myocardial infarction, although early thrombolytic treatment has decreased its incidence. Dressler's syndrome occurs from

one week to several months after myocardial infarction and is considered to be an autoimmune phenomenon.

Aspirin, up to 650 mg every four hours for 2 to 5 days, has been successfully used to treat post-infarction pericarditis. Other nonsteroidal agents risk thinning the infarction zone. Corticosteroid treatment is used for refractory symptoms but can delay infarction healing.

5. Tuberculous Pericarditis

This is possibly the commonest cause of pericarditis and pericardial effusion in India. It is even more common after the advent of HIV infection and AIDS. Infection occurs through neighbouring structures, e.g. lungs, bronchi, lymph nodes or by blood-borne infection.

The patient may have vague complaints of fever, malaise, evening rise in temperature, loss of weight, etc. There may be no cardiac manifestations initially but later on, chest pain, cough and dyspnoea may appear due to an increase in the size of the effusion.

Aspiration of the fluid reveals either straw-coloured or blood-tinged exudative fluid. A systematic, multiple diagnostic approach is essential, e.g. sputum cultures, analyses of pericardial effusion by acid-fast staining, mycobacterial culture or radiometric growth detection (BACTEC-460), adenosine deaminase (ADA), pericardial lysozyme, and PCR for *Mycobacterium tuberculosis*. High ADA (>40 U/L) in pericardial effusion is diagnostic for tuberculous pericarditis (93% sensitivity, 97% specificity). The absolute criteria for diagnosis are the identification of *Mycobacterium tuberculosis* in the pericardial fluid or tissue, and/or the presence of caseous granulomas in the pericardium. However, pericarditis in proven extracardiac tuberculosis is strongly suggestive of a tuberculous aetiology. PCR is as sensitive (75% vs. 83%), but more specific (100% vs. 78%) for tuberculous pericarditis than ADA. Very often, even on a very close search, no evidence of tuberculosis may be found anywhere in the body.

Tuberculous pericarditis should be promptly treated with a combination of antitubercular drugs according to standard protocols. Prednisone should be administered along with antituberculous drugs as it reduces the host reaction to mycobacterial infections, minimises exudation, fibrin deposition, and proliferation of tuberculomas and may decrease symptoms and signs. However, despite combination therapy, many patients develop constriction and if untreated, it is one of the commonest causes of constrictive pericarditis in India.

6. Purulent Pericarditis

This is due to infection of the pericardium by organisms like the *Staphylococcus, Streptococcus, Pneumococcus, Meningococcus and Haemophilus*, etc. The infection may be either blood-borne, extension of an intrathoracic infection or from outside as in cases of stab wounds.

Patient presents with high-grade fever and appears very toxic. If the effusion accumulates very rapidly it may result in cardiac tamponade. Pericardial fluid aspirate should undergo urgent Gram's, acid-fast, and fungal staining followed by cultures for aerobes and anaerobes. Purulent effusions have significantly lower fluid glucose concentrations than non-infectious effusions.

Purulent pericarditis is an absolute indication for pericardial drainage and rinsing of the pericardial cavity, combined with high doses of systemic antibiotic treatment. A combination of antistaphylococcal antibiotic and aminoglycoside, followed by tailored antibiotic treatment according to the results of pericardial fluid and blood cultures, is mandatory.

7. Viral Pericarditis

This is a common cause of pericarditis and is clinically difficult to differentiate from idiopathic pericarditis. Viral pericarditis can be caused by direct viral attack (enterovirus, adenovirus, cytomegalovirus (CMV), Ebstein-Barr virus, herpes simplex virus, influenza virus, parvo B19, hepatitis C virus, HIV, etc.), the immune response or both. Initial presentation is the syndrome of acute pericarditis, often resolving within two weeks but may progress to pericardial effusion which may be serous, suppurative, or haemorrhagic.

The diagnosis depends on the demonstration of rising titers of specific antibodies in the serum. A four-fold rise in serum antiviral antibodies is suggestive but not diagnostic *per se*. In most patients, pericardial viral infection is self-limiting and no specific treatment is necessary.

8. Neoplastic pericarditis

Neoplastic pericarditis is also an important specific diagnosis to rule out in patients with pericarditis. It is responsible for about 5% of unselected cases of acute pericarditis and may metastasise to the pericardium, with the most common being lung and breast cancer and lymphomas. Lung cancer is the commonest malignancy giving early invasion of lymph nodes and thus being easily responsible for pericardial effusion. Primary tumours of the pericardium are less common.

9. Haemopericardium

Accumulation of blood in the pericardial cavity usually occurs after rupture of a cardiac chamber (after myocardial infarction), coronary artery or a dissecting aneurysm. Rarer causes include scurvy, neoplasms and leukaemia. Pericardial tamponade may occur and need drainage.

10. Pneumopericardium

Air in the pericardial cavity may result from stab wounds, perforation of an air-containing organ into the pericardium, by gas-forming organism or by introduction of air into the pericardial cavity. An X-ray of the chest reveals the presence of gas in the pericardial cavity. This usually does not require treatment, but the underlying cause requires treatment.

CHRONIC CONSTRICTIVE PERICARDITIS

Chronic constrictive pericarditis (CCP) is defined as a dense and rigid thickening of one or both layers of the pericardium with adhesions resulting in compression of the heart with impairment in the diastolic filling.

Aetiology

The most common causes include:

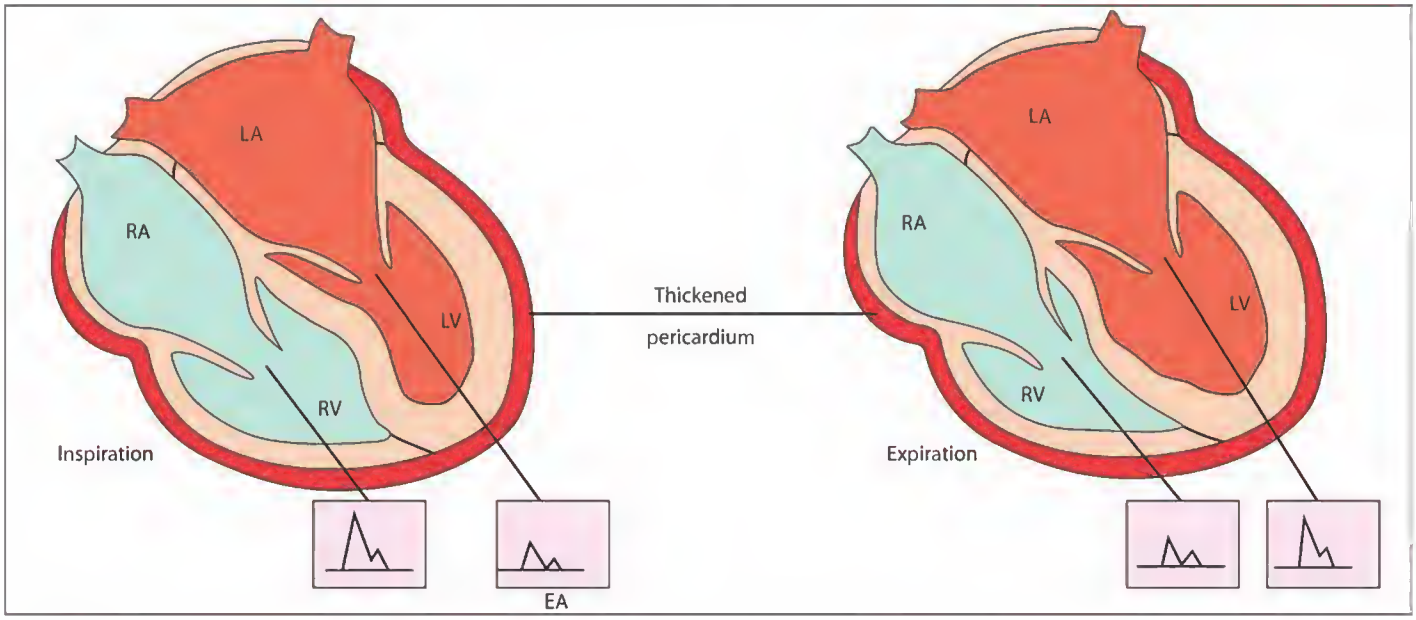
- Tuberculosis
- Idiopathic and viral pericarditis
- Chest irradiation
- Collagen vascular disease

- Post-cardiotomy
- Malignancy

In developing countries with high prevalence of tuberculosis, it is most common cause of CCP. In India, tuberculosis is responsible for nearly two-third of the cases of CCP. The aetiology of CCP in the western world has undergone a significant change, with tuberculosis reported in only 0% to 1% of cases. However, with emergence of the AIDS pandemic these numbers are likely to increase again. The leading identifiable causes of CCP in western world are following cardiac surgery and radiation therapy, besides viral pericarditis, but such cases are possibly missed in India.

Pathophysiology

The pericardium undergoes thickening and calcification (normal thickness of the pericardium is 3 to 5 mm). The thickened pericardium forms an encasement of the heart and is unable to stretch during diastole. The unyielding pericardium impairs the diastolic relaxation of the heart and thereby diminishes venous filling of the right ventricle. However, there is no interference with systole. The pathophysiological hallmark of pericardial constriction is equalisation of the end-diastolic pressures in all four cardiac chambers. This occurs because the filling is determined by the limited pericardial volume, not the compliance of the chambers themselves. Initial ventricular filling occurs rapidly in early diastole as blood moves from the atria to the ventricles without much change in the total cardiac volume. However, once the pericardial constraining volume is reached, diastolic filling stops abruptly. This results in the characteristic dip and plateau of ventricular diastolic pressures. The stiff pericardium also isolates the cardiac chambers from respiratory changes in intrathoracic pressures, resulting in Kussmaul's sign (**Figures 7 and Figures 8A and B**).



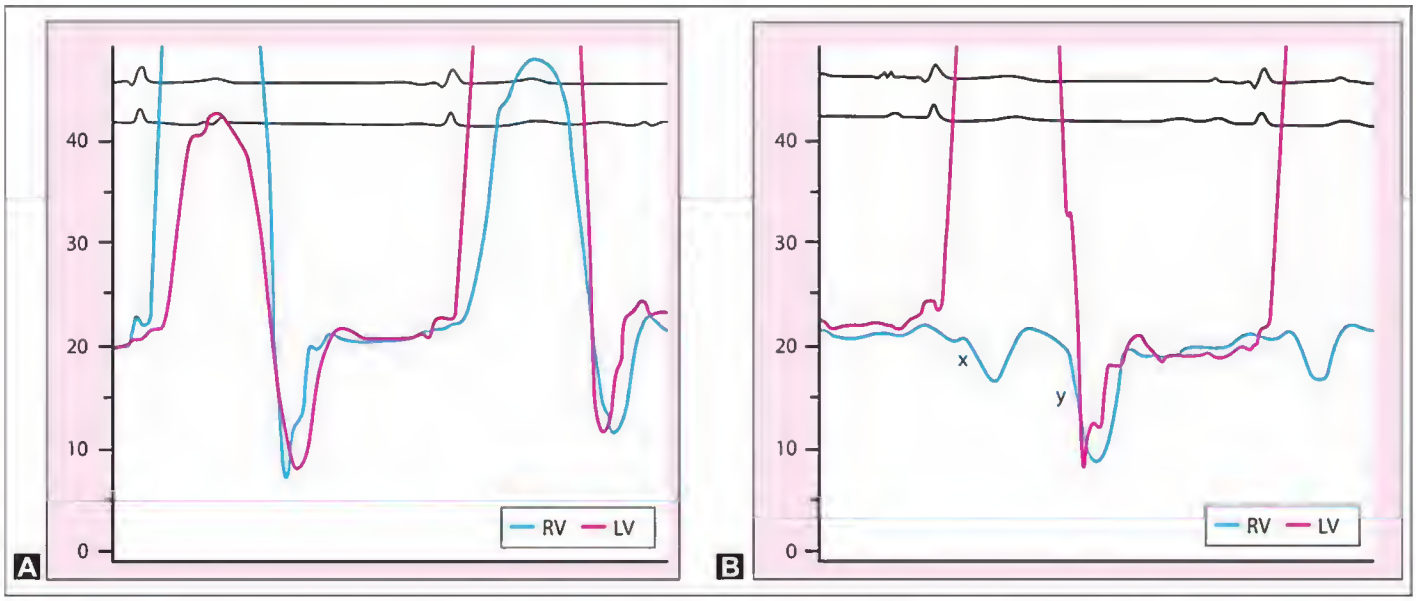


Figure 7: Schematic representation of transvalvular and central venous flow velocities in constrictive pericarditis. During inspiration, the decrease in left ventricular filling results in a leftward septal shift, allowing augmented flow into the right ventricle. The opposite occurs during expiration.

EA = Mitral inflow; LA = Left atrium; LV = Left ventricle; RA = Right atrium; RV = Right ventricle

Figures 8A and B: Pressure recordings in a patient with constrictive pericarditis. (A) Simultaneous right ventricular (RV) and left ventricular (LV) pressure tracings with equalisation of diastolic pressure, as well as 'dip and plateau' morphology. (B) Simultaneous right atrial (RA) and LV pressure with equalisation of RA and LV diastolic pressure. The y-descent is prominent.

Due to the reduction in venous filling, the stroke output falls and to compensate for decreased cardiac output the heart rate rises. The systemic pressure rises because of the limited cardiac filling. The liver and spleen are enlarged and the capsule is thickened as a consequence of chronic congestion.

Haemodynamics in cardiac tamponade and constrictive pericarditis are compared in **Table 4**.

Symptoms and Signs

The commonest complaint is the distension of the abdomen due to ascites and swelling of the feet. The next common complaint is dyspnoea and fatigue.

On inspection, the neck veins are engorged, even in the standing position. A deep 'y' descent (Frederick's sign) is seen. JVP is raised and increases/fails to decrease during deep inspiration (Kussmaul's sign). The arterial pulse is of a low volume and the rhythm may be irregular indicating the presence of atrial fibrillation.

Table 4: Haemodynamics in Cardiac Tamponade and Constrictive Pericarditis

	Tamponade	Constriction
Paradoxical pulse	Usually present	Present in ≈ 1/3
Equal left/right filling pressures	Present	Present
Systemic venous wave morphology	Absent *y* descent	Prominent 'y' descent (M or W shape)
Inspiratory change in systemic venous pressure	Decrease (normal)	Increase or no change (Kussmaul's sign)
'Square root' sign in ventricular pressure	Absent	Present

Inspection of the praecordium reveals a 'quiet' heart and prominent veins may be observed all over the chest. A systolic retraction at the apex may be observed. On palpation, a diastolic 'tap' or 'shock' may be palpated. It is due to the rapid filling of the right ventricle. The characteristic finding on auscultation is the 'pericardial knock'. This is a sound due to rapid filling of the ventricle in the early rapid filling phase. It occurs about 0.08 to 0.12 second after the second sound in contrast to the normal third sound, which occurs a little later (0.13 to 0.16 s). The heart sounds are normal and usually no murmur is heard.

Examination of the abdomen reveals an enlarged, smooth and tender liver. The chief finding in the abdomen, however, is the presence of ascites which is massive and out of proportion to the oedema on the legs (which may be minimal). It tends to refill very rapidly after aspiration.

Investigations

Electrocardiography

The ECG findings are not characteristic but include low voltage of the QRS complexes, flattening or inversion of the T-waves and occasionally atrial fibrillation.

X-ray

The heart size is usually normal or slightly smaller. The characteristic finding of constrictive pericarditis, however, is the calcification of the pericardium. This is best seen in the left lateral or oblique views and is present in about two-thirds of the cases. In the lateral view, if the calcification is seen in the entire pericardium (i.e. anteriorly, inferiorly and posteriorly) the appearance is termed as 'egg-shell pericardial calcification' (**Figure 9**). The lung fields remain clear. Severe venous engorgement may lead to pleural effusions.

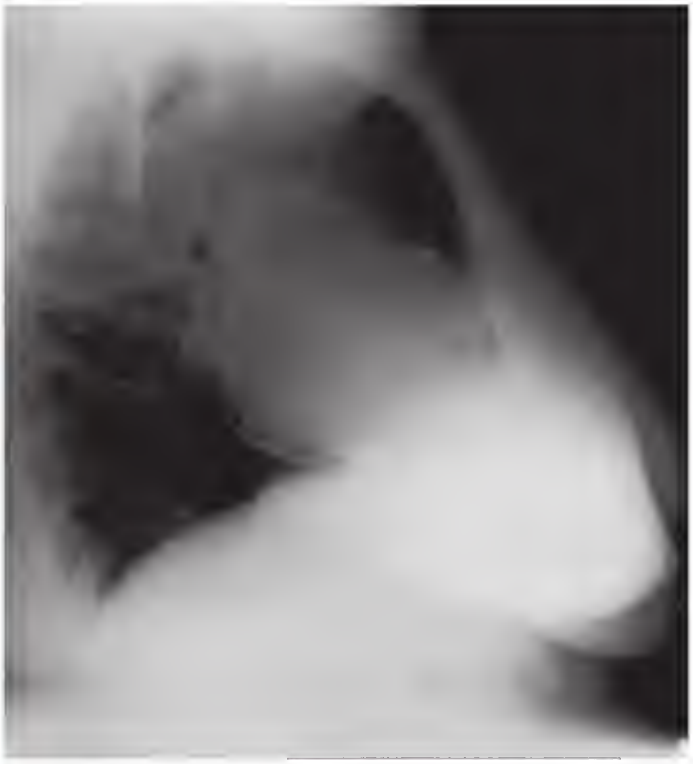

Figure 9: Chest radiograph showing marked pericardial calcifications in a patient with constrictive pericarditis.

Echocardiography

This is perhaps the most useful investigation to diagnose constrictive pericarditis. The presence of thickened and/or calcified pericardium clinches the diagnosis. However, increased pericardial thickness can be missed on a transthoracic echocardiogram. Transoesophageal echocardiography is more sensitive and accurate in determining pericardial thickness.

Doppler echocardiography is important in the evaluation of patients with suspected pericardial constriction. Doppler echocardiography frequently demonstrates restricted filling of both ventricles with a rapid deceleration of the early diastolic mitral inflow velocity (E wave) and small or absent a wave. In addition, there is substantial (>25%) respiratory variation of the mitral inflow velocity (**Figure 10**). There are signs of systemic venous congestion such as dilation of hepatic veins and distension of the inferior vena cava with lack of inspiratory collapse (**Figure 11**).

CT/MRI

CT and MRI allow accurate measurement of pericardial thickness and some assessment of diastolic filling patterns. Ancillary diagnostic findings include conical narrowing of the ventricles, atrial dilation, and enlargement of the inferior vena cava, hepatomegaly, and ascites. Excellent overall sensitivity (88%), specificity (100%), and accuracy (93%) have been reported for MRI. Increased pericardial thickening may not always imply

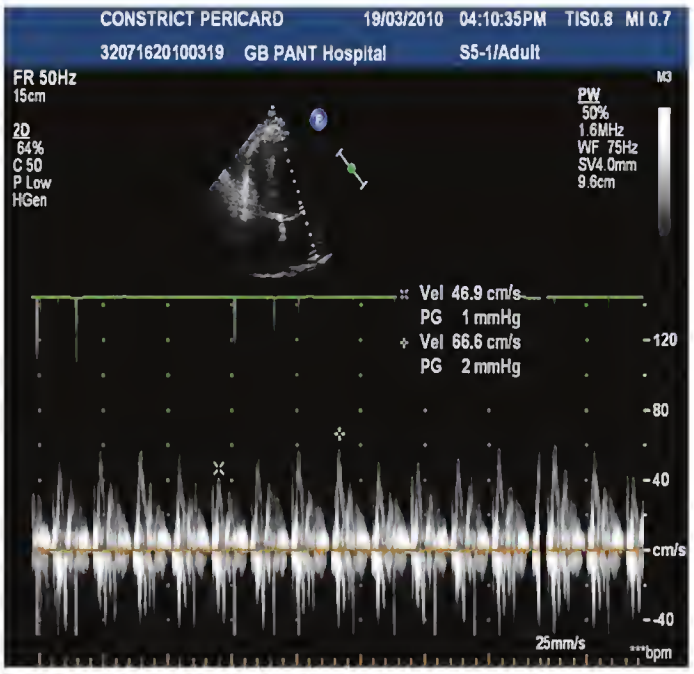

Figure 10: Doppler echocardiography showing respiratory variation of the mitral valve inflow velocity in a case of constrictive pericarditis.

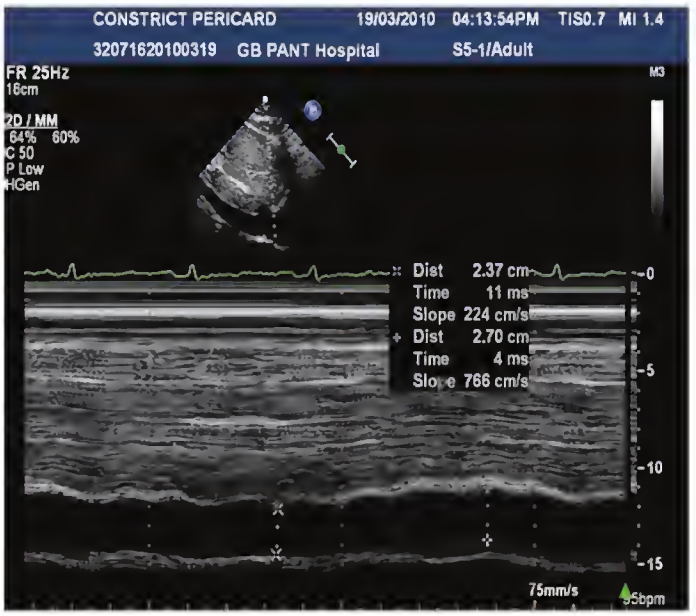

Figure 11: M mode showing dilated IVC with minimal respiratory variation in a case of constrictive pericarditis.

constriction, and conversely, constrictive pericarditis can present with normal pericardial thickness on non-invasive imaging, histology, or a combination of these.

Cardiac catheterisation

Though a very valuable tool in the diagnosis of constrictive pericarditis in the past, it is no longer used routinely after the advent of echocardiography. Catheterisation reveals an elevation of the right ventricular end-diastolic pressure, characterised by an early diastolic 'dip' and a late diastolic 'plateau'. The end-diastolic pressure is high due to incomplete relaxation of the ventricle during diastole and is usually more than one-third of the systolic pressure. The right atrial tracings show a 'M' or 'W' shaped pattern corresponding to the right ventricular pressures. It has been observed that the pulmonary wedge pressure, pulmonary artery diastolic pressure, right ventricular end-diastolic pressure, mean right atrial pressure and superior vena cava pressures tend to be equal or near-equal in constrictive pericarditis.

Diagnosis

The combination of pulsus paradoxus, neck vein signs, ascites and pericardial 'knock' should pose no difficulty in the diagnosis. However, similar clinical pictures may be seen in tricuspid valvular diseases, restrictive cardiomyopathies and cirrhosis of the liver. Tricuspid valvular defects have their characteristic murmurs, which increase in intensity on deep inspiration. Cardiomyopathies may be diagnosed on echocardiograms.

Prognosis

Without surgery the prognosis is poor. Long-standing cases of constrictive pericarditis develop hypoproteinaemia due to a protein-losing enteropathy. They also develop a myocardial failure (probably due to fibrosis) which does not respond to digoxin, even after pericardiectomy.

Treatment

Medical management of constrictive pericarditis, especially in less severe cases, is aimed at relief of fluid overload with careful administration of diuretics and is at best, palliative. Surgical pericardiectomy remains the only definitive management and should be done before calcification and myocardial involvement progresses. However, if the cause is thought to be tuberculosis, then a few weeks on antituberculous drugs should precede the surgery. The results of surgery are very gratifying. Other aetiological causes should get their respective treatments.

CONCLUSION

Pericarditis remains a common disorder, particularly as a complication of modern treatments such as cardiac surgery, percutaneous interventions, and radiation therapy. Pericardial effusion and constrictive pericarditis are infrequent sequelae that can be diagnosed accurately in most cases by use of modern imaging methods. Cardiac tamponade, a medical emergency should be promptly diagnosed and managed with urgent pericardiocentesis. Management of uncomplicated pericarditis rests largely on NSAIDs with the addition of colchicine for relapses. Pericardial effusion can be managed percutaneously in most cases, whereas definitive treatment for constriction remains surgery.

12.30 Surgical Management of Heart Disease

Muhammad Abid Geelani, Nikhil Prakash Patil

INTRODUCTION

The era of cardiac surgery was ushered more than a century ago when Ludwig Rehn of Frankfurt operated to relieve cardiac tamponade and sutured a stab wound to the right ventricle in September 1896. However, 'open-heart surgery' as we know it today began a little over fifty years ago with the development of an artificial 'heart-lung machine' by John H. Gibbon, Jr. On May 6, 1953, the Gibbons-IBM oxygenator was successfully used for total substitution of the heart and lungs for 26 minutes, enabling correction of an atrial septal defect, and thereby the world's first successful open heart surgery. Since then, technological advances and myocardial protection techniques evolving continuously over the last six decades have enabled routine conduction of successful and complex cardiac surgery, totally bypassing the vital function of lungs and heart for hours to days.

Cardiac surgery broadly encompasses: surgery for congenital heart disease; surgery for valvular heart disease; surgery for ischaemic heart disease and cardiac transplantation and related heart failure surgery.

SURGERY FOR CONGENITAL HEART DISEASE

Congenital heart disease (CHD) has an overall incidence of 0.8%. The patient population is diverse. Defects, presentation, diagnosis, treatment and outcome differ widely according to age of presentation and complexity of lesions. These can be broadly classified into acyanotic and cyanotic heart defects.

A. Acyanotic

- Increased pulmonary blood flow (Left to Right shunt)
  - Atrial septal defect
  - Ventricular septal defect
  - Patent ductus arteriosus
  - Partial anomalous pulmonary venous connection

  All these patients must be operated upon before school-going age, unless progressive pulmonary arterial hypertension supervenes, in which case, early surgery is indicated to prevent the development of Eisenmenger complex.
- Normal pulmonary blood flow
  - Aortic stenosis/bicuspid aortic valve
  - Mitral regurgitation
  - Coarctation of aorta
  - Mitral stenosis

B. Cyanotic (Right to Left shunt)

- Increased pulmonary blood flow
  - Truncus arteriosus
  - Single ventricle
  - Transposition of great arteries
  - Total anomalous pulmonary venous connection
  - Hypoplastic left ventricle
- Decreased pulmonary blood flow
  - Tetralogy of Fallot
  - Pulmonary atresia
  - Tricuspid atresia with pulmonary stenosis
  - Total transposition of great arteries with pulmonary stenosis
  - Ebstein malformation

All blue babies must be closely observed for cyanotic spells. Severe and frequent spells constitute an indication for urgent operation. Early surgery is preferred as there is always a risk of paradoxical embolism with its complications.

Surgery may be classified into:

- Palliative, e.g. Blalock-Taussig shunt (BT shunt), cavo-pulmonary shunt (Bi-directional Glenn shunt), pulmonary artery banding.
- Corrective, e.g. atrial/ventricular septal defect repair, ligation of patent ductus arteriosus, arterial switch for simple transposition of great arteries.

Conditions such as patent ductus arteriosus, coarctation of the aorta, atrial septal defect, partial atrioventricular canal and tetralogy of Fallot can now have corrective surgery with hospital mortality ranging from 0% to 5% depending upon the age at surgery and the complexity of the condition. Many complex conditions such as pulmonary atresia, transposition of the great arteries, tricuspid atresia and many other conditions previously considered inoperable are now being successfully treated with acceptable mortality and satisfactory long-term results.

SURGERY FOR VALVULAR HEART DISEASE

Acquired disease of heart valves can be treated by repair procedures or by replacement with an artificial prosthesis (**Figures 1 to 3**). The valves commonly affected are the aortic, mitral and tricuspid valves; the commonest pathologies are rheumatic and degenerative disease. Rheumatic heart disease, which has been practically eradicated from Western countries, continues to be a problem in South Asian countries. Rheumatic mitral stenosis (MS) without mitral regurgitation (MR) may initially be treated by balloon mitral valvuloplasty (BMV) or rarely with closed mitral valvotomy when BMV is not possible because of difficulty in percutaneous access to mitral valve, e.g. in inferior vena cava obstruction or inability to puncture the interatrial septum. But when echocardiography suggests unfavourable anatomy (Wilkins score > 8)* or when a left atrial clot is present, it is best to do as an open-heart procedure and

* A scoring system exists to grade the morphological changes in the mitral valve during assessment with echocardiography. This takes into account 4 characteristics; leaflet mobility, leaflet thickening, valve calcification and involvement of the subvalvular apparatus. The involvement is graded from 0-4. A total score of more than 8 is predictive of a low success post percutaneous mitral valvuloplasty.

Figure 1: Tilting disc mechanical valve (TTK Chitra valve).

Figure 2: Bileaflet mechanical valve.

Figure 3: Bioprosthetic valve (Pericardial).

repair/replacement of the valve may be indicated. Nowadays, BMV is done even in presence of left atrial appendage clot after giving anticoagulation therapy for 6 weeks. All patients in New York Heart Association (NYHA) functional class II or above, having dyspnoea, orthopnoea, severe pulmonary hypertension, left atrial clot, must be referred for percutaneous/surgical intervention.

Mitral regurgitation may be caused by degenerative changes in the leaflet, prolapse of the leaflets, rupture of chordae tendineae or due to annular dilatation or tethering of the subvalvular apparatus secondary to ventricular dilatation. In such cases, a repair procedure may be considered. This is usually combined with implantation of a flexible or rigid annuloplasty ring to support the repair. All patients in NYHA class II and above, having orthopnoea, severe pulmonary hypertension, gradually dilating left ventricle and falling ejection fraction (LVEF), must be referred for early surgical procedure for better outcome.

If a repair is not possible and mitral valve replacement is indicated, there is a wide choice of prosthetic and bioprosthetic valves available. Mechanical heart valves have evolved from a ball and cage design to the tilting disc valve to the bi-leaflet prosthesis. Currently, the bi-leaflet pyrolytic carbon low profile mechanical prosthesis is the most commonly used prosthesis as it has the advantage of central flow and excellent long-term results. The preservation of posterior leaflet with/without anterior chordal apparatus provides better long-term result as it maintains left ventricular geometry. Lifelong anticoagulation is mandatory for all mechanical heart valves to prevent thromboembolic complications. In spite of this, the incidence of thromboembolic complications is 1.5% to 2% per patient year. The alternative to the use of mechanical prosthesis is the use of bioprosthetic valves, which have a biological origin. These are generally stent-mounted porcine valves or pericardium treated with buffered glutaraldehyde to promote cross linkages between the collagen bundles. Anticoagulation is not essential for recipients of bioprosthetic valves after 6 weeks of surgery unless they are in atrial fibrillation. The main disadvantage of bioprosthetic valves is their limited durability; many of them degenerate and even calcify in 10 to 15 years time. The long-term durability of these prostheses have been improved by the use of proprietary anti-calcification treatment and by the development of valves constructed from glutaraldehyde-treated bovine pericardium mounted within a specially designed stent. The hospital mortality for mitral valve replacement for primary non-ischaemic mitral valve disease is between 2% and 7%. The survival rate following surgery is 65% to 80% at 5 years, 50% to 60% at 10 years, and 30% to 40% at 15 years from several reported series.

Most patients who need replacement of the aortic valve are in the older age group and have calcific aortic stenosis. Aortic regurgitation is either due to rheumatic heart disease causing fibrosis and shrinkage of the leaflets or due to annular dilation as in cystic medial necrosis or in aortic aneurysms and dissections. Aortic valve replacement has better early and late survivals than mitral valve replacement because of afterload reduction and low thrombogenicity in a high flow area. Small aortic root and patient-prosthetic mismatch is still a concern which leads to higher gradient across aortic valve and poor exercise tolerance. It is better to use stentless valves in the aortic position (autografts as in the Ross operation, homografts or xenografts) or root enlargement techniques in such situations. Enlarging left ventricle, syncope or angina in aortic valve disease warrant early surgery.

The tricuspid valve is generally treated with repair procedures and the implantation of annuloplasty rings rather than valve replacement as prosthetic valves do not function well in this relatively low pressure area.

If the patients are offered surgery during late stages of the disease, the results of valve replacement are adversely affected because of left ventricular dilatation, pulmonary hypertension and congestive heart failure with hepatic and renal dysfunction. Surgery for valvular heart disease is now standardised in Indian centres but problems of late referrals, cost, maintenance of optimal anticoagulation and proper follow-up are the limiting factors.

SURGERY FOR ISCHAEMIC HEART DISEASE

Coronary artery bypass grafting (CABG) is one of the procedures with the highest impact in the history of medicine. CABG is based on the underlying principle that the symptoms and clinical events of coronary artery disease (CAD) are related to stenotic coronary lesions that can be identified by angiography, and if those lesions are bypassed, then those symptoms and clinical events become less common. Surgical attempts at increasing blood flow to the ischaemic myocardium originated a century ago when Alexis Carrel anastomosed a carotid artery segment between the descending aorta and the left coronary artery in a dog, for which he was later awarded the Nobel prize. Three decades later, Arthur Vineberg started implanting the left internal mammary artery (LIMA) into the anterior myocardial territory of patients with CAD in order to increase arterial inflow and relieve angina, with some experiencing prolonged symptomatic improvement. Surgery on the coronary arteries was introduced clinically in 1958 by William Longmire, who reported on the use of endarterectomy in five patients operated without cardiopulmonary bypass (CPB). The first reported successful CABG operation took place in 1964 in Leningrad, where Vasilii Kolesov grafted a LIMA to the left anterior descending (LAD) artery without CPB. The world's first CABG program started 3 years later in Cleveland, as Favaloro began to routinely use reversed saphenous veins for aortocoronary grafting. CABG today constitutes the keystone of adult cardiac surgery, but novel surgical, percutaneous, and medical alternatives loom large on the horizon. Yet CABG is constantly evolving and remains the most durable means of revascularisation for patients with CAD. Although CAD is largely diagnosed by conventional coronary angiography, evolving less invasive techniques like cardiac CT angiography may become the diagnostic modality of choice in the future.

CABG is indicated in patients with chronic stable angina and left main coronary artery stenosis ≥ 50%, left main equivalent (i.e. proximal stenosis of at least 70% of the proximal LAD and circumflex), three-vessel disease [especially if left ventricular ejection fraction (LVEF) is less than 0.50], and one- or two-vessel disease with either a large myocardial area at risk on non-invasive testing or depressed LVEF.

CABG may also be indicated for symptomatic improvement in low-risk patients with significant CAD who do not fulfil the above criteria but experience disabling myocardial ischaemia or unacceptable lifestyle restrictions on maximal medical therapy. CABG is not preferred over PTCA in patients with one- or two-vessel disease not involving the proximal LAD and with only a small area of viable myocardium or no objective evidence of ischaemia on non-invasive testing.

Several studies have shown that emergent surgery for relentless unstable angina or non-Q wave MI in the context of failed or unfeasible percutaneous coronary intervention (PCI) is associated with an increase in peri-operative mortality compared with semi-urgent CABG, although surgical revascularisation may still be preferable to a conservative strategy. Consequently, an attempt should be made at stabilising these patients with maximal medical therapy (and in some cases the temporary use of an intra-aortic balloon pump) to allow surgery to be performed on a non-emergent basis with a lower operative risk.

Intravenous thrombolytic therapy and primary PCI have supplanted CABG as the first line of therapy for patients in the acute period of ST segment elevation MI. As a result, residual ongoing ischaemia and cardiogenic shock despite maximal non-surgical therapy now constitute the main indication for emergent CABG in acute MI patients. Other acute indications include failed thrombolysis and demonstration of a large myocardial territory at risk in combination with an unsuitable anatomy for PCI, a left main coronary stenosis, an LV failure with severe coronary stenosis outside the initial infarct area, significant valve disease, or a mechanical complication of MI.

PCI may occasionally result in intractable coronary dissection or plaque haemorrhage, threatened proximal occlusion with a large myocardial area at risk, loss of a foreign body in a crucial anatomical position, or coronary rupture. These complications are indications for immediate surgical intervention, but in-hospital mortality is high in these patients (10% to 14%) because of unfavourable selection factors such as haemodynamic compromise and severe impairment of the coagulation system. CABG should NOT be attempted on an emergency basis in stable patients in whom PCI has failed because of unsuitable anatomy or no-reflow state.

Conduit Selection

The choice of conduit is determined by the quality of available conduit, the suitability of the target vessels and the age and co-morbidity of the patient.

Internal mammary artery grafts

The internal mammary artery (IMA) is the best conduit available for CABG and provides short- and long-term survival benefits in all patients subgroups, including those 75 years of age or older. Use of the LIMA to graft the LAD (or a main target vessel on the left coronary circulation if the LAD is free of disease) should be performed except in exceptional circumstances such as pre-existing or iatrogenic damage to the LIMA, poor flow from severe spasm, injury, or dissection, involvement of the LIMA in providing collateral supply to the lower extremity, mediastinal irradiation (if other arterial conduits are available), and emergency CABG with cardiogenic shock.

The use of bilateral IMAs should be considered over single IMA grafting whenever, possible in young patients, as they may lead to lower reoperation rates, decreased late PCI rates, and long-term survival benefits. Relative contraindications to the use of bilateral IMAs include emergency operation, advanced age,

diabetes mellitus, obesity, and severe COPD for which the patient requires systemic steroid therapy.

Radial artery grafts

The radial artery likely constitutes, after the left and right IMA, the next best conduit for CABG. Radial artery harvest is contraindicated in the presence of insufficient collateral supply to the hand or Raynaud's syndrome, in patients with high manual demands such as professional musicians, in the very elderly (who have a high prevalence of radial arteriosclerosis), during emergency operations, and in patients who are likely to require postoperative vasopressors such as those with very poor LV function.

Saphenous vein grafts

Saphenous veins are known not to be the conduit of choice for CABG due to proven lower short- and long-term patency than IMAs. Nevertheless, the long saphenous veins are still used in the majority of CABG operations by a large number of surgeons for practical reasons. They are also particularly useful for specific situations. They constitute the most readily available CABG conduit, provide immediate and reliable coronary flow with a low propensity for spasm or flow compromise during low-output states, and provide a time-honoured means of coronary revascularisation during emergency procedures or in patients with severe co-morbidity and limited life expectancy in whom procedural simplicity, expeditiousness, and reliability are most desirable.

Other conduits

The gastroepiploic artery, short saphenous vein and inferior epigastric artery constitute additional available conduits that are rarely needed for primary revascularisation, but which may be useful as a last resort in patients with severe conduit shortage, e.g. redo surgeries.

Off-pump: CABG versus CPB

CABG can be carried out with CPB (on-pump) or without (off-pump: OPCABG). Many surgeons elect to perform CABG on pump, until recently, the advantages of a still, clear operating field, myocardial protection and haemodynamic and respiratory control, appeared to outweigh the disadvantages of CPB. However, recent improvements in methods of stabilising the heart have led to some institutions adopting OPCABG expecting to see lower morbidity and mortality. OPCABG appears to offer favourable outcomes, leading to reductions in postoperative atrial fibrillation, transfusion requirements, inotrope requirements, ventilation times, length of hospital and intensive care unit stay, and cost compared to on-pump coronary artery surgery. But, till date, no randomised trial has been sufficiently powered to detect the widely expected difference in death or stroke at 30 days or one year. Nevertheless, OPCABG is a suitable alternative to CPB in experienced centres. It should probably be the technique of choice in patients with porcelain (calcified) aorta, poor LV function, renal dysfunction, pulmonary dysfunction and advanced age or other co-morbidity.

SURGERY FOR HEART FAILURE

Heart Transplantation

Dr. Christiaan Barnard performed the world's first human heart transplant operation on 3 December 1967. The patient, Louis Washkansky, was a 54-year-old grocer, suffering from diabetes and incurable heart disease. Washkansky survived the operation and lived for eighteen days. However, he succumbed to pneumonia induced by the immunosuppressive drugs he was taking. Barnard later wrote, 'For a dying man it is not a difficult decision because he knows he is at the end. If a lion chases you to the bank of a river filled with crocodiles, you will leap into the water, convinced you have a chance to swim to the other side.' Though the first patient with the heart of another human being survived for only a little more than two weeks, Barnard had passed a milestone in a new field of life-extending surgery. Since then, nearly 60,000 of these operations have been done worldwide, including over a hundred in Indian centres. The main limiting factor is the availability of suitable donors and the logistics of the procedure. The prognosis for heart transplant patients has greatly increased over the past 20 years. With the current immunosuppressive therapy using anti-thymocyte globulin, corticosteroids and azathioprine or mycophenolate survival is now 80% at 1 year, 70% at 5 years and 50% at 10 years. After the 20% mortality during the first year, the yearly mortality is approximately 4% per year. These results can be achieved only if the patients are carefully followed-up and monitored with percutaneous myocardial biopsy at appropriate time depending upon the clinical progress and modification of the immunosuppressive therapy based on the results of myocardial biopsy. Tony Huesman was the world's longest living heart transplant recipient, having survived for 31 years with a transplanted heart (he died on August 10, 2009 of cancer)—the operation was performed in 1978 at Stanford University by American heart transplant pioneer Dr. Norman Shumway.

In patients with severe pulmonary vascular disease heart-lung transplantation may be indicated but this operation is technically more difficult to perform and to manage post-operatively, and carries significantly lower survival rates.

Cardiomyoplasty using latissimus dorsi muscle is not used anymore but Myosplint and its modification, which prevent dilatation of LV, are currently undergoing clinical trials.

The artificial heart, which is essentially a 'bridge to transplantation', at present holds a very promising future as externally rechargeable energy sources are in the final stages of clinical trials.

12.31 Diseases of the Aorta

Manotosh Panja

INTRODUCTION

The aorta is composed of a thin intima, a thick media and a thin adventitia. The media is composed of laminated but intertwining sheets of elastic tissue in a spiral manner that gives it not only tensile strength but also distensibility and elasticity. The aorta is divided anatomically into thoracic and abdominal segments. The thoracic aorta is further divided into ascending, arch and descending segments, while the abdominal aorta consists of suprarenal and infrarenal segments. Aortic isthmus is the point where aortic arch joins the descending aorta. This is especially vulnerable to trauma as it is the junction of the mobile ascending aorta and arch and relatively fixed descending aorta. This is also the site for coarctation of the aorta. Other aortic anomalies could be right-sided aortic arch, double aortic arches and cystic medial degeneration as in Marfan's syndrome and acquired degeneration of the aortic wall secondary to ageing, arteriosclerosis, hypertension and specific inflammatory, infectious or autoimmune diseases.

AORTIC ANEURYSMS

Aortic aneurysm is a localised dilatation of the aorta having a diameter at least 1.5 times that of the expected normal diameter of that given aortic segment. A true aneurysm involves all the three layers of the aortic wall. It is produced by the progressive distension of the aortic wall that is weakened by the degeneration of the tunica media. Sometimes, there may be a pseudoaneurysm or false aneurysm, which is actually a well-defined collection of blood and connective tissue outside the vessel wall as a consequence of a contained rupture of the aortic wall.

Morphologically, an aneurysm is either fusiform or saccular. Fusiform aneurysm is more common. It is a symmetrical dilatation of the full circumference of the aortic wall. Saccular aneurysm on the other hand involves more localised dilation appearing as an outpouching of only a portion of the aortic wall.

Incidence

The post-mortem incidence of aortic aneurysm is 1% to 3%. There has been a gradual decline in the incidence of syphilitic aneurysms, but this has been offset by an increase in the atherosclerotic variety.

ABDOMINAL AORTIC ANEURYSMS

Abdominal aortic aneurysms (**Figure 1**) are far more common than thoracic aneurysms. They are 8 to 10 times more frequent in men than in women. Their incidence shows a rapid rise after 55 years in men and 70 years in women.

Aetiopathogenesis

These aneurysms are usually atherosclerotic. Very rarely they may be traumatic, congenital or myxomatous. Most are infrarenal and fusiform, varying in size from a few millimetre to ten centimetre. Only 2% to 5% are suprarenal. Absence of vasa vasorum in the infrarenal aorta coupled with atherosclerotic thickening of intima may jeopardise nutrient and oxygen supply to the media of this segment. This may hasten degeneration of tunica media in genetically predisposed subjects due to increased elastolytic activity and lead to aneurysm formation. Surprisingly, diabetes mellitus patients are not prone to development of abdominal aortic aneurysm.

Figure 1: Post-mortem specimen of abdominal aortic aneurysm. Bilateral renal artery stenosis with infrarenal aortic involvement.

Clinical Features

Symptoms

Backache, abdominal pain, limb oedema and venous congestion are common. Acute pain and hypotension secondary to rupture may occur.

Signs

There is palpable pulsatile mass in the abdomen, presence of peripheral vascular disease, signs of distal embolisation, and haemodynamic collapse.

Majority of the cases are asymptomatic and are detected on incidental examinations like abdominal X-ray or ultrasound.

Younger patients (50 years old or less) are more likely to be symptomatic. The most frequent complaint is a steady, gnawing pain in the hypogastrium or lower back, lasting for several hours or days at a time and not affected by movement. A pulsatile mass extending variably from the xiphoid process to the umbilicus may be felt. Stagnation of blood in the aneurysmal sac forms mural thrombus which may embolise to distal arteries leading to absence of femoral and lower limb pulses and bruits over affected arteries. Rarely, an expending aneurysm can compress inferior vena cava or one of the iliac veins to produce lower limb oedema and venous congestion.

The major risk of abdominal aortic aneurysm is its rupture. Expansion or impending rupture are heralded by sudden onset of new or worsening pain that is characteristically constant, severe, localised to back or lower abdomen and sometimes radiating to the groin, buttocks and legs. The pulsatile abdominal mass, if present already, may become tender on palpation. Abrupt onset of back pain and abdominal pain with tenderness, and hypotension characterises actual rupture, but this pathognomonic sign is present in only one-third cases. In 80% of the cases rupture occurs in the left retroperitoneum and is signalled by haematomas in the flanks and groin. Most of the remainder rupture into the peritoneal cavity, causing uncontrolled haemorrhage and result in abdominal distension. Rupture into the duodenum presents as massive gastro-intestinal haemorrhage. Rarely, it may rupture into inferior vena cava, iliac or renal vein producing haemodynamic collapse and acute high-output cardiac failure. Rupture is associated with high mortality; 60% die before any medical intervention and 50% of those survive after operative correction.

Diagnosis and Size Estimation

Aneurysm may be detected and their size estimated by physical examination, routine roentgenography, abdominal cross-sectional ultrasonography, digital subtraction angiography, abdominal aortic angiography, CT scan and MRI.

In about 70% of cases, plain X-rays show a curvilinear or linear rim corresponding to the aneurysm wall. In fact aneurysm usually presents as a paravertebral soft tissue mass. With rupture, there is distortion of the psoas muscle shadow and absence of gas in the bowel over the aneurysm. Abdominal ultrasound is the most easily available and inexpensive way of detecting an aneurysm and assessing its size, wall thickness and presence of thrombus. Aortography is a risky procedure and is used in selective pre-operative cases to assess suprarenal extent of the aneurysm, any associated iliofemoral disease and for defining renal and mesenteric arterial anatomy. It may underestimate aneurysmal size in the presence of non-opacified mural thrombus lining its wall. CT scan is an extremely accurate method for both diagnosing and sizing the abdominal aortic aneurysms. MR angiography is also a highly effective method in delineating aneurysm anatomy pre-operatively and it is safe alternative to aortography. Pre-operative aortography is largely replaced by CT scan and MRI now-a-days considering their non-invasive nature and high sensitivity and specificity.

Treatment

Medical therapy with beta-blockers slows the expansion of aneurysm although its efficacy is less in aneurysm of bigger size. Aneurysmectomy and replacement by a synthetic prosthesis, usually Dacron, is advised for all abdominal aortic aneurysms 6 cm in diameter or wider since three-fourth of them will rupture. Operative mortality is 4% to 6% in elective repair. The benefit of surgery for asymptomatic aneurysms 4 to 5 cm in size is not yet established. Complications of surgery include stenosis or occlusion of the prosthetic graft, false aneurysm formation, infection and rupture. Endovascular treatment in the form of percutaneously implanted expanding endovascular stents are new interventional options for the treatment of abdominal aortic aneurysms not suitable for surgery (older patients, patients at higher risk for surgery). Endoleaks (persistent residual flow in aneurysmal sac) are a major disadvantage with this option.

THORACIC AORTIC ANEURYSMS

Thoracic aortic aneurysms are divided according to anatomical location into ascending arch and descending aortic aneurysms, each differing in aetiology, natural history and therapy.

Ascending aorta aneurysms most often result from cystic medial necrosis. Other causes are Marfan's syndrome, syphilis, mycotic aneurysm secondary to aortic bacterial endarteritis and rarely atherosclerosis. Aortic arch aneurysms may be due to atherosclerosis, cystic degeneration, syphilis or other infections while descending aortic aneurysms are predominantly atherosclerotic. The basic pathogenetic mechanism is progressive dilatation of the aortic wall weakened by tunica media degeneration.

Clinical Manifestations

Forty per cent of the patients are asymptomatic and are diagnosed on incidental physical examination or X-ray. Symptoms reflect either a vascular consequence of the aneurysm or a local mass effect. Vascular consequences are aortic regurgitation and secondary congestive heart failure due to aortic root dilatation, myocardial ischaemia due to coronary artery compression by enlarged sinuses of Valsalva, rupture of sinus of Valsalva into the right heart producing continuous murmur with congestive heart failure and thromboembolism causing stroke, lower extremity ischaemia, renal infarction or mesenteric ischaemia. Local mass-effects depend on anatomical location. Ascending aortic aneurysm may cause superior vena cava syndrome due to compression of the superior vena cava. Arch aneurysms cause superior vena cava syndrome; tracheal or main stem bronchus obstruction leading to wheeze, cough, dyspnoea (may be positional), haemoptysis and recurrent pneumonitis. Descending aortic aneurysms may cause trachea or main stem bronchus compression, oesophageal compression producing dysphagia or recurrent laryngeal nerve compression producing hoarseness.

Steady, deep, boring and sometimes excruciating chest or back pain develop due to compression of intrathoracic structures or due to erosion of adjacent bone. Aneurysms eroding through the chest wall are visible as pulsating masses. The most serious consequence of thoracic aneurysm is rupture that is heralded by sudden increase in the intensity of pain. Rupture most commonly occurs into the left intrapleural space or the intrapericardial space and presents as hypotension. Next common site is the oesophagus that presents as life-threatening haematemesis. Thoracic aneurysm may also develop aortic dissection.

Diagnosis

Many thoracic aneurysms, except for smaller ones, are evident on chest X-ray. Transthoracic Echocardiography (TTE) is useful in the imaging of aortic valve and proximal aortic root. Transoesophageal Echocardiography (TEE) can help in assessment of aneurysm of ascending and descending aorta but it cannot visualise aneurysm of the arch. Contrast CT-scan and MR angiography are very accurate in detecting and sizing aneurysms. Aortography was a preferred pre-operative modality to define the anatomy of the aneurysm. However, as in the case of abdominal aorta, CT and MR angiogram are now often sufficient in most of the cases to define aortic and branch vessel anatomy. MR angiography is preferable to CT scanning when the aortic root is involved.

Treatment

Medical therapy is directed towards risk factor reduction and control of blood pressure. Aneurysmectomy and replacement by a prosthetic sleeve or composite graft-valve (in case of ascending aorta) is indicated for aneurysms 6 cm or larger; however, in case of Marfan's syndrome, bicuspid aortic valve or rapidly growing aneurysms, early surgery is indicated. Propranolol may be used to delay the surgery in smaller aneurysms. Surgical repair of arch aneurysms is particularly challenging with high incidence of stroke. Descending thoracic aneurysmectomy may produce post-operative paraplegia due to interruption of spinal cord blood supply. Transluminally placed endovascular stent grafts is an alternative approach for treating descending aneurysms in patients with higher risk for surgery.

DISSECTION OF THE AORTA

Aetiopathogenesis

Aortic dissection is initiated by entry of blood through an intimal tear into a degenerated tunica media of the thoracic aorta. The medial degeneration may occur due to classical cystic medial necrosis or connective tissue disorders like Marfan's or Ehlers-Danlos syndrome. The blood jet divides the media into two producing a false lumen. The inner portion of the dissected wall forms an intimal flap. The intimal flap may be pushed into the true lumen, by the false lumen distended with blood, or it may be torn open by the blood jet producing an exit site. Old age (50 to 70 years), female sex, pregnancy, hypertension, bicuspid or unicuspid aortic valve, giant cell arteritis, Noonan and Turner syndromes and cocaine abuse may predispose to dissection. Aortic dissection occurs at a rate of 5 to 10 cases per million population per year.

Classification (Figure 2)

DeBakey classification

Type I: Begins in the ascending aorta and extends to the descending aorta and arch.

Type II: Confined to the ascending aorta.

Type III: Originates in the descending aorta and extends distally or rarely, retrograde into arch and ascending aorta.

Stanford classification

Type A: All dissections involving the ascending aorta, regardless of the site of origin.

Type B: All dissections not involving the ascending aorta.

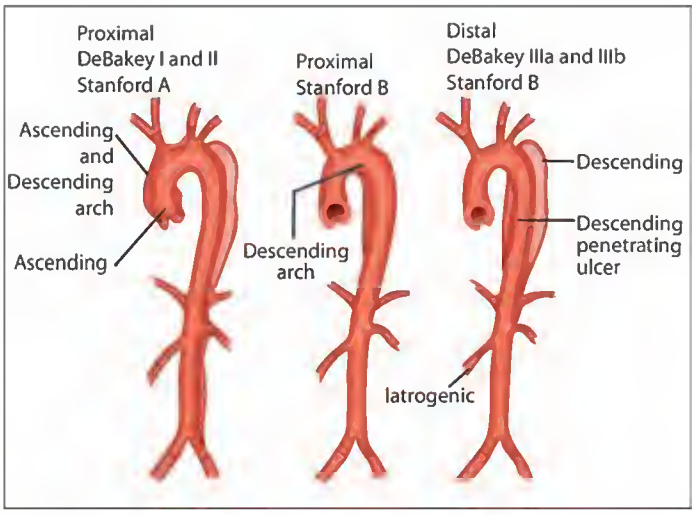

Figure 2: Schematic diagram of classification of aortic dissection.

Descriptive classification

Proximal: DeBakey types I and II or Stanford type A.

Distal: DeBakey type III or Stanford type B.

Proximal dissections are twice more common and more lethal than distal dissections.

Clinical Picture

A tearing, ripping or severe stabbing pain, from its initiation and with a tendency to migrate from its point of origin to other sites following the course of dissection is typically present in majority of cases except for those with chronic dissections. Severe pain from onset differentiates it from myocardial infarction. Anterior chest pain or neck, throat, jaw or face pain usually signifies ascending aorta involvement and inter-scapular or back, abdomen or lower limb pain that of descending thoracic aorta.

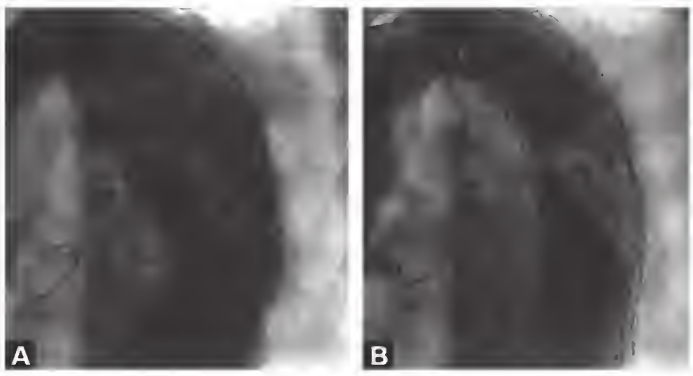
Obstruction of the branches by compression of the true lumen by the distended false lumen or by obstruction of the vessels orifices by a mobile intimal flap may produce pulse deficits, pseudohypotension, syncope, cerebrovascular accident, cardiac arrest or sudden cardiac death, ischaemic peripheral neuropathy and paraplegia. Pulse deficits and neurological manifestations are more common in proximal dissection. Hypertension is seen in 80% to 90% of distal dissection and hypotension is more common in proximal dissection.

Aortic regurgitation due to dilatation of aortic root and annulus, detachment of aortic leaflet or prolapse of a mobile intimal flap through aortic orifice is the characteristic of proximal dissection and results in congestive cardiac failure. The murmur has a musical quality and radiates along the right sternal border. Syncope without a focal neurological sign heralds rupture of a proximal dissection into pericardial sac producing cardiac tamponade or that of distal dissection into the intrapleural space.

Investigations

Anaemia may develop from significant haemorrhage or sequestration of blood in the false channel. A mild-to-moderate polymorphonuclear leucocytosis (10,000-14,000/mm^3) is common. Lactate dehydrogenase (LDH) and bilirubin levels are sometimes elevated. Serum glutamic oxaloacetic transaminase (SGOT) and CK-MB are usually normal, unless associated myocardial infarction develops along with

dissection. ECG abnormalities are particularly common in Stanford type A aortic dissections. ST depression is most common abnormality. Sometimes, patients present with inferior wall MI due to involvement of right coronary sinus. Chest X-ray may reveal widening of the aortic arch in 40% to 50% of cases, change in configuration of the aorta on successive X-ray, obliteration of the aortic knob with displacement of the trachea to the right, localised hump on the aortic arch and an increase in distance from intimal calcification to the outer edge of the aortic shadow of > 1 cm (calcium sign).



TTE is a useful tool for the diagnosis of ascending aortic dissections. However, it is limited by its inability to show the distal extent. TEE is highly sensitive and specific for evaluating proximal aortic dissection.

Development of helical CT with multiplanar and 3D reconstruction and CT angiography has made CT scan a highly sensitive (83% to 94%) and specific (87% to 100%) mode for diagnosis of aortic dissection. It is fast replacing the conventional angiography (**Figures 3A and B and Figure 4**) as a standard diagnostic test in many centres.

MRI although highly sensitive and specific it is used preferably for chronic aortic dissection and post surgical follow-up.

Treatment

Therapy is aimed at halting the progression of the dissecting haematoma. Without treatment 25% of the patients die within 24 hours, more than 50% within the first week, 75% within one month, and more than 90% within one year.

Figures 3A and B: Aortogram showing aortic dissection. (A) pre-stenting and (B) post-stenting.

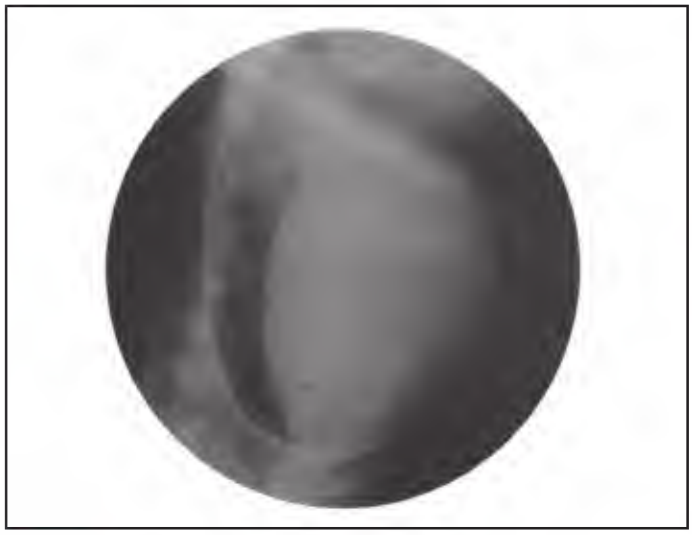


Figure 4: Aortogram showing dissection of aorta.

Early emergency treatment

All patients should be admitted immediately to an intensive care unit. Initial therapeutic goals are the elimination of pain and reduction of systolic blood pressure to 100 to 120 mm Hg with a potent vasodilator like sodium nitroprusside. Nitroprusside when used alone can cause increase in the dp/dt so it should be used with a beta-blocker.

Propranolol is used in incremental doses of 1 mg intravenous every five minutes until there is an evidence of satisfactory beta-blockade, usually indicated by a pulse rate of 60 to 80 beats/min. Labetalol and esmolol can also be used in this setting. Patients who have contraindication for beta-blocker therapy should be put on cardioselective calcium channel blockers. In chronic stable dissection propranolol is given orally in dose of 20 to 40 mg six hourly.

Definitive subsequent therapy

Results of surgical therapy is superior to medical therapy in acute (< 2 weeks) proximal dissection and, conversely medical therapy offers a relative advantage over surgery in most cases of uncomplicated acute distal dissection (**Table 1**).

Table 1: Indications for Definitive Therapy in Aortic Dissection

Surgical	
	Treatment of choice for acute proximal dissection
	Treatment of choice for acute distal dissection complicated by progression with vital organ compromise
	Rupture or impending rupture
	Aortic regurgitation (rare)
	Retrograde extension to the ascending aorta
	Dissection in Marfan's syndrome
Medical	
	Treatment of choice for uncomplicated distal dissection
	Treatment for stable, isolated arch dissection
	Treatment of choice for stable chronic dissection (uncomplicated dissection presenting two weeks or later after onset)

Long-term medical therapy to control hypertension and reduce dp/dt is indicated for all patients regardless of whether they have received definitive surgical or medical therapy. Follow-up of patients should include repeated physical examinations, periodic chest X-rays, CT scans or digital substraction angiograms (DSA) for evidence of localised aneurysm formation. MRI also promises to be a valuable tool for follow-up.

INTRAMURAL HAEMATOMA

It is an acute aortic syndrome which is typically characterised by haemorrhage within medial layer of aortic wall, but unlike classic aortic dissection, there is no evident tear in intimal layer. It is proposed that it results from the rupture of vasa vasorum within aortic wall although some believe that it results from intimal tear which is too small to be visualised. The risk factors, signs and symptoms resemble classic aortic dissection. Among the various available diagnostic modalities CT scan is the most preferred diagnostic tool to visualise the intramural haematomas.

The natural history of intramural haematoma is debatable but they can proceed in four possible ways absorption of

haematoma, persistence of haematoma, development of aortic aneurysm, and conversion to classic aortic dissection.

Treatment of this aortic syndrome is similar to classic aortic dissection in the sense that proximal aortic intramural haematoma should be operated while distal intramural haematoma should be managed medically.

AORTO ARTERITIS (TAKAYASU'S ARTERITIS)

Takayasu's arteritis (TA) is a chronic inflammatory disease of the aorta and its major branches. Though the disease was named after him, Takayasu was not the first to describe this disease entity. 'Pulseless' disease was reported by Adams way back in 1827. In 1908, Takayasu described a peculiar 'wreath-like' appearance of arteriovenous anastomosis around the optic papilla.

The disease has a worldwide distribution, though the majority of cases are seen in Japan, India, South Africa, Mexico and parts of South America. Mongoloid races are affected the most, followed by the Indo-Aryan. The disease predominantly affects young females. The female: male ratio being 7:1 in Japan, 5:1 in Mexico and 3:1 in India.

Aetiopathogenesis

The specific cause of the disease is not known, though the bulk of evidence favours an autoimmune aetiology. Association with rheumatic fever, streptococcal infection, rheumatoid arthritis, other collagen vascular disease and tuberculosis were described. The disease has two stages. The early active phase, there is non-specific granulomatous panarteritis involving all the layers of the wall of the aorta and its branches but unlike other forms of the aortitis, pulmonary artery may be involved in this disease. The disease progresses variably to a chronic sclerotic phase, characterised by intimal hyperplasia leading to purely stenotic lesion in 85% of the patients, purely dilatative in 2% and mixed lesion in 13% of the patients.

Classification

Lupi-Herrera *et al* in 1977, described four varieties of disease based on predominant site of involvement: Type I (Shimizu-Sano) aortic arch and its branches (**Figure 5**); Type II (Kimoto) thoraco-abdominal aorta and its branches; Type III (Inada) combines features of both Type I and Type II; and Type IV (Oata) pulmonary artery (**Figure 6**). Another variety of arteritis is proposed as Type V aorto-arteritis associated coronary artery (Panja *et al*) (**Figure 7**). Criteria of American College of Rheumatology for the Classification of Takayasu Arteritis (1990) are given in **Table 2**.

Clinical Manifestations

The disease affects teenagers in three-fourths of cases, though no age is immune to this disease. More than half of the patients present with features of active disease viz. fever, anorexia, malaise, weight loss, night sweats, arthralgias, pleuritic pain and fatigue. Localised pain and tenderness may be noted over the affected arteries. Occasionally, it may present as fever of unknown origin.

In the sclerotic phase, the manifestations include diminished or absent pulses in 96%, bruits in 94%, hypertension in 74% and heart failure in 28% patients. Retinopathy leading to retinal detachment and loss of vision is seen in 25% of the cases.

Patients with types I and III disease present as 'reverse coarctation' manifested by absent or diminished pulse and

Figure 5: Aortogram showing involvement of aortic arch with both common carotid arteries with aorto-arteritis.

Figure 6: Pulmonary artery involvement in a patient with aorto-arteritis.

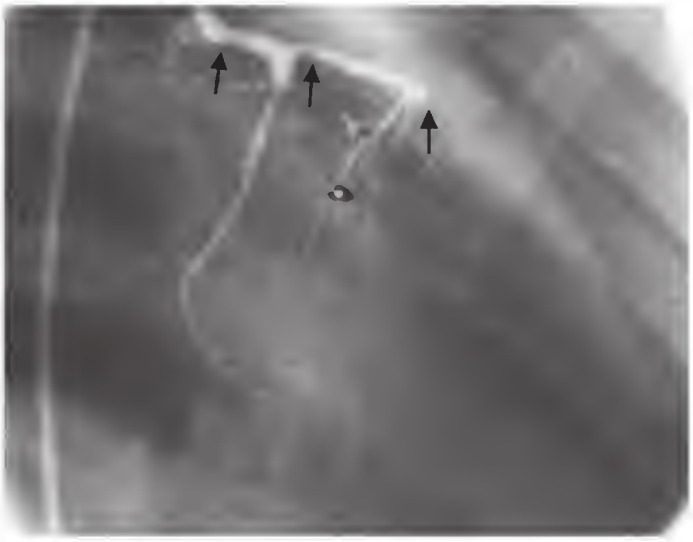

Figure 7: Severe coronary artery involvement in a patient of aorto-arteritis.

blood pressure in the upper limbs, bruits over diseased arteries and syncope. Type II disease is manifested by abdominal angina, claudication of limbs and hypertension due to renal artery involvement.

Hypertension, a major complication of this disease, arises due to renal artery stenosis (35.85%) (**Figure 8**), involvement of baroreceptors by aortitis, loss of elasticity of aorta and coarctation like lesion. Congestive heart failure occurs due to hypertension, dilated cardiomyopathy or more rarely aortic regurgitation. Coronary artery involvement may cause angina, myocardial infarction. Pulmonary artery involvement may result in a clinical picture similar to primary pulmonary hypertension.

Investigations

During the systemic phase, elevated ESR, low-grade leucocytosis and mild anaemia of chronic disease are frequent. IgG or IgM values are elevated in more than half of the patients. C-reactive protein may be elevated with increased anti-streptolysin titre, rheumatoid factor, anti-endothelial antibodies and elevated fibrogen levels.

Chest X-ray is usually unrevealing although a rim of calcification is sometimes seen in the walls of the affected arteries. Arteriography reveals irregular intimal surface with stenosis of the aorta or its branches, post-stenotic dilatation, saccular aneurysm and even complete occlusion of vessels. The affected thoracic aorta has been described as having a rat-tail appearance. Arterial biopsy may be positive in 20% to 35% of the cases. Gallium-67 radionuclide scan may demonstrate uptake in aorta and its branches. High resolution ultrasono-graphy is useful in monitoring disease of common carotid and subclavian arteries.

MRI, MR angiography and CT scan are useful for serial examination and diagnosis in early phase of Takayasu arteritis.

Figure 8: Bilateral renal artery involvement with left common iliac artery involvement in patient with aorto-arteritis.

Use of contrast may reveal inflammatory lesion prior to development of stenosis. Ishikawa and American College of Rheumatology have proposed criteria for the diagnosis of Takayasu arteritis (**Table 2**).

Table 2: 1990 Criteria of American College of Rheumatology for the Classification of Takayasu Arteritis

Criteria	Definition
Age of onset	Development of symptoms or findings related to Takayasu arteritis at age <40 years
Claudication of extremities	Development and worsening of fatigue and discomfort in muscles of one or more extremity while in use, especially the upper extremities
Decreased brachial artery pulse	Decreased pulsation of one or both brachial arteries
BP difference in arms	Difference of >10 mm Hg in systolic pressure between arms
Bruit	Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta
Arteriogram	Arteriographic narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities, not due to arterio-sclerosis, fibro-muscular dysplasia, or similar causes: changes usually focal or segmental

For purposes of classification, a patient shall be said to have Takayasu's arteritis if at least three of these six criteria are present. The presence of any three or more criteria yields a sensitivity of 90.5% and a specificity of 97.8%.

Natural History

The disease is basically progressive, though the rate of progression varies considerably. The cause of death is usually heart failure, encephalopathy, renal failure, rupture of aneurysms and cerebral haemorrhage.

Treatment

Medical treatment is recommended for those suffering from active and early lesions, those in whom surgery is not possible or considered too risky because of extensive and multifocal involvement of the arterial tree and where surgery is contra-indicated due to uncontrollable congestive cardiac failure or progressive renal failure. Steroids are often effective in relieving the constitutional symptoms. Cyclophosphamide, cyclosporine, mycophenolate mofetil and methotrexate can be tried in cases which fail to respond to steroids. Etanercept and infliximab may be used for inducing clinical remission in steroid-dependent patients. Anticoagulant anti-platelet and drugs like warfarin, aspirin and dipyridamole are recommended to treat transient ischaemic symptoms and to prevent progression. Aggressive treatment of hypertension is important. Surgical treatment for late complications includes endarterectomy, bypass of obstructed arteries especially renal arteries, resection of localised coarctation, excision of saccular aneurysms and rarely aortic valve replacement.

Percutaneous transluminal coronary angioplasty (PTCA) with or without stenting has emerged as a useful effective and less invasive therapeutic option for Takayasu's disease. This option is especially effective for discrete lesions.

CARDIOVASCULAR SYPHILIS

It is very rare as a result of aggressive antibiotic treatment of syphilis in its early stages. Cardiovascular complications occur in approximately 10% of cases of untreated syphilis. The latent period may extend from 5 to 40 years, with a usual time of 10 to 25 years. During the secondary phase of the disease the bacteria directly invade the aortic media. The direct infection and subsequent inflammatory response cause destruction of muscular and elastic media followed by its fibrosis.

Clinical Manifestation

In the absence of' aortic regurgitation an aneurysm may undergo significant enlargement without producing symptoms. Eventually it may expand to compress and erode contiguous structure, particularly the sternum and the anterior right thoracic cage. This causes pain at the point of involvement. Ascending aortic aneurysms and those involving the arch may cause a tracheal tug, stridor and dysphagia. There may be hoarseness due to compression of the left recurrent laryngeal nerve and cough from pressure against the left main stem bronchus. Patients may have anginal symptoms due to associated stenosis of the coronary ostia.

Diagnosis

There is a history of syphilis and other manifestations of tertiary syphilis in 10% to 30% of cases. About 15% to 30% of patients have negative routine serological tests for syphilis (Wassermann, Kahn and VDRL). Serological tests directed against a specific treponemal antigen are almost invariably positive. The chest X-ray may show calcification in the ascending aorta proximal to the brachiocephalic vessels.

Angiography may delineate the aneurysm and help to quantify the severity of aortic regurgitation. In patients suspected to have coronary ostial stenosis and in patients where surgical correction is contemplated, the coronary artery anatomy, and particularly the ostia, should be visualised by coronary angiography. CT and MRI are quite helpful in evaluating the aneurysm.

Treatment

All patients who are seen one year or more after the initial contact should be given a course of antibiotic therapy, i.e. injection benzathine penicillin 2.4 million units IM weekly for three weeks. For patients allergic to penicillin, tetracycline 500 mg four times daily for 30 days is recommended.

GIANT CELL ARTERITIS

This disease is found predominantly in elderly people and characteristically involves medium-sized arteries. The aorta and its branches are affected in about 15% cases. The aetiology of giant cell arteritis is unknown. However, the possibility of an autoimmune or infectious origin has been considered. The typical pathological lesion is granulomatous inflammation of the media of small-to-medium calibre arteries about the size of the temporal artery, with a special predilection for the vessels of the head and the neck.

Clinical Manifestations

It typically affects patients over the age of 50 years and occurs predominantly in females. The typical presentation consists of fever, malaise and headache. Other constitutional symptoms include anorexia, weight loss, myalgias, night sweats and lassitude. Headaches are often intense and unbearable and occur over the involved arteries, usually the temporal arteries, but occasionally over the occipital region. Blindness may occur due to involvement of the ophthalmic artery. The syndrome of polymyalgia rheumatica is seen in nearly 40% of these patients. Physical examination reveals the patient to be febrile. The involved vessels are thickened and tender, pulse may be lost and bruits may be heard over the sites of arterial occlusion.

Investigations

A high erythrocyte sedimentation rate (ESR) is virtually inevitable, normocytic, normochromic anaemia may be present. Antinuclear antibody and rheumatoid factor are not found. The diagnosis is usually confirmed by biopsy of the temporal artery (TA). Colour duplex ultrasonography of TA is a promising alternative for temporal artery biopsy. Angiography may help to confirm the diagnosis in cases of larger vessel and aortic involvement. CT, MRI are used as second-line diagnostic procedure.

Treatment

Treatment consists of prednisolone 60 to 80 mg per day for 1 to 2 years. With ESR as guide, steroid may be tapered to a maintenance dose of 5 to 15 mg per day for 1 to 2 years. Cyclosporine and azathioprine or cyclosporine and methotrexate are used in steroid-resistant cases. The overall prognosis with treatment is good.

OTHER ARTERITIS SYNDROMES

These may be seen in association with ankylosing spondylitis, psoriatic arthritis, ulcerative colitis, and Reiter's syndrome.

AORTIC TRAUMA

Aortic injuries may occur with severe blunt trauma as in motor vehicle accident, blast injuries, crush injuries and severe falls. The most common site of tear is the aortic isthmus just distal to the origin of the left subclavian artery. Other sites include the supravalvular portion of the ascending aorta, the aortic arch, the innominate artery, abdominal aorta and combinations of these.

12.32 Vascular Disorders of the Extremities

Gurpreet Singh Wander, Bishav Mohan

INTRODUCTION

Vascular disorders of the extremities can involve the arterial, venous or the lymphatic systems. These are generally more common in the lower limbs than in the upper limbs. These disorders can have an acute onset or may develop chronically. The diagnosis is made in most cases by a thorough clinical, ultrasonographic and Doppler evaluation. These abnormalities can be primary in origin or they may be manifestations of a systemic disorder.

ARTERIAL DISORDERS

Vascular occlusion, acute or chronic, is the major arterial disorder of the extremities. **Table 1** outlines the arterial disorders.

Table 1: Classification of Arterial Disorders

Occlusive
Acute occlusion (embolic, thrombotic, traumatic)
Chronic occlusion (Atherosclerotic, Takayasu's arteritis)
Gangrene
Wet (due to acute occlusion)
Dry (due to chronic occlusion)
Aneurysm
Arteriovenous fistula
Thromboangiitis obliterans (Buerger's disease)
Vasospastic disorders
Raynaud's disease
Livedo reticularis
Acrocyanosis

Chronic Arterial Occlusion

It presents less dramatically than acute occlusion and is much more common. Atherosclerotic peripheral arterial disease (PAD) affects the leg eight times more often than the arm. The pathophysiology of PAD is similar to coronary artery disease. The most important risk factors are smoking, diabetes, hyperlipidaemia and hypertension. The clinical manifestations depend on the anatomical site, the presence or absence of collateral supply, the rapidity of onset and the occurrence of external trauma.

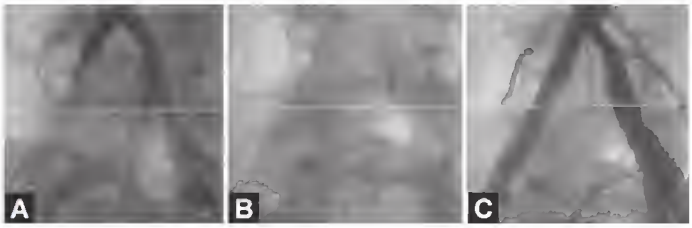
Takayasu's arteritis (pulseless disease) is another common cause of chronic PAD involving the aorta and its major arteries. Most commonly upper limb vessels are affected. Its prevalence is high in young women of Indian, Japanese and Mexican descent. There is a panarteritis in the acute stage, culminating in fibrotic occlusion in the chronic stage. No definitive therapy is available for this disease. However, in acute stage steroids are of some use. Vascular interventions (balloon angioplasty and metallic stents) are often used with variable results.

In Indian subcontinent, diabetics form the largest group of patients with atherosclerotic PAD. The occlusive disease in diabetics is more extensive and complicated due to associated neuropathy and increased risk of infection. Most patients with chronic PAD have bad prognosis due to associated coronary and cerebral atherosclerosis. Diabetic foot is one of the dreaded complication with high rate of amputation. This can be managed with combined approach of preventive measures (education, foot care, special shoes) and treatment strategies (angioplasty ± stents). These have reduced the below knee amputation rate.

Patients often present with intermittent claudication when the limb ischaemia is less critical. This is a cramp-like pain felt in the calf muscles, brought on by walking and relieved on standing still. The distance walked is called 'claudication distance' and is relatively constant for a patient.

Patients with critical limb ischaemia (CLI) are defined as those with rest pain that is felt in the foot at rest and made worse by lying down or elevation of the foot. Characteristically, the pain is worse at night and relieved by hanging the foot out of the bed. Other changes include coldness, numbness, paraesthesias and colour change (ischaemic limbs become blanched on elevation and develop a purple discolouration on dependence). Severe arterial insufficiency can result in painful superficial erosions between the toes, on the dorsum of feet and around the malleoli. Later, this can progress to ulceration and frank gangrene (**Figure 1**). A severely ischaemic foot is frequently paralysed and cold but may feel warmer as it takes on the temperature of its surroundings.

In the upper limb, atheromatous occlusive disease can involve subclavian artery and may cause claudication and rarely frank ischaemia of an arm. The subclavian lesion may also cause distal embolisation and consequent loss of digits. Subclavian steal syndrome may occur if the first part of the subclavian artery is obstructed and the vertebral artery provides a collateral circulation into the arm by reversing its direction of blood flow. The classic syndrome of syncopal attack and visual disturbance associated with arm exercise and a diminished blood pressure in the affected limb is rare. Asymptomatic reversal of flow in the vertebral artery recognised by duplex scanning or angiography is much more common.



Relevant investigations include tests for diabetes mellitus, lipid abnormalities and anaemia. Doppler ultrasound is a very sensitive type of stethoscope that can be used in conjunction with a sphygmomanometer to assess the systolic pressure in relatively small vessels. Ankle: brachial pressure index (ABPI) is the ratio of systolic pressure in the ankle to that in the arm. Values under 0.9 indicate mild ischaemia whereas < 0.5 indicate severe ischaemia. Duplex imaging combines B-mode ultrasound with Doppler ultrasound to give detailed knowledge about vessel-wall thickness, blood flow and turbulence. The 'gold standard' for arterial occlusive disease is angiography, which involves the injection of radio-opaque dye in the vessels

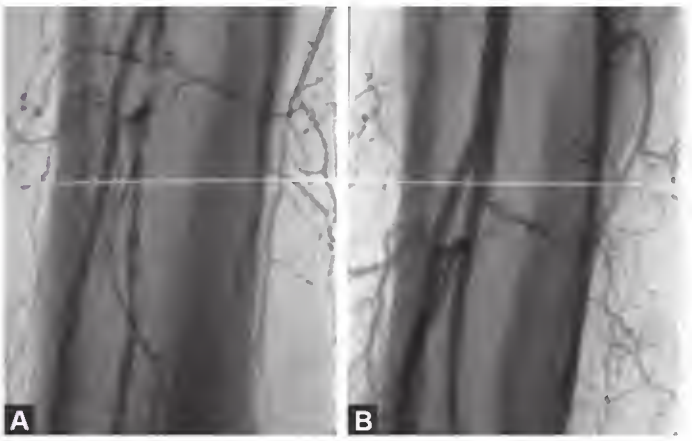


Figure 1: Patient with chronic arterial occlusion of left lower limb showing discolouration of left foot, thinning of ankle and foot, and dry gangrene of distal digits.

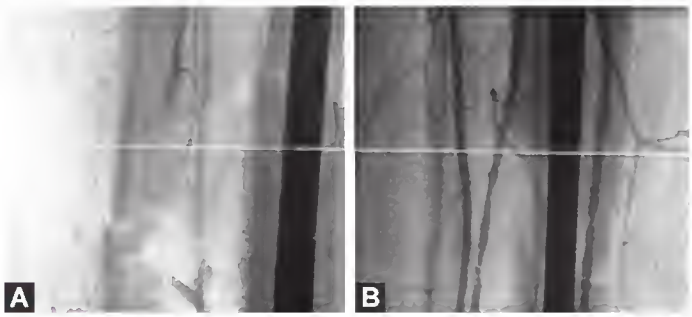
and then using a real time or single shot X-ray to detect the status of the vessels. Digital subtraction angiography (DSA) helps in better delineation of the vessels by subtracting the images of overlying tissues. More recently, ultra fast CT-angiography done by injection of intravenous contrast helps in studying the arterial tree without the need for arterial injection as in conventional angiography. Renal function test should be done before sending the patient for contrast imaging. Magnetic resonance angiography (MRA) provides multiplanar imaging without the need of ionising radiation.

Arterial occlusive disorders can be managed conservatively in most cases. Encouraging exercise within the limits of disability is a good way of increasing exercise capacity. Spontaneous improvement occurs after a few months due to formation of collaterals. Drugs that have a role in occlusive arterial disorders include those for underlying diabetes, hypertension and lipid abnormalities. Antiplatelet agents like aspirin (75 to150 mg od) or clopidogrel can be used. Cilostazol, a phosphodiesterase inhibitor with vasodilator and antiplatelet properties has been shown to improve claudication distance. Naftidrofuryl oxalate may alter tissue metabolism, thus increasing claudication distance. Pentoxifylline improves RBC rheology (flexibility) and has some blood thinning capacity, thus helping to improve circulation. Prostacyclins may have some minor role in the management of the critically ischaemic limb. Lumbar sympathectomy has been used for pain relief. In vessels with localised blocks, transluminal angioplasty and stenting may be performed by inserting a balloon catheter into an artery and inflating it within a narrowed or blocked area. In certain cases, a metallic stent may need to be inserted to keep the lumen patent (**Figures 2Ato C, and Figures 3A and B**). In feasible cases, a surgical vascular bypass may be performed around the occluded part of the vessel to permit distal perfusion. The long-term results of reconstructive aortoiliac surgery are good and they are usually only marred by a progressive disease producing femoro-popliteal occlusions at a later stage. Stem cell therapy (therapeutic angiogenesis) has generated a lot of interest. However, the results need to be documented in large randomised control trials.



Figures 2A to C: (A) Bilateral common iliac stenosis, (B) Stents placed in both common iliac arteries, (C) Post-stenting angiogram showing normal flow.

Figures 3A and B: (A) Angiogram showing stenosis in the peroneal artery, (B) Post-angioplasty angiogram showing normal flow.

Acute Arterial Occlusion

Sudden occlusion of an artery may be due to emboli from a remote site, thrombus formation on a pre-existing atheroma or trauma (**Figures 4A and B**). The emboli can arise from an atrial source as in atrial fibrillation or left ventricular mural thrombus following myocardial infarction. These tend to lodge at vessel bifurcation. Acute occlusion is an emergency and threatens limb viability. It needs immediate diagnosis and early management since delay can compromise limb viability.

Figures 4A and B: This patient presented with a tibial fracture and absent distal pulses: (A) Angiogram showing sudden cut-off of arterial blood flow at the level of the fracture; (B) After stabilisation of the fracture, injection of local vasodilators and ballooning of the blocked segment, flow is restored.

The classical signs in the lower limb are the 6 P's – *pain, pallor, paresis, pulselessness, paraesthesia and poikilothermia*. The limb is cold and, almost immediately, the toes cannot be moved. Sensation to touch is soon lost and distal pulses become impalpable. B-mode ultrasound imaging shows lack of pulsation in arteries and Doppler confirms the diagnosis by showing lack of blood flow.

Appropriate treatment is the immediate intravenous administration of heparin. This can halt the extension of the thrombus and maintain patency in the surrounding vessels. Pain relief is essential because pain is severe and constant. Surgical embolectomy for larger vessels till the popliteal artery is the treatment of choice when done within 12 hours of ischaemia. Thrombolysis using streptokinase or urokinase is preferred for distal vessels. This has to be done within 6 to 12 hours to preserve limb viability. Patients presenting late often go on to develop gangrene of the distal toes and the feet.

Gangrene

The combination of rest pain, colour changes and hyperaesthesias with or without ischaemic ulceration is frequently referred to as pre-gangrene. Gangrene implies death of macroscopic portions of tissue. It is commonly seen affecting the distal part of the limb. A gangrenous part lacks arterial pulsation, venous return, capillary response to pressure (colour return), sensation, warmth and function. The colour changes from pale through dusky-gray to mottled until finally taking on the characteristic dark brown, green-black or black appearance.

Dry gangrene

This occurs when the tissues are desiccated by gradual occlusion of the vessels. It is typically due to atheromatous occlusion of the arteries. The affected part becomes dry and wrinkled, discoloured and greasy to touch.

Wet gangrene

This occurs when the artery is suddenly occluded and there is venous obstruction as well. Infection and putrefaction are present and the affected part becomes swollen and discoloured and the epidermis may be raised in blebs. Crepitus may also be palpated (**Figure 5**).

Treatment includes general measures like hydration, pain control and control of infection. Once gangrene has set in, the reestablishment of blood flow by percutaneous intervention or surgery does not help. Unviable portions of tissue need to be amputated to relieve pain and prevent the spread of infection and gangrene.

Aneurysm

An aneurysm is a localised dilatation of a segment of the arterial system. Aneurysms can be true (involving the vascular intima, media and adventitia) or false (with a fibrous wall). In appearance, they may be fusiform, saccular or dissecting. Aetiology can be atheromatous, traumatic, syphilitic or due to collagen disease.

These can present due to expansion, thrombosis or embolisation. Intrinsically, a pulsatile swelling is present along the course of an artery, which diminishes on application of proximal pressure. The sac is usually compressible unless thrombosed. A thrill may be felt and a systemic bruit auscultated.

Figure 5: Wet gangrene of both lower limbs due to acute arterial occlusion with blebs, denuded skin and blackish discolouration of both feet.

Extrinsically, pressure on veins or nerves may cause distal oedema or altered sensation.

Arteriovenous Fistula

This is a communication between an artery and vein. This may be congenital or acquired due to surgical trauma and catheter access. AV fistulas may also be created in the upper limb to facilitate haemodialysis. Haemodynamically significant fistulas may lead to a wide pulse pressure and a thrill is present. A continuous bruit can be heard over the fistula. Pressure on the artery proximal to the fistula may cause the swelling to diminish, the thrill and bruit to cease and the pulse rate to fall (Nicoladoni's or Branham's sign) and the pulse pressure to return to normal. Embolisation by autologous material (fat/muscle) or gelatine sponges, silicon spheres can obliterate the fistula. Large, painful or bleeding AV fistula can be managed surgically or with endovascular grafts/stents.

Thromboangiitis Obliterans

This involves occlusive disease of the small and medium sized arteries, thrombophlebitis of superficial and deep veins, and Raynaud's phenomenon. It is also known as Buerger's disease. It is most common in Asian males under the age of 30, generally smokers. Treatment is primarily cessation of smoking. This helps halt the progression of the disease but does not lead to reversal of the established occlusion. Sympathectomy for pain relief is also done. Stem cell therapy has also been tried.

Vasospastic Disorders

Raynaud's disease

It predominantly affects the upper limbs in young women. The peripheral pulses are normal. Due to an abnormal response to

cold temperature, the vessels constrict and then dilate. This produces a classic triphasic colour change; pallor, cyanosis followed by redness of the digits. This is often accompanied by pain.

Raynaud's syndrome shares the clinical features of Raynaud's disease but is much more severe. It is generally a manifestation of collagen vascular disease. It may also follow the use of vibrating tools and is then known as 'vibration white finger'. Treatment is primarily directed at the underlying condition. Calcium channel blockers may have a role in management.

Livedo reticularis

This involves purplish mottling of the skin due to spasm of dermal arterioles in lower extremities, especially on cold exposure.

Acrocyanosis

It is an uncommon condition seen in females and is characterised by bluish discolouration in hands and fingers. No specific therapy is required.

VENOUS DISORDERS

Blood returns from the limbs via the deep and superficial veins. In the upper limb, the superficial veins are more important. The superficial veins in the leg are the long and short saphenous veins, and they carry only 10% of the blood from the lower limbs.

There is a foot-pump that ejects blood from the plantar veins as pressure is placed on the foot during walking. On exercise, the thigh and calf muscles contract compressing the veins and ejecting blood towards the heart. Venous valves control the direction of flow of blood in the veins. During muscle relaxation phase, the pressure within the calf falls to a low level and blood from superficial veins flows through the perforating veins into the deep veins. Venous diseases are of two main types; venous thrombosis and venous incompetence.

Venous Thrombosis

Venous thrombosis of the deep veins involves the lower limbs more frequently than the upper limbs. In most cases, deep vein thrombosis (DVT) is asymptomatic and resolves without sequelae. However, often patients are left with a post-thrombotic limb that is persistently swollen, often complicated by venous ulceration. During the acute phase, DVT needs to be taken seriously since the thrombi can dislodge and embolise to the pulmonary circulation. A clot from the lower limb veins detaches from its site and passes via the inferior *vena cava* and right heart to the pulmonary arteries. It may totally occlude the perfusion to a part or all of one or both lungs. In 10% patients who die in the hospital, the cause of death is pulmonary embolism following a DVT.

The main causative factors are part of the Virchow's triad; stasis (slowing of the blood flow), hypercoagulability (increased tendency to clot) and vessel wall damage (which releases thrombogenic substances). The term 'thrombophilia' implies an increased tendency for clotting, often for prolonged periods of time. This can be inherited or acquired. The common genetic causes responsible for venous thromboembolism are mutations involving factor V Leiden (20% to 40%) and prothrombin (6%) genes. Inherited deficiency of protein C (3%), protein S (3%) and antithrombin III (1%) have also been shown to lead to venous thrombosis in young patients. Common acquired thrombophilic states are previous surgery (especially orthopaedic like joint replacement), trauma, pregnancy, certain malignancies, stroke, heart failure, prolonged immobilisation and drugs such as oral contraceptives and hormone replacement therapy (**Table 2**). Long haul air travel has been associated with an increased incidence of DVT due to the immobilisation.

Table 2: Predisposing Causes for Venous Thrombosis

Hypercoagulable states	
	Mutations of factor V (Leiden), prothrombin gene
	Deficiency of protein C, protein S, antithrombin III
	Antiphospholipid antibody
	Disseminated intravascular coagulation
Surgery	
	Orthopaedic, thoracic, abdominal
Neoplasia	
	Pancreas, lung, ovary, testes, breast
Trauma	
	Fractures, spinal injuries
	Immobilisation (any cause)
Hormonal	
	Pregnancy, oral contraceptives

The most significant clinical findings are tenderness in the calf and ankle oedema. Pain in the calf on dorsiflexion of the ankle (Homan's sign) is rare and often misleading. Other signs and symptoms are swelling, pain, redness, dilated superficial veins and low-grade pyrexia (**Figure 6**). Some

Figure 6: Superficial and deep vein thrombosis of right leg showing oedema and calf swelling due to DVT. There is an accompanying superficial vein thrombosis as evidenced by the linear redness and swelling.

patients with DVT may have no symptoms in the leg but initially present with sudden onset dyspnoea due to pulmonary embolism.

For diagnosis, a quantitative D-dimer analysis is done to measure the levels of fibrin degradation products. It is recommended to rule-out DVT in clinically suspicious patients. It is, however, not very specific and hence the value of a positive test is limited. The best method for diagnosis is B-mode and Doppler ultrasound in which we look for flow in the veins and augmentation on calf compression. Ascending phlebography is rarely done.

Immobilisation is usually needed only for first 24 hours. Treatment involves anticoagulation after the diagnosis is made. Standard treatment involves unfractionated intravenous heparin (UFH) with dose adjusted according to activated partial thromboplastin time (aPTT). The onset of action is rapid and it is given for about 5 days. The aim is to minimise the risk of pulmonary embolism and to encourage the resolution of the thrombus. Subcutaneous injections of low molecular weight heparin (LMWH) are an alternative method and have been found to produce reliable anticoagulation. These are given twice daily and are easier to administer. They also do not require aPTT monitoring. Many LMWHs are now commercially available and are preferred over UFH nowadays. At the same time, the patient should be started on oral anticoagulants (e.g. warfarin, acenocoumarol) to reduce risk of recurrence of DVT. Duration of treatment is usually for 6 to 12 months. Patients who have inherited thrombophilia require lifelong anticoagulation. The effect of warfarin is monitored by measuring the international normalised ratio (INR), which should be prolonged to 2.0 to 3.0 times the control values. Inferior *vena cava* (IVC) filters are implanted in patients with contraindication to oral anti-coagulants (GI bleed), recurrent DVT and high risk DVT. Retrievable filters are preferred over permanent ones.

Prevention of DVT can be done by both mechanical and pharmacological methods. Graduated elastic compression stockings have been shown to reduce the incidence of deep vein thrombosis. Intermittent pneumatic compression devices are used only peri-operatively. Pharmacological methods include UFH and LMWH. LMWHs are generally preferred. These are considered in all immobilised patients especially those with orthopaedic surgery, congestive cardiac failure and occlusive strokes. Prevention of thrombosis during long distance air travel requires the use of graduated compression stockings, exercise during the flight and avoidance of alcohol and sleeping tablets.

Superficial Vein Thrombosis

This is a frequent complication of varicose veins and may also follow cannulation of a vein for intravenous infusion. Spontaneous superficial thrombophlebitis may occur in the presence of polycythaemia, polyarteritis and Buerger's disease and may also herald the presence of a visceral cancer. This condition does not carry the risks of deep vein thrombosis and is normally treated symptomatically with simple analgesics and anti-inflammatory drugs.

Axillary Vein Thrombosis

This may occur following excessive exercise or as a complication of thoracic outlet syndrome. It is occasionally associated with a cervical rib. The arm becomes swollen and the superficial veins become distended. Early treatment with anticoagulants may result in rapid resolution. In severe cases, the use of fibrinolytic therapy, streptokinase or TPA may be considered. Definite treatment of thoracic outlet syndrome by surgical decompression of the subclavian may be needed, e.g. by resection of the first rib.

Venous Incompetence

Unidirectional venous flow requires the competence of the valves in the superficial and deep veins as well as the venous perforators. Dysfunction of these valves leads to venous incompetence and varicose veins. The incidence of varicose veins in developing countries is lower than in the western nations due to genetic, lifestyle and dietary differences. Varicose veins develop more frequently in people who stand during their work and during pregnancy under the influence of oestrogen and progesterone.

Symptoms include tiredness, aching, tingling, ankle swelling and a cramping sensation in the legs, which progressively worsen towards the end of the day and are relieved by elevating the leg. Patients with more severe venous disease may notice skin changes. Some patients may be asymptomatic and may present for cosmetic reasons.

On examination, there is an increase in size of the calf muscles, ankle oedema, and skin complications like brown pigmentation, eczema and severe ulcerations. Later on, lipodermatosclerosis may develop. Contraction of the skin and subcutaneous tissue is seen and the ankle becomes narrow. A combination of narrow ankle and prominent calf is often referred to as a champagne bottle leg. Venous ulceration may also develop in these areas. Diagnosis can be made by a thorough clinical examination and Doppler ultrasound evaluation.

The treatment depends on the size of the varices, their extent and the symptoms they produce. Compression stockings are used in early stages of disease. Injection sclerotherapy involves the injection of an irritant solution, sodium tetradecyl. Surgical treatment involves the ligation of the source of reflux (usually the saphenopopliteal or saphenofemoral junction) and removal of the incompetent saphenous trunks and the associated varices. Endovenous radio frequency and laser ablation have been used in patients with persistent symptoms and/or who develop ulceration.

LYMPHATICS DISORDERS

Lymphatic system is composed of interstitial fluid that bathes tissues of the body, lymphatic capillaries that collect interstitial fluid, transporting vessels and the lymph nodes. The lymphatic capillaries absorb interstitial fluid and empty into transporting vessels, which traverse the extremities and join with the visceral channels to form the cisterna chyli adjacent to the upper abdominal aorta. These pass through the diaphragm to become the thoracic duct. The thoracic duct empties into the left

subclavian vein. A separate smaller right lymphatic duct drains the right upper extremity and neck, and enters the right subclavian vein. Normally between 2 litres and 4 litres of interstitial fluid is filtered each day and returned to the vascular system by the lymphatic system. Diseases of the lymphatics include lymphoedema due to lymphatic obstruction, lymphangiomas and tumours.

Lymphoedema

Lymphoedema is caused by excessive accumulation of interstitial fluid in the extravascular, extracellular fluid compartment due to defects in the lymphatic transport system. Inadequate removal of the interstitial fluid by the lymphatic system may be the result of absent hypoplastic or obstructed lymphatic vessels. In the limb, interstitial fluid accumulates mainly in the cutaneous tissues and presents as a swollen extremity. In the early stages, the oedema is pitting but later it typically becomes non-pitting. The skin becomes thickened, hypertrophic and hyperkeratotic. It should be distinguished from other causes of unilateral leg swelling such as DVT (**Table 3**). Lymphoedema may be primary or secondary (**Table 4**).

Table 3: Differences Between Swelling of the Extremity Due to Lymphatic and Venous Obstruction

Lymphatic Obstruction	Venous Obstruction
Swelling typically involves the distal aspect of the extremity and characteristically involves the dorsum of the feet and toes	Swelling is present distal to the site of obstruction and uniformly involves the extremity uniformly
Swelling is usually painless. Pain and redness occur only if there is associated cellulitis	There is pain, redness and dilated superficial veins in the affected extremity
Oedema is pitting in nature and responds to limb elevation, however later on it characteristically becomes non-pitting and does not respond to limb elevation	Oedema is pitting in nature in the initial phase and responds to limb elevation
Due to lymphoedema, skin becomes thickened, hypertrophic and then hyper-keratotic	Due to increase in foot vein pressure, skin around the ankle becomes pigmented due to leakage of blood and fibrin into the surrounding tissues. With passage of time, the skin becomes eczematous and ulcerated

Table 4: Types of Lymphoedema

Primary
- Lymphoedema congenita
- Lymphoedema precox
- Lymphoedema tarda

Secondary
- Filariasis
- Tuberculosis
- Neoplasia
- Recurrent lymphangitis
- Surgery
- Radiotherapy

Primary lymphoedema

This is relatively uncommon and often associated with inherited disorders like Turner's and Klinefelter's syndromes. 'Lymphoedema congenita' is a severe form of lymphoedema that is usually apparent at birth or during early infancy. Familial cases are termed as Milroy's disease. These patients have associated lymphatic abnormalities such as intestinal and pulmonary lymphangiectasia.

'Lymphoedema precox' presents at about the time of puberty and is the most common form of primary lymphoedema accounting for >80% of the cases. 'Lymphoedema tarda' refers to lymphoedema that appears at about the third or fourth decade of life.

Secondary lymphoedema

It is usually due to acquired lymphatic obstruction. The causes of obstructive lymphoedema are infiltration of regional lymph nodes by tumour, surgical excision of regional lymph nodes in the treatment of malignancy, repeated infections, inflammatory processes causing fibrosis and irradiation.

In tropical and subtropical countries infestation by filarial parasites is the most frequent cause of secondary lymph-oedema. Eight filarial species infect humans out of which only two; *Wuchereria bancrofti* and *Brugia malayi* are found in India and South-East Asia. *W. bancrofti* is the most widely distributed human filarial parasite. In India, the disease is rampant in Uttar Pradesh, Bihar, Andhra Pradesh, Orissa, Tamil Nadu, coastal Kerala and Gujarat. Tuberculous lymphangitis may also cause lymphoedema. In Western countries lymphoedema occurs most commonly in the arm after surgical excision of lymph nodes for carcinoma of the breast.

Lymphangiography is used to diagnose lymphoedema and to demonstrate the nature of lymphatic abnormality. However, as this procedure is invasive and because of the risk of oil embolism, it is being replaced by isotope lymphangiography. MRI imaging has also been employed to investigate the lymphatic system.

Treatment includes prolonged bed rest, limb elevation, elastic stockings, meticulous skin hygiene, avoidance of local injury and prompt treatment with antibiotics if cellulitis occurs. Surgery is reserved for those with severe disabling lymphoedema. It includes the excision of hypertrophic tissue, pedicle transfer of normal lymphatic bearing tissue and microvascular bypass.

Lymphangiomas

Lymphangiomas are benign overgrowths of lymphatic vessels. It is not certain whether these are congenital malformations, hamartomas or true neoplasms.

Capillary lymphangiomas are small, circumscribed, pale-white to pink lesions composed of network of endothelium-lined, thin-walled lymphatic spaces separated by lymphoid

aggregates. These mainly involve skin or mucous membranes of the head and neck.

Cavernous lymphangiomas are more common than the capillary variety. They are slow growing, congenital lesions and are composed of numerous dilated lymphatic channels filled with lymph and often surrounded by a fibrous capsule.

Lymphangiosarcoma

It is a rare malignant lesion that develops in a lymphoedematous/ extremity. Malignant transformation is more frequent in cases of secondary lymphoedema. It appears as purple-red nodules in the skin. It is an aggressive and rapidly fatal tumour.

12.33 Pregnancy and Heart Disease

Amal Kumar Banerjee

INTRODUCTION

Management of pregnancy in patients with heart disease continues to pose a challenge to the clinicians. Heart disease is the third leading cause of death in 25 to 44-year-old women. Because it is relatively common in women of childbearing age, heart disease of varying severity complicates about one per cent of pregnancies. Rheumatic heart disease accounts for most of the cases and mitral stenosis being the commonest lesion, in India.

NORMAL PHYSIOLOGIC CHANGES IN PREGNANCY

There is an increase in blood volume, by about 50%, and relatively haemoglobin concentration falls, causing the physiological anaemia of pregnancy. Cardiac output increases as early as 5 weeks after the last menstrual period and rises to 45% above baseline at 24 weeks' gestation. Increased cardiac output is achieved by an increase in heart rate, which rises progressively until 32 weeks' gestation, and in stroke volume, which begins to increase by 8 weeks and peaks as early as 20 weeks. Twin pregnancies result in an additional 15% rise in cardiac output in mothers. The cardiovascular system is taxed further by stage one of labour, which is associated with an additional 12% increase in demand for cardiac output. This demand increases to a mean of 34% above the already increased baseline value as labour progresses to its final stages. After delivery stroke volume decreases by 2 weeks post-partum, but a small further reduction occurs up to 6 months after delivery. The stroke volume remains at pregnancy levels for the first 2 days post-partum and then falls dramatically. Heart rate remains elevated for 2 days post-partum and returns to the baseline by 10 days after delivery. Cardiac output similarly decreases from pregnancy levels to normal levels between 24 hours and 10 days post-partum. Systemic vascular resistance and diastolic blood pressure decrease as a result of changes in aortic compliance and arterial venous shunting in the uterus.

DIAGNOSIS OF HEART DISEASE

Many of the physiological changes of normal pregnancy tend to make the diagnosis of heart disease more difficult due to alterations in the physical examination of the pregnant patient (**Table 1**). Symptoms and clinical findings that may indicate heart disease (**Table 2**), should be carefully recognised. Pregnant women who have none of these findings, rarely have serious heart disease.

Diagnostic Studies

The physiologic changes associated with pregnancy may also alter the results of non-invasive evaluations of the heart (**Table 3**).

In most cases, conventional testing including electrocardiography, Doppler echocardiography and chest radiography will provide necessary data. If indicated, right-heart catheterisation can be performed with limited X-ray fluoroscopy. All X-ray procedures should generally be avoided, particularly early in pregnancy.

Table 1: Physical Findings During Normal Pregnancy

Mild jugular venous distension
Lower-extremity oedema
Decreased breath sounds at bases
Upward and leftward deviation of point of maximal impulse
Volume-loaded ventricle (active praecordium)
Increased valve closure sounds
'Flow' murmurs (pulmonic and aortic)
Mammary soufflé (left sternal border)
Wide pulse pressure
Increased heart rate

Table 2: Some Clinical Indicators of Heart Disease During Pregnancy

Symptoms
Progressive dyspnoea or orthopnoea
Nocturnal cough
Haemoptysis
Syncope
Chest pain
Clinical Findings
Cyanosis
Clubbing of fingers
Persistent neck vein distension
Systolic murmur grade 3/6 or greater
Diastolic murmur
Cardiomegaly
Persistent arrhythmia
Persistent split-second sound
Criteria for pulmonary hypertension

Table 3: Changes in Non-invasive Test Results That Occur During Pregnancy

Test	Changes
Electrocardiography	Leftward axis deviation
	Increased ventricular voltage
	Increased rate
	Repolarisation changes
Chest X-ray film	Upward diaphragm displacement
	Horizontal heart placement
	Enlarged pulmonary silhouette
Echocardiography	Increased left ventricular diastolic dimension
	Increased left ventricular wall thickness
	Mild increase in contractility

GENERAL MANAGEMENT

Poor maternal functional class, cyanosis, myocardial dysfunction, left-heart obstructive lesions, prior arrhythmia, and prior cardiac events are prognostic of complications during pregnancy. The

likelihood of cardiac complications during pregnancy is 3%, 30% and 66% when none, one or more than one of these are present.

A three tiered risk classification of maternal mortality (**Table 4**), has been developed. This will help in counselling the woman regarding advisability of conception or continuation of pregnancy.

Most current management recommendations have been based on expert opinion and/or retrospective series. To date, there has been only one large multicenter study to prospectively ascertain maternal and foetal outcomes in women with cardiac disease. This Canadian study also derived and validated a risk index for the prediction of maternal cardiac complications during pregnancy (**Table 5**).

Women with heart disease who are at intermediate or high-risk for complications should be managed in a high-risk pregnancy unit by a multidisciplinary team from obstetrics, cardiology, anaesthesia, and paediatrics.

Table 4: Risks for Maternal Mortality Caused by Various Heart Disease

Cardiac Disorder	Mortality (%)
Group 1 – Minimal Risk	0 to 1
Atrial septal defect	
Ventricular septal defect	
Patent ductus arteriosus	
Pulmonary or tricuspid disease	
Tetralogy of Fallot, corrected	
Bioprosthetic valve	
Mitral stenosis, NYHA classes I and II	
Group 2 – Moderate Risk	5 to 15
2A:	
Mitral stenosis, NYHA classes III and IV	
Aortic stenosis	
Aortic coarctation without valvular involvement	
Tetralogy of Fallot, uncorrected	
Previous myocardial infarction	
Marfan's syndrome, normal aorta	
2B:	
Mitral stenosis with atrial fibrillation	
Artificial valve	
Group 3 – Major Risk	25 to 30
Pulmonary hypertension	
Aortic coarctation with valvular involvement	
Marfan's syndrome with aortic involvement	

NYHA = New York Heart Association.

Table 5: Risk Factors for Maternal Cardiac Adverse Events During Pregnancy

Adverse Maternal Cardiac Event	Risk Factor
Pulmonary oedema	General
Arrhythmia	NYHA functional class III or IV or cyanosis
Stroke	Systemic ventricular EF < 40%
Death	Mitral valve area < 2 sq cm, aortic valve area < 1.5 sq cm, peak left ventricular outflow gradient > 30 mmHg
	Cardiac event (arrhythmia, stroke, pulmonary oedema) prior to pregnancy

The general risk factors can be used to create a maternal risk index for adverse cardiac events related to pregnancy: 0 risk factors < 5% risk, 1 risk factor = 27% risk, ≥ 2 risk factors = 75% risk.

Congestive Heart Failure

Management of congestive heart failure (CHF) during pregnancy, is not much different from that at other times. Salt restriction and limitation of activity to a level below that, which causes symptoms are appropriate. In a woman with significant symptoms or pulmonary oedema, standard therapy can be used with the exception of ACE-inhibitors. Congestive heart failure is one situation, where maintaining a woman in supine position may be beneficial by causing preload reduction with obstruction of return of blood from the inferior vena cava to the heart.

Low-Cardiac-Output Syndrome

A low cardiac output is an ominous sign in pregnancy with heart disease. Although potentially treatable causes such as tamponade or severe valvular stenosis should be considered, it is most often due to intravascular volume depletion. This should be prevented when possible and corrected when recognised.

Thromboembolic Complications

The risk of venous thromboemboli increases five-fold during and immediately after pregnancy, and there is an increase in arterial emboli as well. Prevention is optimal, and prophylactic full-dose heparin or low-molecular-weight heparin is indicated in those at high-risk of a thromboembolic complication. If a thrombus or embolus is identified, 5 to 10 days of intravenous heparin therapy followed by full-dose subcutaneous heparin is recommended. If a thromboembolus is life-threatening, like a massive pulmonary embolus or a thrombosed prosthetic valve, thrombolytic therapy can be used.

Pulmonary Hypertension

Pulmonary hypertension, whether primary or secondary, is associated with 30% to 70% maternal mortality and even with maternal survival, foetal loss exceeds 40%. The mother is most vulnerable during labour and in the first post-partum week. If detected early in pregnancy, interruption is advised. When detected late in pregnancy, close follow-up is necessary. Intravascular volume depletion should be promptly corrected, since it puts these patients at greatest risk. Systemic vascular resistance and pressure must be maintained in patients with pulmonary hypertension who have a right-to-left shunt, and meticulous attention is necessary to avoid air or thrombus emboli from intravenous catheters, which may lead to systemic emboli. At the time of labour and delivery, a central venous line allows adequate fluid administration, and a radial artery catheter makes determinations of blood pressure and oxygen saturation easier. These lines should be continued for 48 to 72 hours post-delivery.

Arrhythmias

The rules for the treatment are the same as in the non-pregnant patient, with the possible exception that a rhythm causing haemodynamic instability should be treated more promptly and aggressively because of the concern about diversion of blood flow away from the uterus.

Complete heart block, which in this age group is most likely to be of congenital origin, is consistent with a successful pregnancy. If required, a permanent pacemaker can be implanted.

Endocarditis

Infective endocarditis is uncommon during pregnancy and the puerperium. The clinical presentation and management of endocarditis during pregnancy is the same as at other times.

SPECIFIC FORMS OF HEART DISEASE

Rheumatic Heart Disease

Rheumatic mitral valve disease continues to be the most prevalent heart disease encountered in pregnant women in India. Women with rheumatic valvular heart disease (VHD), have high rate of clinical deterioration and a marked increase in morbid events during pregnancy, including CHF, arrhythmias and need to either initiate or increase cardiovascular drug therapy or to hospitalise patients during pregnancy. Pregnancy with VHD, may be associated with an increased incidence of intrauterine growth restriction (IUGR), preterm deliveries, and lower birth weight, especially in cases with moderate and severe stenosis of the mitral or aortic valve.

Acute Rheumatic Fever

This disease occurs only rarely during pregnancy and management is similar to that of non-pregnant patients.

Mitral Stenosis

This is the commonest VHD in pregnancy and represents a common health problem in our country. The increased preload of normal pregnancy, as well as other factors that require increased cardiac output, may cause ventricular failure with pulmonary oedema in these women with relatively fixed cardiac output. About 25% of women with mitral stenosis experience cardiac failure for the first time during pregnancy. In some cases, this may be confused with idiopathic peripartum cardiomyopathy. The most prominent complaint is dyspnoea due to pulmonary venous hypertension and pulmonary oedema. Other common symptoms are fatigue, palpitations, cough and haemoptysis.

The therapeutic approach is to reduce the heart rate and decrease blood volume. Limited physical activity is generally recommended. Prophylactically beta-blocking agents can be used and digoxin may be considered in patients with AF. For chronic AF, anticoagulation with heparin is also indicated. If symptoms of pulmonary congestion develop, activity is restricted even more, dietary sodium is restricted and diuretic therapy is started. Labour and delivery are particularly stressful for women with tight stenosis. Epidural analgesia for labour, with strict attention to avoid intravenous fluid overload, is ideal. Vaginal delivery is preferable. In symptomatic patients with moderate-to-severe stenosis (mitral valve area < 1.5 cm^2), haemodynamic monitoring is indicated during labour and delivery with haemodynamic optimisation by diuretics, beta-blockers, digoxin or nitroglycerin. Intrapartum endocarditis prophylaxis is required.

Closed mitral commissurotomy is associated with only minimal risk to the foetus and therefore, preferable to the open technique. It should be recommended only in centres where it is done routinely.

The safety and efficacy of percutaneous balloon mitral valvuloplasty (PBMV) has been reported by several investigators. Now, PBMV during pregnancy has been reported without foetal loss and should be the preferred modality of treatment in this subset of patients. Mitral valve repair or replacement during pregnancy should be considered only in cases with severe stenosis (mitral valve area < 1.0 cm^2), refractory to optimal medical therapy, PBMV is not feasible or when close follow-up during pregnancy, labour and delivery is not possible. When valve replacement is indicated, selection of the type of prosthesis should be based on its haemodynamic profile and durability and the need for anticoagulation.

Mitral Regurgitation

This condition is well tolerated in pregnancy. In symptomatic patients, diuretics are indicated, and digoxin may be beneficial in cases with impaired left ventricular systolic function.

Aortic Stenosis

Rheumatic aortic stenosis is unusual finding in pregnancy and may occur in conjunction with mitral valve disease in about 5% of pregnant patients with rheumatic valvular disease. Most patients with aortic stenosis (Valve area > 1.0 cm^2), tolerate pregnancy well. But patients with more severe stenosis may experience clinical deterioration with exertional dyspnoea, near-syncope or syncope and pulmonary oedema. Serious symptoms during pregnancy, if resistant to medical treatment, may necessitate termination of pregnancy or repair of the valve either surgically (valve replacement) or by percutaneous balloon valvuloplasty. For women with critical aortic stenosis, intensive monitoring during labour is necessary and epidural analgesia seems ideal, thus avoiding potentially hazardous hypotension.

Aortic Regurgitation

This condition is well tolerated in pregnancy. Symptoms necessitate salt restriction, diuretics and digoxin.

Prosthetic Valve Disease

A prosthetic valve is a relative contraindication to pregnancy. Maternal mortality is 3% to 4% with mechanical valves and foetal, loss is common. The critical issue is anticoagulation in cases with mechanical prosthesis. Full anticoagulation throughout pregnancy is recommended with subcutaneous heparin, maintaining anticoagulation at the high therapeutic level by following levels of factor Xa. Just before delivery, heparin is stopped. Protamine sulphate may be used to counter excessive bleeding. Anticoagulant therapy with warfarin or heparin may be restarted 6 hours following vaginal delivery. But anticoagulation should be withheld for at least 24 hours, following caesarean delivery. Antibiotic prophylaxis is necessary during labour.

Mitral Valve Prolapse

Pregnant women with mitral valve prolapse, rarely have cardiac complications. For women who are symptomatic, beta-blockers are used. Antibiotic prophylaxis for labour and delivery in patients with mitral valve prolapse, accompanied by valve thickening and/or regurgitation, seems warranted.

Congenital Heart Disease

A good maternal outcome can be expected in most cases with acyanotic congenital heart disease. Maternal functional capacity and cyanosis determine foetal outcome. Foetal wastage is about 45% in cyanotic mothers compared with 20% in acyanotic mothers with congenital heart disease. Prematurity and IUGR are common in cyanotic mothers. Risk of congenital heart disease is increased for the offspring of mothers with congenital heart disease with a reported incidence of 4% to 8%.

Elective induction of labour, when foetal maturity is confirmed, may be used in high-risk patients for better planning of haemodynamic monitoring. Vaginal delivery is preferred for

most patients, and caesarean section is indicated in stable patients only for obstetric reasons. Oxygen should be given to hypoxaemic mother during labour. Haemodynamic and blood gas monitoring is necessary in patients with impaired functional capacity, cardiac dysfunction, pulmonary hypertension, and cyanotic malformations. Blood loss should be treated promptly.

Antibiotic prophylaxis for vaginal delivery in all patients with congenital heart disease (except secundum type of ASD, 6 months or more after repair of septal defects or surgical ligation and division of patent ductus arteriosus), is necessary.

Atrial Septal Defect

Atrial septal defect is well tolerated in pregnancy. Pulmonary hypertension and atrial arrhythmias occur rarely and antibiotic prophylaxis is not indicated.

Ventricular Septal Defect

Isolated ventricular septal defect is usually well tolerated in pregnancy. The occasional congestive heart failure or arrhythmias, developing during pregnancy, can be managed in the usual manner. The incidence of ventricular septal defect in the offspring has been reported to be 4% to 11%. Volume depletion during or after delivery, may lead to shunt reversal, in patients with pulmonary hypertension. Prompt volume replacement is necessary to prevent further complications.

Patent Ductus Arteriosus

A patent ductus arteriosus is tolerated well during pregnancy. On occasion, congestive heart failure can occur, but standard treatment is effective. Antibiotic prophylaxis is recommended. Peripartum decrease in systemic blood pressure should be promptly corrected.

Congenital Aortic Valve Disease

Most patients with mild aortic stenosis have favourable outcome of pregnancy, provided that they are diagnosed early. Appropriate care, including haemodynamic monitoring during labour and delivery and appropriate anaesthesia are associated with favourable outcomes. Moderate and severe aortic stenosis may be associated with symptomatic deterioration during pregnancy and may lead to maternal morbidity and even mortality. Exertional dyspnoea, chest pain, light headedness, and syncope may develop in the second or third trimester. Increased incidence of cardiac defects has been reported in live born infants of mothers with left ventricular outflow obstruction. Optimal management strategies of a pregnant woman with severe aortic stenosis include early abortion followed by valve replacement and repeat pregnancy, and continuation of pregnancy and plan for percutaneous balloon valvuloplasty or surgical intervention who show clinical deterioration not controlled by medical therapy. These procedures have been performed successfully in pregnant women but are not free from complications. So, these interventions should be reserved for patients with severe disease, not manageable by medical therapy and should be avoided during first trimester.

Coarctation of Aorta

Both maternal and foetal outcome is usually favourable. In case of severe hypertension, congestive heart failure and aortic dissection may occur. To prevent aortic dissection and rupture of cerebral aneurysm, physical activity should be limited and blood pressure must be adequately lowered. Surgical correction can be performed successfully in patients with severe, uncontrolled systolic hypertension or heart failure.

Pulmonic Stenosis

Isolated pulmonic stenosis is usually well tolerated in pregnancy. Occasionally, progressive right ventricular failure, symptoms related to stenotic valve or intracardiac shunt at either the atrial or ventricular level with cyanosis may develop. Percutaneous balloon valvotomy should be considered in such situations.

Tetralogy of Fallot

Successful pregnancy can be achieved, but maternal mortality is high and foetal loss can exceed 50%. During labour and delivery, right to left shunt may increase. Maternal haematocrit above 60%, arterial oxygen saturation below 80% and syncopal episodes are poor prognostic signs. In cyanotic women, the rate of spontaneous abortion, premature deliveries and IUGR is high. Close monitoring of systemic blood pressure and blood gases during labour is necessary for cyanotic or symptomatic patients. Incidence of cardiac defects reported born to such mothers infants ranges between 3 and 17%.

Patients who have significant residual defects after repair, such as residual ventricular septal defect, pulmonic stenosis or regurgitation, and ventricular dysfunction, are still at higher risk during pregnancy. Patients who had undergone shunt procedures to improve cyanosis, may develop pulmonary hypertension, which increases the risk of pregnancy. After surgical repair, maternal and foetal outcomes improve markedly.

Eisenmenger's Syndrome

This condition leads to poor foetal outcome, with high incidence of foetal loss, prematurity, IUGR and perinatal death.

Since there is a high-risk of maternal mortality, patients with Eisenmenger's syndrome should be advised against pregnancy, and early abortion should be recommended for those who are already pregnant. In an overview of 125 pregnancies in patients with Eisenmenger's syndrome, primary and secondary pulmonary hypertension, maternal mortality was uniformly high at 36%, 30% and 56% respectively. The overall neonatal mortality was 13%.

Management of a patient who decides to proceed to term, must include close follow-up for early recognition of clinical deterioration. Anticoagulation is necessary in the third trimester and 4 weeks post-partum, to prevent peripartum thrombo-embolism. Since premature delivery is common, patients should be hospitalised for any sign of premature uterine activity. Early hospitalisation ensures restricted activity and close follow-up. Spontaneous delivery is preferred to induction, and should lower the chance of prematurity or the need for caesarean section. Blood pressure, ECG and blood gas monitoring are essential during labour and delivery to ensure early detection and correction of problems. High concentration of oxygen may be beneficial. Most patients with stable condition, tolerate vaginal delivery, but an attempt is to be made to shorten the second stage of labour by the use of forceps. A planned caesarean section is often preferred, to avoid risk of foetal distress during vaginal delivery and potential need for emergency caesarean section. Swan-Ganz catheter should be avoided.

Ebstein's Anomaly

Pregnancy with acyanotic Ebstein's anomaly is well tolerated. But in cyanotic cases, pregnancy is associated with increased risk of maternal heart failure, prematurity and foetal loss. The management during labour and delivery in symptomatic or cyanotic cases, includes antibiotic prophylaxis, oxygen inhalation, haemodynamic and blood gas monitoring, and measures to prevent a fall in systemic blood pressure due to peripheral vasodilatation or blood loss.

Complex Cyanotic Congenital Heart Disease

In India, very few successful pregnancies have been reported in patients with partially corrected and uncorrected cyanotic heart disease, like pulmonary and tricuspid atresia, transposition of great vessels, truncus arteriosus, single ventricle, double-outlet right ventricle and double-inlet left ventricle. A report (outside India) has demonstrated complications like, heart failure, thromboembolic events, supraventricular tachycardia, peri-partum infective endocarditis, high incidence of foetal wastage, premature deliveries, IUGR and both cardiac and non-cardiac congenital malformations, in such situations.

Marfan's Syndrome

In this condition, pregnancy may be associated with cardiovascular complications and a high-risk of having a child who will inherit the condition. Cardiovascular complications include dilatation of ascending aorta, leading to aortic regurgitation and congestive heart failure, and proximal and distal dissections of aorta with occasional involvement of the iliac and coronary arteries. Patients with aortic diameter less than 40 mm, usually tolerate pregnancy well. Marfan's syndrome may be associated with cervical incompetence, abnormal placental site and post-partum haemorrhagic complications. Women with Marfan's syndrome should be advised to avoid pregnancy and if already pregnant, interruption is recommended. Preconception echocardiographic assessment of the aorta and periodic follow-up during pregnancy are necessary and transoesophageal echocardiography is preferred. During pregnancy, physical activity should be restricted and beta-blockers should be administered. Substantial dilatation of aorta, necessitates therapeutic abortion or surgical intervention. Caesarean section should be preferred to minimise, haemodynamic stresses of vaginal delivery.

Hypertrophic Cardiomyopathy

In this condition, pregnancy is associated with a favourable outcome in most cases but there may be increased morbidity and even mortality. If congestive heart failure or abnormal rhythms occur, standard therapy is appropriate. Hypovolaemia should be avoided. Beta-blockers or calcium channel blockers may be used if necessary. Vaginal delivery is safe and second stage of labour may be shortened by the use of forceps. Antibiotic prophylaxis is necessary during labour and delivery.

Peripartum Cardiomyopathy

Symptoms usually occur during last trimester and is detected in the early peripartum period. The clinical presentation and haemodynamic changes are same as in other forms of dilated cardiomyopathy. The incidence is greater in elderly multiparous women with pre-eclampsia and twin pregnancies. There is relatively rapid recovery of cardiac size and function in large number of patients with recurrence of left ventricular dysfunction in subsequent pregnancies. About 50% to 60% of the patients show complete or near complete recovery of clinical status and cardiac function, usually within first 6 months post-partum. Rest of the patients demonstrate either further clinical deterioration, leading to early death or persistent left ventricular dysfunction and chronic heart failure.

Acute heart failure necessitates prompt treatment with oxygen, diuretics, digoxin and vasodilator agents. Anticoagulant therapy is necessary. The temporary use of an intra aortic balloon pump or left ventricular assist device may help stabilise the patient's conditions pending improvement. Intravenous immune globulin use, has shown a favourable effect on recovery of left ventricular dysfunction. Subsequent pregnancies should be discouraged.

CONCLUSION

With important exceptions, most women with cardiac disease can be expected to do well during pregnancy with appropriate management based on systematic risk stratification. Pregnancies deemed to be at intermediate or high-risk should be managed and delivered in a tertiary care setting. More thorough pre-pregnancy cardiovascular evaluations, is likely to better identify patients who are capable of proceeding safely with pregnancy and delivery. Best outcome is based on the strong relationships between physicians in cardiology and in high-risk obstetrics.

13.1 Clinical Approach—Gastrointestinal Disorders

AC Anand

Patients with gastrointestinal diseases can have varied presentations. Symptoms like dysphagia, heartburn, abdominal pain, nausea, vomiting and haematemesis point to diseases of the upper gastrointestinal tract, while constipation, diarrhoea and haematochezia are commonly due to disease of the lower gastrointestinal tract. Diagnosis from individual gastrointestinal symptom may however be difficult at times as symptoms may overlap in a variety of diseases. For example, even the classic symptoms of peptic ulcer such as relief of pain by antacids or food and nocturnal pain are commonly seen in functional dyspepsia.

DYSPHAGIA, ODYNOPHAGIA AND HEARTBURN

Dysphagia, odynophagia and heartburn point towards oesophageal diseases as a cause of the symptoms. Dysphagia is difficulty in passage of solids or liquids from the mouth to the stomach. It should be distinguished from odynophagia, which is pain on swallowing. Heartburn is a burning sensation behind the sternum.

It is important to differentiate dysphagia into causes that mostly affect the pharynx or proximal oesophagus (high/oropharyngeal dysphagia) and low oesophageal dysphagia. Oropharyngeal (transfer) dysphagia is due to diseases of the neuromuscular mechanism of the pharynx and cricopharyngeus. The patient is unable to initiate and execute the swallow mechanism. There may be coughing or regurgitation of fluids from the nose while swallowing besides associated features of cranial nerve palsies in the form of dysarthria and hoarseness of voice. Low oesophageal dysphagia is due to diseases involving the body of the oesophagus and gastro-oesophageal junction.

The common causes of dysphagia are given in **Table 1** and the approach to a patient with dysphagia is summarised in **Figure 1**. The diagnosis can be confirmed by barium swallow, upper GI endoscopy and oesophageal motility study as indicated.

NAUSEA, RETCHING AND VOMITING

Nausea is an unpleasant feeling of wanting to vomit; this may be associated with autonomic features like increased salivation and sweating. Retching is a strong involuntary effort at vomiting. Vomiting is associated with bringing out of gastric contents through the mouth.

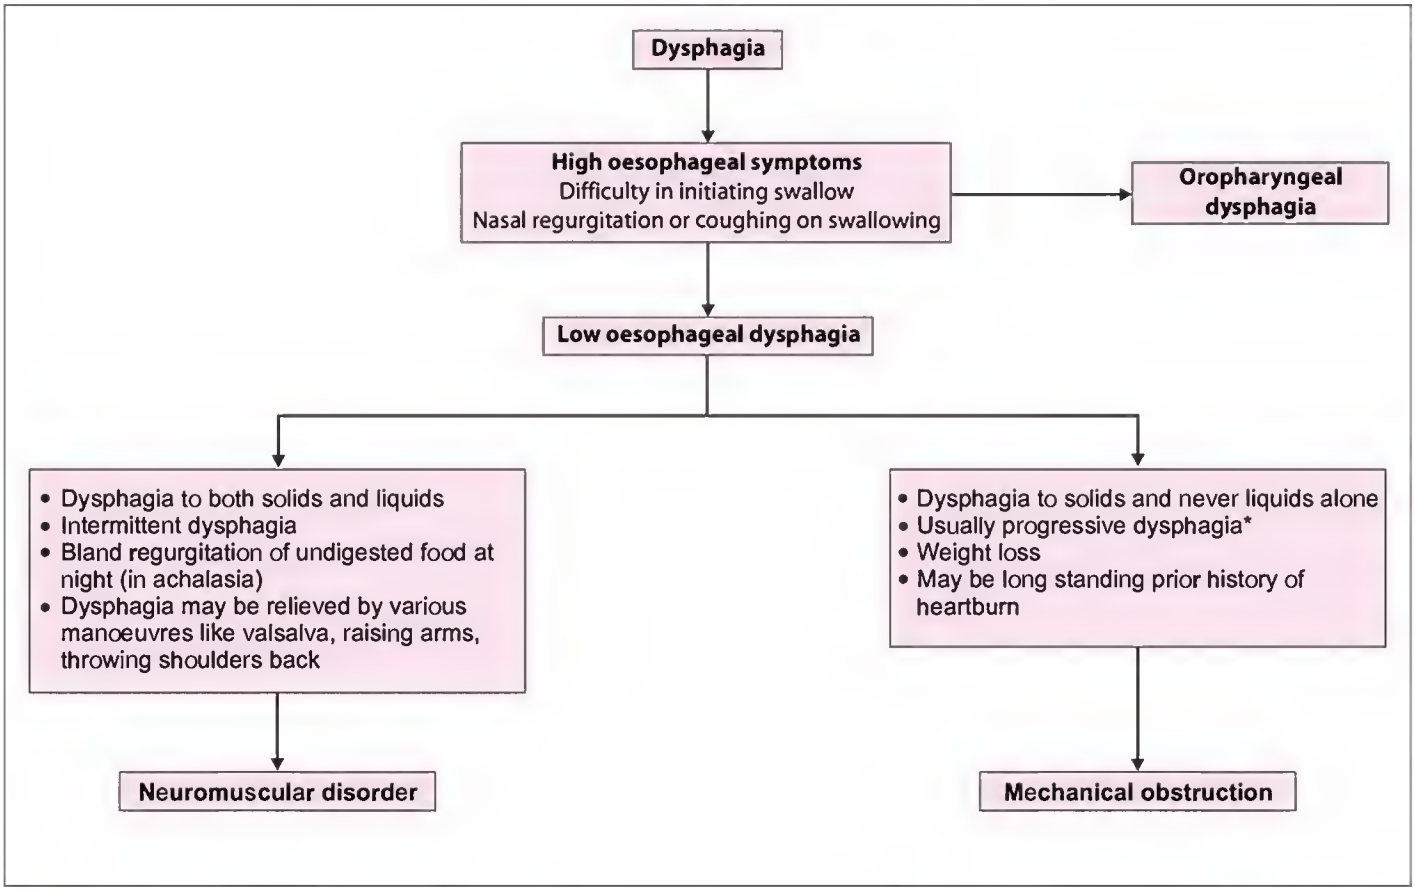

Figure 1: Approach to a case with dysphagia.
** May be intermittent dysphagia in an oesophageal ring.*

Gastrointestinal disorders causing vomiting include infections, bowel obstruction, cholecystitis, pancreatitis, infectious hepatitis, appendicitis and peptic ulcer. Vomiting may also be due to drugs, motion sickness, raised intracranial tension, meningitis, azotaemia, pregnancy, systemic illness and psychogenic causes.

Associated symptoms like abdominal pain and constipation point to a gastrointestinal aetiology. Vomitus may be projectile in raised intra-cranial tension. There may be stale food in vomitus in gastric outlet obstruction. The vomitus is bilious in obstruction distal to the duodenum. Vomiting of psychogenic aetiology occurs during or soon after a meal.

Table 1: Causes of Dysphagia

Oropharyngeal or high dysphagia	Neurological	Cerebrovascular accident Motor neurone disease Parkinson's disease Multiple sclerosis Myasthenia gravis
	Anatomical or muscular	Oropharyngeal malignancy (uncommon) Zenker's diverticulum Retropharyngeal abscess Cervical osteophyte
Low oesophageal dysphagia	Motility disorder	Achalasia Scleroderma Chagas disease Diffuse oesophageal spasms
	Mechanical obstruction	Webs Schatzki ring Neoplasm Strictures Dysphagia lusoria (due to aberrant subclavian artery)

DYSPEPSIA

Dyspepsia comprises of a group of upper abdominal symptoms including bloating, pain, postprandial fullness, heartburn and belching. Dyspepsia is defined as chronic or recurrent pain or discomfort centred in the upper abdomen. The first step in assessment is to select patients who will require early endoscopy and/or investigations to rule out serious diseases such as malignancy. The warning signs and symptoms that should alert the physician to a possibility of malignant disease are shown in **Table 2**.

Table 2: Alarm Symptoms in a Patient with Dyspepsia that Indicate High Risk for Serious Underlying Disease

Anaemia
Weight loss
Gastrointestinal bleed
Recent onset of progressive symptoms
Age >45 years
Dysphagia

ABDOMINAL PAIN

Abdominal pain can have three broad patterns: visceral, parietal, and referred.

Visceral Pain

Visceral pain is dull crampy and poorly localised. It is often in the midline because abdominal organs transmit afferents to both sides of the spinal cord. Pain location corresponds to those dermatomes that match the innervation of the diseased organ. Generally, visceral pain from abdominal organs proximal to the ligament of Treitz is felt in the epigastrium; pain from organs between the ligament of Treitz and the hepatic flexure of the colon is felt in the periumbilical region; and that from organs beyond the hepatic flexure is perceived in the lower abdomen midline. Pain arising in hollow organs may wax and wane due to peristaltic waves.

Parietal Pain

Parietal pain is well localised and sharp and is due to peritoneal irritation by the inflamed organ, e.g. appendicitis.

Referred Pain

Referred pain may be seen, for example, as shoulder pain due to liver abscess causing diaphragmatic irritation.

Assessment of cause of abdominal pain includes a careful history of onset, duration, progress, location, radiation, character and aggravating and relieving factors.

Clinical examination starts with inspection, which may show scars, hernias, splinting of abdominal movements, and visible peristalsis. A patient with peritonitis would lie still and the abdomen would be tender and would appear rigid. In contrast, a patient with ureteric colic may be rolling in bed due to pain. Visible peristalsis may be seen in bowel obstruction. Palpation may show a lump or tenderness. Guarding or rebound tenderness may be seen in peritonitis. Percussion may show ascites or obliteration of hepatic dullness in bowel perforation. Auscultation may reveal hyperactive or absent bowel sounds, besides bruits. Rectal examination can reveal a rectal growth or a pelvic abscess.

GASTROINTESTINAL BLEEDING

Bleeding from the GI tract can present as melaena, haematochezia or haematemesis; patients with occult bleed may present only with anaemia.

Melaena is black, tarry foul-smelling stool and usually signifies the presence of >50 mL of blood. It usually implies a proximal GI source. It takes about 12 hours of transit time for melaena to develop. It can rarely develop as a result of bleeding from right colonic sources.

Haematochezia (maroon bloody stools) can come from a proximal GI source if intestinal transit is rapid but usually signifies a lower GI source. Fresh red blood is commonly due to rectal or left colonic disease.

Haematemesis is blood in vomitus. It may be fresh bright-red or older coffee-ground material and signifies an upper GI bleed. The presence of haematemesis or melaena signifies an upper GI source but patients with rapid upper GI bleed may present with haematochezia.

Preliminary clues to the site of haemorrhage include the presence of haematemesis, hyperactive bowel sounds, and increased blood urea nitrogen out of proportion to creatinine (upper GI), or fresh rectal bleeding (colonic). Insertion of a nasogastric tube and aspiration may help in localisation of bleeding. However, it may be negative in some cases of upper GI bleed.

In upper GI bleeding, from a management point of view, it is important to differentiate between variceal and non-variceal aetiology. The clinical evaluation of upper GI bleed is shown in **Table 3**. Gastrointestinal endoscopy is usually required to make a definitive diagnosis. In obscure GI bleeding, one may need an isotope scan, angiography, or capsule or double-balloon enteroscopy to determine the source of bleeding.

Table 3: Differentiating Variceal from Non-Variceal Bleed

Variceal source suspected if GI bleeding is associated with
Jaundice
Ascites
Splenomegaly
Past history of treatment for liver disease
Clinical stigmata of chronic liver disease (spider naevi, palmar erythema, testicular atrophy, gynaecomastia, etc.)
Non-variceal source is suspected if bleeding is associated with
Absence of the above
History of epigastric pain
Past history of peptic ulcer
Recent NSAID intake
Recurrent vomiting/retching (Mallory-Weiss tear)

CONSTIPATION

Patients usually define constipation not only by infrequent stools (typically fewer than three per week), but also by associated symptoms which are equally important, and probably more important, such as: hard stools, the need for excessive straining, a sense of incomplete bowel evacuation, and excessive time spent on the toilet or in unsuccessful defaecation.

Constipation is a common symptom, more so in the elderly. A number of commonly used drugs in the elderly often aggravate constipation, including calcium supplements, iron supplements, diuretics, calcium-channel blockers, etc. A history of recent onset of constipation and/or blood mixed with stool raises the possibility of a malignant colonic lesion.

A thorough physical examination should be performed to exclude systemic or neurological illnesses that may cause constipation. Abdominal examination may reveal abdominal mass or palpable stools. Anorectal examination may reveal fissures, haemorrhoids, lack of anal sphincter tone or a rectal stricture.

Stool for occult blood is a useful screening test, while colonoscopic examination would be required to rule out local diseases.

DIARRHOEA

Diarrhoea is defined as increase of volume, frequency or fluidity of stool. It could be acute or chronic. Acute diarrhoea (< 4 weeks) is usually due to infections and is often self-limited. It may be associated with fever, pain in abdomen or dehydration.

Chronic diarrhoea (>4 weeks) may be associated with malabsorption and weight loss.

Evaluation of a case of chronic diarrhoea requires detailed clinical history. Malabsorption will be associated with semisolid (occasionally watery) stools that are bulky, float on water, and stick to the pan. The stools may be explosive in character and be associated with flatulence and borborygmi. It may contain undigested food particles, increase with lactose intake, and decrease on fasting. There may be mild periumbilical pain relieved by passage of flatus or stools. Small volume stools associated with blood, mucous and tenesmus are suggestive of large bowel diarrhoea. The clinical clues to aetiology of chronic diarrhoea are given in **Table 4**.

The approach to chronic diarrhoea (>4 weeks) should follow the following steps:

Table 4: Chronic Diarrhoea: Clinical Clues

Clubbing: Immunoproliferative small intestinal disease, Crohn's disease, coeliac disease
Fever: Tuberculosis, lymphoma, Whipple's disease, Crohn's disease/ulcerative colitis
Response to antibiotics: Bacterial overgrowth, giardiasis, tropical sprue, Whipple's disease
Response to steroids: Inflammatory bowel disease (IBD), microscopic colitis, eosinophilic gastroenteritis, Addison's disease
Arthritis: IBD, coeliac disease, Whipple's disease, collagen disorder
Lymphadenopathy: HIV, Whipple's disease, tuberculosis, lymphoma
Dermatitis herpetiformis: Coeliac disease
Pyoderma gangrenosum: IBD
Abdominal mass: Crohn's disease, lymphoma, tuberculosis

Step 1: Rule-Out Irritable Bowel Syndrome

Red flag symptoms that are against the diagnosis of irritable bowel syndrome are shown in **Table 5**.

Table 5: Red Flag Symptoms that make the Diagnosis of Irritable Bowel Syndrome Unlikely

Fever
Weight loss
Nocturnal diarrhoea
Blood in stools
↓ Haemoglobin, ↓ albumin, ↑ ESR
Recent symptoms in middle age/elderly

Step 2: Large Bowel versus Small Bowel (Table 6)

Table 6: Large Bowel Diarrhoea versus Small Bowel Diarrhoea

Large bowel diarrhoea	Small bowel diarrhoea
Presence of blood and mucous	Malodorous, floating, greasy, containing undigested food particles
Rectal/anal symptoms such as tenesmus/dyschezia	Large-volume stools
Small-volume jelly-like stools	Mid-abdominal cramps with borborygmi
Associated hypogastric cramps	

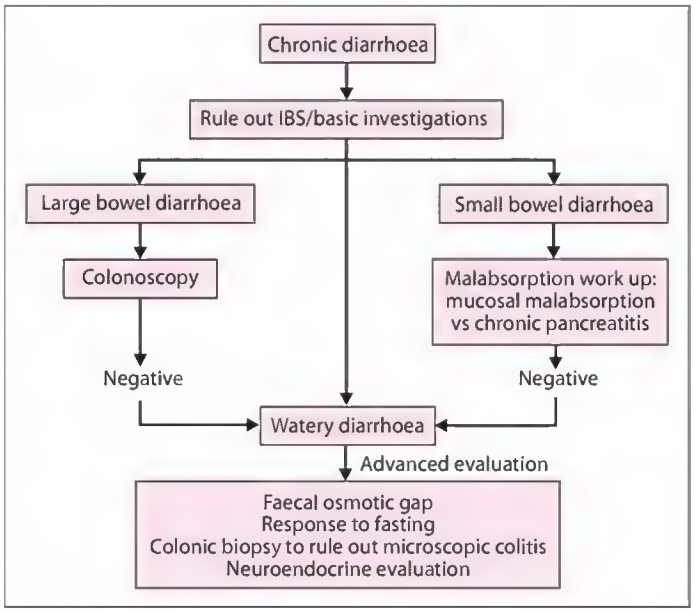

Figure 2: Approach to chronic diarrhoea: Basic clinical segregation of patient into small bowel diarrhoea and large bowel diarrhoea is usually adequate in directing evaluation. A small subgroup of patients with watery diarrhoea, in whom evaluation for the above have been negative, require advanced evaluation.

Step 3: Chronic Pancreatitis versus Mucosal Malabsorption

Features of carbohydrate malabsorption with lactose intolerance causing explosive stool with flatulence are suggestive of mucosal malabsorption. This can be confirmed by an abnormal d-xylose test. In chronic pancreatitis, classical history of pancreatic pain with radiation to back and imaging evidence of chronic pancreatitis are often clearly evident. The d-xylose test would be normal in chronic pancreatitis and faecal fat excretion is often more than 14 gm/day, much more than that seen in mucosal malabsorption. A clinical approach to chronic diarrhoea is shown in **Figure 2**.

13.2 Investigations—Gastrointestinal Disorders

Ashok Chacko

INTRODUCTION

The gastrointestinal (GI) tract can be evaluated by examination of luminal contents, upper and lower GI endoscopy and various laboratory tests which may help in establishing diagnosis. In this chapter, author discusses about tests for luminal contents and laboratory tests while the endoscopy of GI tract has been covered in next chapter (see Chapter 3 Endoscopy—Diagnostic and Therapeutic Utility).

STOOL EXAMINATION

Stool examination must be performed in all patients with abdominal symptoms, especially diarrhoea. Stool inspection, often neglected, is important as it gives information regarding volume, consistency and presence of blood and mucous.

Stool microscopy helps in detection of RBC and pus cells—suggesting bacillary dysentery and inflammatory bowel disease, parasitic ova/cysts, and fat in stools (Sudan stain) suggesting malabsorption. In immunocompromised patients with diarrhoea, stool evaluation for parasites like *Cryptosporidium, Microsporidium, Isospora belli* and *Cyclospora* should be performed. Stool culture is not done routinely except in persistent diarrhoea. Stool positive for occult blood suggests GI blood loss and warrants further evaluation.

Acidic stools (pH <6) suggests carbohydrate malabsorption. Increased stool alpha 1-antitrypsin clearance helps in diagnosis of protein losing enteropathy. Stool DNA tests (k-ras, APC, p53) are promising screening tests for diagnosis of sporadic colorectal cancer.

Stool osmotic gap (290 - 2 [$Na^+ + K^+$]) is useful to distinguish osmotic from secretory diarrhoea. An osmotic gap >50 mOsm/kg is characteristic of osmotic diarrhoea whereas secretory diarrhoea has osmotic gap <50 mOsm/kg.

GASTRIC ACID SECRETION

Measurement of gastric acid output to evaluate peptic ulcer disease is not relevant now. It is occasionally used to distinguish Zollinger-Ellison syndrome (ZES) from achlorhydria in patients with elevated serum gastrin. Basal acid output (BAO) > 15 mmol per hour suggest ZES (normal BAO <5 mmol/h). Low values are seen in achlorhydria.

ABSORPTION

Tests of absorption are shown in **Table 1**. In assessment of suspected malabsorption, blood tests (CBC, folate, vitamin B12, albumin, anti TTG/endomysial antibody), barium meal follow through and endoscopy with distal duodenal biopsy are performed in most cases.

PANCREATIC EXOCRINE FUNCTION

Tests to evaluate pancreatic exocrine function are shown in **Table 2**. Clinical use of the tests are limited because stimulation tests need intubation and tubeless tests are not sensitive to diagnose early chronic pancreatitis.

Table 1: Tests of Small Intestinal Absorption

Absorption	Test	Method	Comments
Xylose (measures small bowel absorptive surface area)	Blood/urine xylose	Quantification in blood (1h) or urine (5 h collection) after ingestion of 5 g xylose Normal: Blood >0.55 mmol/L Urine >20% of ingested xylose	Rapid small bowel transit, renal failure, *ascites*, incomplete urine collection give false positive results
Fat	72 h faecal fat	Quantification of stool fat while patient ingests 50 g fat/d Normal: <6 g per day	Non-invasive, slow, unpleasant
	^{14}C triolein breath test	Measurement of $^{14}CO_2$ in breath after ingestion of ^{14}C triolein	Non-invasive, fast, not quantitative
Vitamin B12	Schilling test	Quantification of ^{57}CO and ^{58}CO (used to label free vitamin B12 and vitamin B12 - intrinsic factor complex) in 24-hour urine Normal: >10% with equal ratio of both isotopes after antibiotics	*Gastric disease*: Free vitamin B12 absorption decreased *Ileal disease*: Free vitamin B12 and vitamin B12 - IF factor complex absorption decreased *Bacterial overgrowth*: vitamin B12 normal
Lactose	Breath hydrogen	Measurement of breath hydrogen every 30 min for 2 hours after 50 g of lactose Hypolactasia >20 ppm	Early rise of breath H_2 in small bowel bacterial overgrowth
Bile acids	^{75}SeHCAT test	Isotopic quantification of 7 days whole body retention of oral dose ^{75}SeHCAT	Accurate and specific
		Normal: >15%	Involves radiation
		Abnormal: <5%	Slow

Table 2: Tests of Exocrine Pancreatic Functions

Test	Method	Comment
Secretin stimulation test	Injection secretin intra-venously followed by duodenal aspiration Aspirate assayed for bicarbonate	Invasive, expensive Chronic pancreatitis: low volume, low bicarbonate
Pancreolauryl test	Pancreatic esterases cleave fluorescein dilaurate after oral ingestion. Fluorescein absorbed and quantified in urine	Avoids duodenal intubation Test takes 2 days Low sensitivity for early chronic pancreatitis
NBT-PABA test	Pancreatic chymotrypsin releases PABA which is assayed in urine	Less reliable as compared to pancreolauryl test
Faecal chymotrypsin/ elastase	Immunoassay of chymotrypsin/elastase in stool	Simple, quick, does not detect mild disease

TESTS FOR MUCOSAL PERMEABILITY

Mucosal permeability of small bowel can be evaluated by ^{51}Cr-EDTA and sugar tests (lactulose-rhamnose). Urinary quantification of label after oral ingestion of ^{51}Cr-EDTA is performed. Increased level of label in urine suggests increased intestinal permeability.

The small intestine absorbs monosaccharides but not undigestable disaccharides (lactulose) unless mucosa is leaky. Lactulose-rhamnose test detects increased intestinal permeability and is abnormal in IBD, coeliac disease, tropical sprue, NSAIDS. The test is rarely used clinically as it is not specific.

MUCOSAL BIOPSY

If is obtained either by 'cupped biopsy forceps' passed through an accessory channel of an endoscope or by Crosby capsule per orally under fluoroscopic guidance. It provides definite histological diagnosis of the diseases of oesophagus, stomach, small bowel (duodenum, proximal jejunum), distal ileum and colon. Detection of *Helicobacter pylori* in stomach is rapidly performed by placing two gastric biopsy specimens (antrum, body) into a container using rapid urease kit which changes colour in a few minutes from yellow to red.

TESTS OF GASTROINTESTINAL MOTILITY

Radiological, manometric and radioisotope tests are used for evaluation of gut motility.

Oesophageal Motility

A careful barium swallow (using video fluoroscopy and bread barium) may give information about oesophageal motility. Oesophageal manometry which measures peristaltic performance, contraction wave configuration (amplitude, velocity), basal and post-swallow lower oesophageal sphincter pressure is the 'gold standard' test to evaluate motor disorders of oesophagus, like achalasia cardia and diffuse oesophageal spasm.

Monitoring gastro-oesophageal acid reflux with pH sensitive electrodes over 24 hours distinguishes refractory gastro-oesophageal reflux from other causes of chest pain and in relating atypical symptoms to episodes of reflux. A small portable recording device allows time of symptoms, meals and sleeping to be recorded which can be correlated with episodes of low pH.

Gastric Emptying

Delayed gastric emptying due to diabetic gastroparesis or gastric surgery may cause bloating, early satiety, nausea and vomiting. Endoscopy and barium studies are often normal. Gastric transit can reliably be measured by calculating the amount of radio isotope retained in the stomach after a test meal of solids and liquids labelled with different isotopes (Technetium/Indium).

Small Intestinal Transit

Oro-caecal transit can be estimated by lactulose-hydrogen breath test. Lactulose, a non-absorbable disaccharide reaches the colon intact. Bacterial metabolism of lactulose in the colon produces hydrogen. The time interval between ingestion of lactulose and rise in breath hydrogen give a measure of oro-caecal transit. Radionuclide techniques can also measure small bowel transit. Small bowel transit is seldom measured in clinical practice.

Colonic and Anorectal Motility

Total and segmental colon transit can be measured by plastic radio-opaque marker technique. The test is useful for evaluation of chronic constipation and helps differentiate slow transit constipation from obstructed defaecation. Obstructed defaecation and anorectal physiology are assessed by defaecating proctography and anorectal manometry.

BREATH TESTS

Breath tests are enlisted in **Table 3**.

Table 3: Breath Tests

Test	Indication	Positive Test
Hydrogen breath test		
Glucose	Small bowel bacterial overgrowth	>12 ppm rise over baseline within 120 min.
Lactulose	Small bowel transit	Time to first sustained response within 3-5 hours
Lactose	Hypolactasia	20 ppm rise over baseline within 3 h.
^{14}C-Xylose breath test	Bacterial overgrowth	$^{14}CO_2$ > 0.3% at 2-3 h
^{14}C-Glycocholic acid breath test	Bacterial overgrowth	$^{14}CO_2$ > 0.3% at 2-3 h
^{14}C-triolein breath test	Fat malabsorption	Breath $^{14}CO_2$ < 0.0005%
^{13}C or ^{14}C-Urea breath test	Confirm *H. pylori* eradication	$^{13/14}CO_2$ > 5-fold baseline at 20 min.

RADIOISOTOPE TESTS

Radioisotope tests are shown in **Table 4**.

Table 4: Radioisotope Tests

Test	Isotope	Indication
Gastric emptying	^{99m}Tc pertechnetate ^{111}In-DTPA	Gastroparesis
Urea breath test	^{14}C/^{13}C Urea	Confirm *H.pylori* eradication
Meckel's scan	^{99m}Tc-pertechnetate	Meckel's diverticulum in obscure GI bleed
Labelled red cell scan	^{51}Cr labelled erythrocytes	Obscure GI bleed
Labelled leucocyte scan	^{111}In or ^{99m}Tc HMPAO labelled leucocytes	Distribution of activity (extent) in inflammatory bowel disease
Albumin tagged scan	^{125}I-Albumin, ^{51}Cr-Albumin	Protein losing enteropathy

TUMOUR MARKERS

CA 19:9	Pancreatic and biliary malignancy
CEA	Colonic malignancy
Chromogranin	Neuroendocrine tumour

Molecular Tests

Disorder	Gene Affected
Familial adenomatous polyposis	APC
Multiple endocrine neoplasia	Menin
Hereditary non-polyposis colon cancer	hMSH 2, hMLH1
Peutz-Jegher syndrome	LKB1

13.3 Endoscopy—Diagnostic and Therapeutic Utility

Gourdas Choudhuri

INTRODUCTION

Advancement in endoscopy has revolutionised our approach to diagnosis and management of various gastrointestinal disorders. The word endoscopy is derived from Greek, 'end' meaning within and 'skopein' meaning to view or observe. In this chapter upper gastrointestinal endoscopy, colonoscopy and endoscopic retrograde cholangio-pancreatography (ERCP) will be discussed in brief.

HISTORY

The first attempt at looking into the body cavity was made by Adolf Kussmaul who devised the first gastroscope in 1868, made up of a rigid metal tube. Subsequently Rudolf Schindler (1888-1968) improved this instrument but it was Basil Hirschowitz who pioneered the use of fibre optics (glass fibre that conduct light) that greatly improved the flexibility and manoeuvrability of the instrument. In 1957 he himself swallowed the first fibre optic gastroscope. The use of electronic chips (charge couple devices or CCD) to transmit the image from the tip of the endoscope to a video screen resulted in the present generation of video endoscopes since the 1980s.

UPPER GASTROINTESTINAL ENDOSCOPY (UGIE)

Indications

This largely depends on the suspected diagnosis, availability of facilities and expertise, and patient's choice. The common diagnostic and therapeutic indications for UGIE are given in **Table 1** and shown in **Figures 1 to 6**.

Contraindications

The absolute contraindications are given in **Table 2**. Apart from these conditions special precautions should be taken in patients with Zenker's diverticulum, compromised cardiovascular and pulmonary reserve and coagulopathy. Taking biopsy should be avoided in patients with coagulopathy. Pregnancy is not a contraindication for UGIE, but should only be performed for pressing indications.

Table 1: Indications for Upper Gastrointestinal Endoscopy

Diagnostic	Upper gastrointestinal bleeding: past or present
	Patients with splenomegaly or suspected chronic liver disease: for presence and grading of oesophago-gastric varices
	Upper abdominal distress that persists despite an appropriate trial of therapy
	Upper abdominal distress associated with symptoms or signs that suggest serious organic disease.
	Dysphagia or odynophagia
	Oesophageal reflux symptoms that are persistent or recurrent despite appropriate therapy
	Persistent nausea and vomiting of unknown cause
	Surveillance for malignancy
	Gastric or oesophageal ulcers
	Familial adenomatous polyposis
	Adenomatous gastric polyps
	Barrett's oesophagus
	Occult gastrointestinal bleeding
	Small bowel biopsy
	Cirrhotic patients in whom prophylactic therapy is considered
	After caustic ingestion to assess for acute injury
Therapeutic	Treatment of bleeding lesions
	Sclerotherapy or banding of varices
	Removal of foreign bodies
	Removal of selected polypoid lesions or superficial neoplasms
	Placement of feeding or drainage tubes
	Dilation of stenotic lesions
	Palliative treatment of stenosing neoplasms
	Drainage of pancreatic pseudocysts

Table 2: Contraindications for Upper Gastrointestinal Endoscopy

The risks to patient health or life are judged to outweigh the most favourable benefit of the procedure.
Adequate patient cooperation cannot be obtained.
A perforated viscus is known or suspected.

Figure 1: Upper gastrointestinal endoscopy showing large oesophageal varices with red colour signs.

Figure 2: Upper gastrointestinal endoscopy showing polypoidal, ulcerated growth suggestive of oesophageal cancer.

Figure 3: Upper gastrointestinal endoscopy showing a benign gastric ulcer.

Figure 4: Oesophageal variceal sclerotherapy. Note the blue scleropathy needle.

Figure 5: Glue injection being done in a patient with large, bleeding fundal varices.

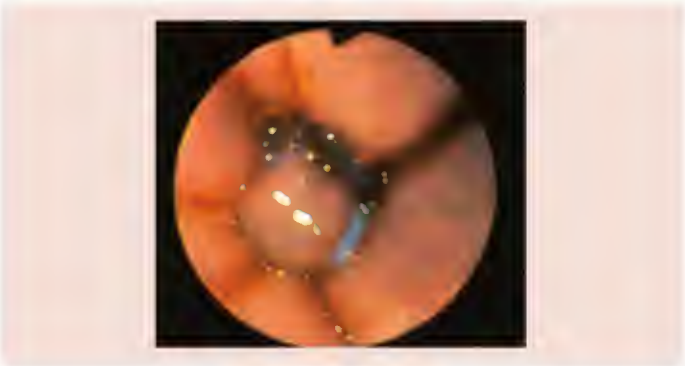

Figure 6: Oesophageal variceal band ligation. Note the blue 'O' ring on one of the varix.

Preparation and the Procedure

The procedure is performed after anaesthetising the pharynx with lignocaine spray or gel. Tense and apprehensive patients may need intravenous sedation with midazolam or propofol. The procedure is performed with the patient lying in the left lateral position. The endoscope is inserted through the mouth, pharynx, oesophagus, stomach and then further down to the second part of the duodenum under vision.

Complications of UGIE

Endoscopic examination of the upper gastrointestinal tract is a fairly safe procedure with overall complications being less than 1% and mortality rate <0.01%. Serious complications following diagnostic UGIE like perforation (0.01% to 0.11%) and bleeding (0.03% to 0.1%) are rare. Pulmonary complications like aspiration, decreased oxygen saturation and pulmonary infection are known to occur. The cardio-pulmonary complications include premature beats, arrhythmias and respiratory depression, which occur mostly due to use of pre-medications at the time of UGIE. There is a small risk of transmission of diseases like hepatitis B, hepatitis C, *Helicobacter pylori*, *Pseudomonas*, *Salmonella* and mycobacteria. Transient bacteraemia has been reported following oesophageal dilatation and sclerotherapy in up to 30% of cases; it has importance for patients with valvular heart disease who need prophylaxis with antibiotics for prevention of sub-acute bacterial endocarditis.

COLONOSCOPY

Since early 1970s colonoscopy is in common use in gastro-enterology. Although it is a more difficult and time consuming procedure compared to UGIE, it has become widely accepted as the most useful test for evaluation of the colon and terminal ileum.

Indications

The indications can be divided into two categories; diagnostic and therapeutic (**Table 3**) and shown in **Figures 7 to 9**.

Table 3: Indications for Colonoscopy

Diagnostic	Unexplained rectal bleeding
	Unexplained lower gastrointestinal symptoms and signs, such as recent onset constipation or feeling of incomplete evacuation, especially in the elderly
	Non-diagnostic radiographic examination
	Polyp and cancer screening or follow-up
	Inflammatory bowel disease
	Stricture or colonic narrowing (with and without inflammatory bowel disease)
	Diverticular disease
	Infectious colitis
	Radiation colitis
	Ischaemic colitis
	Endometriosis
	Pneumatosis cystoides intestinalis
Therapeutic	Polypectomy
	Foreign body removal
	Dilation of strictures in colon or terminal ileum
	Therapeutic: Haemostasis
	Tumour resection (palliative)
	Colonic decompression (volvulus and pseudo-obstruction)
	Placement of stents for non-resectable malignant obstruction

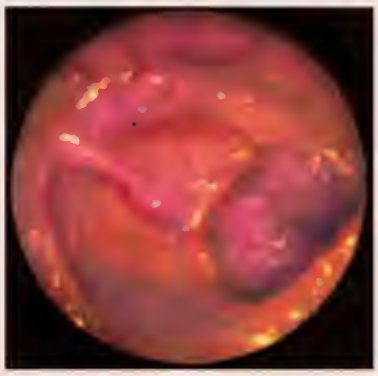

Figure 7: Colonoscopy showing a nodular polypoidal growth in the rectum suggestive of rectal cancer.

Figure 8: Colonoscopy showing ulcerations and pseudopolyps in a patient with ulcerative colitis.

Patient Preparation

A clean colon is mandatory for proper evaluation. Various agents are used to prepare the bowel for colonoscopy; they include polyethylene glycol (PEG) with electrolytes or sodium picosulphate. Before giving peroral bowel preparation in any patient, overt or impending bowel obstruction should be ruled out, to avoid precipitating acute intestinal obstruction.

Sedation and analgesics are more frequently used during colonoscopy than during UGIE. Most centres use midazolam alone or in combination with pentazocine.

Contraindications

Contraindications are listed in **Table 4**.

Table 4: Contraindications to Colonoscopy

Acute inflammation of the colon (fulminant), including ulcerative colitis, Crohn's colitis, ischaemic colitis, diverticulitis, and radiation colitis
Peritonitis
Suspected or impending intestinal perforation
Pregnancy (second and third trimester)
An uncooperative patient
Bleeding disorder
Acute cardiorespiratory disease or recent myocardial infarction
Shock
Large aortic or iliac artery aneurysm
Recent pelvic or colonic surgery

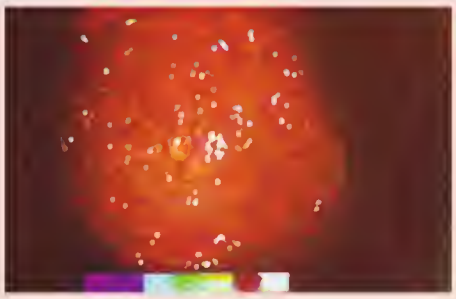

Figure 9: Colonoscopy showing multiple large polyps.

Complications

Apart from side-effects of sedatives and analgesics used and complications of peroral bowel preparation, some serious complications can occur during colonoscopy (**Table 5**).

Table 5: Complications of Diagnostic and Therapeutic Colonoscopy

Diagnostic Colonoscopy	Therapeutic Colonoscopy
Complications of bowel preparation	Perforation
Premedication related problems	Haemorrhage
Bacteraemia	Mucosal burns
Haemorrhage	Incomplete polypectomy
Perforation	Explosion
Diastatic serosal tears	Accidental removal of a urete-rosigmoidostomy stoma
Post-colonoscopy distension	Accidental removal of an intussuscepted appendiceal stump
Vaso-vagal reflex	Electrical ileal perforation
Splenic trauma	
Cardiac and electrocardiographic abnormalities	
A dynamic ileus	
Pneumatosis cystoides intestinalis	
Incarceration or impaction of an instrument in a hernia	
Aortic aneurysm dissection	
Cardiopulmonary problems	

The incidence of perforation and haemorrhage increase from <0.07% during diagnostic colonoscopy to 2.2% following therapeutic procedures like polypectomy. Deaths have rarely been reported following colonoscopy (<0.01%). Bacteraemia following colonoscopy has been reported in up to 27% of cases. Rarely transmural burns and explosion can occur after using electro-surgical instruments.

ENDOSCOPIC RETROGRADE CHOLANGIO-PANCREATOGRAPHY (ERCP) (FIGURES 10 and 11)

Endoscopic retrograde cholangio-pancreatography is a procedure by which the biliary and pancreatic ductal systems are visualised by injecting radio-opaque contrast solutions after endoscopic cannulation of the duodenal papilla. This is a difficult and potentially risky procedure which should be undertaken only by a properly trained and experienced endoscopist. In expert hands the procedure is successful more than 95% of times.

Indications

List of indications for diagnostic and therapeutic ERCP is given in **Table 6**.

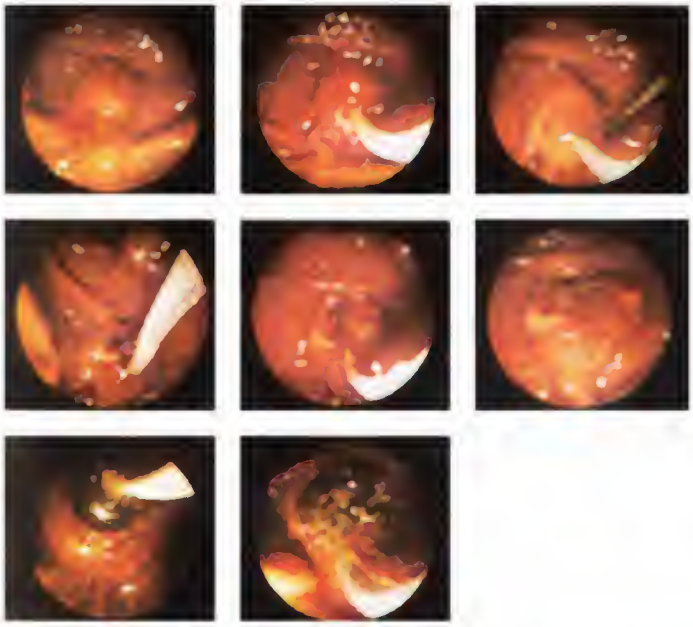

Figure 10: Impacted stone at the ampulla of vater being extracted during ERCP.

Figure 11: Biliary stent inserted during ERCP.

Table 6: Indications for ERCP

Diagnostic	Cholestatic jaundice
	Acute cholangitis
	Choledocholithiasis
	Sphincter of Oddi manometry
	Suspected sclerosing cholangitis
	Choledoschoscopy
	Bile for cytology and other studies
	Evaluation of peri-ampullary neoplasm
	Biliary pancreatitis, recurrent acute pancreatitis, chronic pancreatitis
	Evaluation of pancreatic pseudocyst
	Pancreatic fistula, pancreatic ascites
	Pancreatic juice aspiration for study
	Taking brush cytology or biopsy for confirmation of diagnosis
Therapeutic	Biliary drainage for cholangitis, pruritus, post-operative bile leak
	Extraction of stones, round worms or hydatid daughter cysts from bile duct
	Bile duct stricture dilatation
	Pancreatic duct stone extraction, pancreatic duct stricture dilatation
	Pancreatic duct stenting for pain in chronic pancreatitis, pancreatic ascites and fistula

Contraindications

The contraindications are same as those for upper gastrointestinal endoscopy. With advancement in non-invasive imaging such as MRCP or endoscopic ultrasound, ERCP is rarely required at present for diagnostic purposes. It should be undertaken in patients with suspected biliary obstruction only with sufficient preparations to drain the biliary system as well. The procedure also requires fluoroscopic guidance and hence contraindicated during early pregnancy.

Complications of ERCP

ERCP is a potentially risky procedure especially when therapeutic biliary and pancreatic procedures are performed. The complication rates are high if ERCP is done as an emergency procedure and by an inexperienced endoscopist. The complication rate is 5% to 10% and mortality is 0.5% to 1%. Major complications include post-ERCP pancreatitis in about 5%, haemorrhage (following sphincterotomy) in 2% to 3%, cholangitis 1% to 3% and retro-duodenal perforation in 1%. The list of complications of ERCP is given in **Table 7**.

Table 7: Complications of ERCP

Exposure to radiation	Perforation of duodenum
Pancreatitis	Haemorrhage
Allergy to contrast	Biliary/pancreatic sepsis
Trapped dormia basket	Splenic trauma
Subcapsular biloma of liver	Emphysematous cholecystitis

In addition to the three common standard procedures mentioned above, several new ones are now gaining importance.

1. Endoscopic ultrasound (EUS) is an instrument with a high frequency ultrasound probe mounted on the distal tip of a video-endoscope, and has emerged as the most accurate method for loco-regional staging of upper GI and pancreatobiliary tumours and for imaging the wall of the upper GI tract. It provides high resolution cross sectional imaging and is especially useful for imaging sub-mucosal or intramural lesions.
2. Enteroscopes are long video-endoscopes specially designed to inspect the small intestine. There are 2 types depending on whether it has a double or single balloon. These ballon enteroscopes can be used to inspect up to the mid ileum from the peroral route or from the anal route. They also have an operating channel for fulgurating bleeding lesions, removing polyps or taking biopsy.
3. Cholangioscope is a thin instrument that can be passed into the bile duct for imaging of stones or tumours. A variety of thin instruments can be passed through the operating channel of the ERCP scope, and can be useful for managing tight biliary obstruction due to cholangiocarcinomas or large biliary stones.
4. Contrast endoscopy: There are several new techniques that sharpen the distinction between normal and abnormal mucosa, facilitating better recognition and assessment of extent, as well as more accurate targeting of biopsy. They include chromoendoscopy or narrow band imaging.
5. Confocal endomicroscopy provides very high magnification and enables the cells of the surface layer to be viewed for

diagnosing dysplastic or anaplastic changes. Using this instrument one can diagnose a malignancy during the endoscopic procedure itself, without having to wait for the histopathology report.

FUTURE OF ENDOSCOPY

Endoscopes are now being used to enter the peritoneal cavity by producing a controlled gastric perforation. Having reached there, a diseased appendix or gallbladder can be removed through the natural orifice, i.e. mouth without an external scar. Thus, the procedure is called NOTES (Natural Orifice Trans Endoscopic Surgery). It is being actively developed in several advanced centres and holds promise in the near future.

13.4 Diarrhoea and Malabsorption

BS Ramakrishna

Diarrhoea and malabsorption are disorders that are common in India possibly because of the prevailing lower levels of hygiene and unsafe water supplies. Diarrhoea is characterised by increased liquidity of stool or increased frequency of stool and is defined in different ways depending on the context in which the definition is required. For field studies of the prevalence or incidence of diarrhoea, diarrhoea is defined as three or more stools, taking the form of the container into which they are passed, in a 24 h period. For hospital-inpatient studies, diarrhoea is defined by a stool weight greater than 400 g/24 h (cf. Western definition of 200 g/24 h). In the outpatient clinic, diarrhoea is diagnosed when there is an increase in the frequency and liquidity of the stool compared to an earlier time period. Diarrhoea is categorised as 'acute' or chronic' depending on whether it has lasted less than 2 weeks or more than 4 weeks. In the setting of infectious gastroenteritis, diarrhoea lasting longer than 2 weeks is labelled as 'persistent' diarrhoea. Malabsorption syndromes are one of several causes of chronic diarrhoea. This chapter will review the causes and diagnostic pathways for diarrhoea and malabsorption especially as they pertain to India.

ACUTE DIARRHOEA

Acute diarrhoea is usually due to acute infectious gastroenteritis, although several other causes are shown in **Table 1**. Acute infectious gastroenteritis is a major cause of morbidity and childhood mortality. Over 1.5 million children (approximately 500,000 in India) continue to die worldwide each year because of the consequences of acute diarrhoea. This is significantly less than diarrhoea mortality of five million children per year twenty years ago. Currently, it is estimated that over a half of the diarrhoea deaths in children are associated with malnutrition.

Clinical Features

Acute diarrhoea presents with two basic syndromes—*watery diarrhoea* and *blood and mucous diarrhoea* (also called *dysentery*). When vomiting is very prominent and overshadows diarrhoea, the possibility of viral gastroenteritis or of food poisoning must be considered first. Watery diarrhoea is due to excessive fluid secretion from the small and/or large intestine. In its most dramatic form it is seen in cholera, where the patient may typically lose several litres of fluid in the stool in hours and present to the emergency department with peripheral vascular collapse and un-recordable blood pressure. Cholera, enterotoxigenic *Escherichia coli* infection, and viral gastroenteritis present with acute severe watery diarrhoea. The fluid secretion in watery diarrhoea is due to the effect of enterotoxins that increase the mucosal concentrations of cyclic nucleotides—cyclic AMP and cyclic GMP—which inhibit sodium absorption while turning on chloride secretion in the intestine. These ion movements lead to excessive retention and secretion of fluid into the lumen of the intestine. While cholera toxin and *E. coli* heat-labile enterotoxins were the prototypic enterotoxins, it is now shown that even viruses (rotavirus) and protozoan parasites (*Cryptosporidium*) produce enterotoxins that drive fluid secretion. Rotavirus infection is one of the most common causes of acute diarrhoea in infants and children and is a major cause of childhood deaths due to diarrhoea.

Acute blood and mucous diarrhoea (or dysentery) is usually due to invasive bacteria such as *Shigella* species, or enteroinvasive *E. coli*, as well as due to the protozoan pathogen, *Entamoeba histolytica* that causes amoebic dysentery. Bacillary dysentery is characterised by frequent small volume stools which are mostly a

Table 1: Causes of Acute Diarrhoea

Condition	Proximate Cause or Agent		
Infectious gastroenteritis	**Bacteria** *Vibrio cholerae* *Shigella* species - *S. dysenteriae*, *S. flexneri*, *S. boydii*, *S. sonnei* Pathogenic *Escherichia coli* (enterotoxigenic, enteroinvasive, enterohaemorrhagic, enteroaggregative) *Salmonellae* (non-typhoidal) *Campylobacter jejuni* *Clostridium difficile* *Aeromonas* species *Plesiomonas* species *Yersinia enterocolitica*	**Viruses** Rotavirus Calicivirus Enteric adenovirus Astrovirus	**Parasites** *Entamoeba histolytica* *Giardia intestinalis*
Antibiotic-associated diarrhoea	Alteration in commensal flora of gut Overgrowth of *Clostridium difficile*		
Traveller's diarrhoea	Altered bacterial flora in upper gut Pathogen (e.g. *Giardia*, enterotoxigenic *Escherichia coli*)		
Post-operative and nosocomial diarrhoea	Alteration in commensal flora of gut Drugs including antibiotics Enteral feeding		

mixture of blood and pus with little faecal matter. Fever and lower abdominal pain relieved by bowel movement may occur. Amoebic dysentery is characterised by fewer stools (frequency of 4 to 6 per day) which are larger in volume and contain mostly dark blood.

Diagnosis

In acute watery diarrhoea it is generally not necessary to investigate for the cause. Examination of the stool by dark field microscopy of a hanging drop shows actively motile bacteria in cholera infection. Stool culture establishes a bacterial aetiology when present, while rotavirus is diagnosed by enzyme immunoassay of the stool for rotavirus antigen. In patients with dysentery, it is very necessary to examine stool or a rectal swab smear under the microscope for evidence of pus cells, macrophages that have ingested red blood cells (bacillary exudate) and presence of *E. histolytica* trophozoites that have ingested RBCs. Presence of amoebic cysts alone does not establish a diagnosis of amoebic dysentery, since there are non-pathogenic amoebae in the intestine. Stool culture is necessary for the diagnosis of invasive bacterial pathogens. *Clostridium difficile* infection, that causes antibiotic-associated diarrhoea and colitis, is diagnosed by detecting toxin in the stool using enzyme immunoassay.

Complications

Haemoconcentration, pre-renal uraemia and renal failure due to acute tubular necrosis may occur as a consequence of acute watery diarrhoea. Death in acute gastroenteritis is usually due to the excessive loss of fluid with electrolyte imbalance, principally hypokalaemia and acidosis since the intestinal secretion is rich in potassium and bicarbonate. Persistent diarrhoea leading to malnutrition is another cause of death in children presenting with acute infective gastroenteritis. Complications associated with a dysenteric illness include sepsis, encephalopathy, haemolytic uraemic syndrome with renal failure, and rarely toxic megacolon, all of which may be associated with mortality. It is recently recognised that a significant number of individuals are afflicted with post-infective irritable bowel syndrome following an episode of acute gastroenteritis.

Management

In resource-poor settings, it is generally not necessary to investigate patients with acute watery diarrhoea before initiating therapy. It is necessary to evaluate the patient for evidence of dehydration. In adults, presence of tachycardia and orthostatic or postural hypotension signifies 10% loss of blood volume, while supine hypotension indicates loss of over 20% of circulating blood volume. In children and adults with severe dehydration, the lost fluid has to be replaced quickly by the intravenous route over a period of four to six hours. In cholera and severe diarrhoea, the choice of replacement fluid is Ringer's lactate solution which is similar in composition to the fluid lost in the stool and corrects the electrolyte losses. A volume equivalent to 10% of the body weight is infused over 4 hours in such individuals, the first 30% in one hour and remaining 70% in three hours. In patients with mild dehydration, it is sufficient to rehydrate the patient through the oral route. Oral rehydration therapy, which is based on the fact that glucose-linked sodium absorption in the small intestine is preserved in most patients with acute gastroenteritis even when sodium absorption in the absence of glucose is impaired, efficiently rehydrates patients with mild dehydration and prevents mortality. When oral rehydration solution (ORS) cannot be taken orally as in patients with profuse vomiting, intravenous rehydration is indicated. Antibiotics are not necessary in most patients with acute watery diarrhoea with the exception of cholera where antibiotic treatment significantly shortens diarrhoea. In suspected cholera it is usual to treat patients with an antibiotic to which the *Vibrio* in that geographic region is considered to be sensitive, either doxycycline 300 mg stat or ciprofloxacin 500 mg twice daily for three days or azithromycin 500 mg stat can be used. Antibiotics prolong faecal excretion of non-typhoidal *Salmonella* in immunocompetent individuals, and are therefore not administered. However, antibiotics need to be given to the very young and the elderly patient with salmonellosis, as well as to patients who have a prosthetic joint or valve.

The management of dysenteric illnesses is with an antibiotic to which the organism is sensitive, such as metronidazole 800 mg three times daily for amoebic dysentery or ciprofloxacin 500 mg twice daily for shigellosis. Patients with amoebic dysentery should typically receive diloxanide furoate for two weeks after treatment with metronidazole in order to ensure that the cyst forms of the parasite are eradicated. Antibiotics are used with care in enterohaemorrhagic *E. coli* infection since there is some evidence that some antibiotics may paradoxically worsen illness.

Prevention

Handwashing before and after eating or feeding a child is the most effective preventive intervention. Disinfection of drinking water at home is achieved by a variety of means. Safe drinking water and implementation of safe food handling practices are very important in a general context when eating out. Rotavirus vaccines have been introduced in several parts of the world. The first vaccine to be widely used was withdrawn because of development of intussusception in some patients. Rotavirus vaccines have now been shown to protect against severe diarrhoea in Mexico and Africa but are not yet included in the extended primary immunisation schedule in India. Cholera vaccines using an attenuated strain (Dukoral) are not widely available. A new killed whole cell vaccine has been shown to be effective in a large trial in India and may be widely available soon.

CHRONIC DIARRHOEA

Diarrhoea lasting longer than four weeks is termed as chronic diarrhoea. Infections, tropical sprue, coeliac disease and bacterial overgrowth in the small intestine are the major causes of chronic diarrhoea seen in clinical practice. These and rarer causes of chronic diarrhoea are listed in **Table 2**. This section will briefly describe an approach to the diagnosis of chronic diarrhoea but will not elaborate on the individual diseases.

Clinical Features

Patients with chronic diarrhoea must be carefully evaluated in order to separate functional from organic disease. The duration of the history, associated symptoms, co-morbid illnesses, diet history, medication history and family history are all important. A nutritional evaluation is important. The presence of nocturnal diarrhoea, presence of blood in the stool, and evidence of nutritional deficiencies suggests an organic cause such as malabsorption or inflammatory bowel disease. In order to facilitate investigation, it is usual for the specialist to categorise chronic diarrhoea as either small bowel or large bowel in origin.

Small bowel diarrhoea may be either secretory (large volume watery stool) or suggestive of steatorrhoea (pale, bulky, frothy, foul smelling) and is often not accompanied by pain. Large bowel diarrhoea is small in volume and is usually associated with abdominal pain, localised to the iliac fossae and relieved by defaecation, and with mucous and/or blood in the stool.

Table 2: Causes of Chronic Diarrhoea and Malabsorption

Tropical sprue Coeliac disease	Small intestinal mucosal atrophy
Small intestinal bacterial overgrowth	Strictures in small intestine, Motility disorders of gut Surgical bypass of gut with blind loop
Inflammatory bowel disorders	Tuberculosis Crohn's disease Ulcerative colitis Collagenous enteritis and colitis Microscopic colitis
Infections	Strongyloidiasis Capillariasis Isosporiasis Cryptosporidiasis Microsporidiosis HIV enteropathy
Chronic pancreatitis	Alcoholic, idiopathic and tropical pancreatitis
Malignancies	Lymphoma Carcinoid syndrome Pancreatic endocrine neoplasm (VIPoma)
Infiltrative disorders	Whipple's disease Eosinophilic gastroenteritis
Drug-related diarrhoea Laxative abuse	Antibiotics, chemotherapeutic agents, laxatives
Idiopathic bile acid malabsorption Factitious diarrhoea	

Diagnosis

Routine haematology and clinical chemistry are useful to separate organic from functional disease. Normal haemoglobin and red cell parameters, normal leucocyte counts, sedimentation rate, faecal examination for parasites and faecal occult blood, and liver function tests usually indicate absence of significant organic pathology in an untreated patient with chronic diarrhoea. Faecal testing for occult blood and for parasites (routine microscopy and special stains for protozoan parasites) is usually done on three consecutive samples. Further testing is usually dependent on clinical judgement of the cause of chronic diarrhoea. Where appropriate, patients may be tested for antibodies to the human immunodeficiency virus after counselling and for antibodies to tissue trans-glutaminase (to exclude coeliac disease). Patients with small bowel type of diarrhoea may undergo testing for malabsorption and imaging studies of the small bowel and lymph nodes followed by endoscopy and biopsies of the small intestine. In patients with large bowel type diarrhoea, the directed investigation consists of either sigmoidoscopy and rectal biopsy or ileocolonoscopy and biopsies. A significant minority of patients with chronic diarrhoea of organic nature will remain undiagnosed after all the above tests. In this group, unusual causes of chronic diarrhoea such as a pancreatic endocrine tumour or idiopathic bile acid malabsorption may need to be considered.

MALABSORPTION

Malabsorption syndromes are encountered not uncommonly in specialist gastroenterology practice in India. Over the last few decades, the profile of such diseases has changed significantly. Tropical sprue, once common all over India, has been replaced as the most common malabsorption syndrome by coeliac disease particularly in children in the Northern states of India. **Table 3** lists several malabsorption syndromes that occur in India.

Table 3: Malabsorption Syndromes and their Diagnosis

Syndrome	Diagnosis
Tropical sprue	Establish malabsorption Exclude other causes Demonstrate villus atrophy in small bowel biopsy
Coeliac disease	IgA antibody to tissue transglutaminase Small bowel biopsy showing increased intraepithelial lymphocyte number and villus atrophy Clinical, haematological, biochemical or histological response to gluten withdrawal
Parasites	Examination of wet mounts (stained and unstained) of stool or jejunal fluid for helminths larva or ova and protozoan cysts Examination of faecal smears with special stains—safranin, methylene blue, modified AFB stain EIA of faeces for antigens of *Giardia*, *Cryptosporidium*, microsporidia Small bowel biopsy
Bacterial overgrowth	Low serum vitamin B12 with normal or high folate Glucose breath hydrogen test Quantitative culture of jejunal fluid or mucosal biopsy
Pancreatic insufficiency	Increased faecal fat Pancreolauryl test Faecal chymotrypsin and elastase Pancreatic calcification on radiology
Eosinophilic gastroenteritis	Peripheral eosinophilia Small bowel biopsy showing increased eosinophilic infiltration
Immuno-proliferative small intestinal disease and lymphoma	Immunochemical detection of alpha heavy chain in serum Barium meal showing picket fence appearance of mucosa, and aneurysmal dilatation in frank lymphoma CT appearances of uniform thickening of bowel wall with lymph node involvement Small bowel biopsy showing characteristic effacement of crypts by lymphoplasmacytic infiltrate ranging from benign looking cells to lymphosarcoma
Intestinal lymphangiectasia	Duodenoscopy showing milky white spots especially after high fat meal Small bowel biopsy demonstrating dilated lymphatics in villi
Whipple's disease	Small bowel biopsy showing infiltration of lamina propria by PAS positive macrophages
Abetalipo-proteinaemia and hypobeta-lipoproteinaemia	Acanthocytosis on peripheral blood smear Small bowel biopsy demonstrating vacuolisation of surface epithelial cells

Clinical Features

Patients with malabsorption usually present with gastrointestinal symptoms, particularly chronic diarrhoea and weight loss. The basis for diarrhoea and other manifestations of malabsorption is shown in **Table 4** which will help the physician to understand why symptom constellations and specific physical signs are associated with particular disease processes. Although diarrhoea is the most common symptom in patients with malabsorption, earlier recognition of the malabsorption disorders in recent years has led to the emergence of atypical presentations without diarrhoea.

Table 4: Symptoms and Signs in Malabsorption and their Genesis

Symptom	Correlating physical sign	Pathophysiology
Diarrhoea	Dehydration Hypotension	Water malabsorption due to unabsorbed osmolytes, e.g. sugars Water secretion due to unabsorbed bile acids or fatty acids
Steatorrhoea	Reduction of skinfold thickness Loss of buccal fat pad	Fat malabsorption due to mucosal disease Fat maldigestion due to pancreatic insufficiency
Borborygmi, flatulence, bloating	Abdominal distension	Carbohydrate malabsorption due to mucosal disease or disaccharidase deficiency
Weight loss	Reduction of skinfold thickness Loss of buccal fat pad	Energy, fat and protein malnutrition Inflammation
Tiredness and weakness	Muscle wasting	Vitamin and mineral deficiency
Night blindness	Bitot's spots, keratomalacia	Vitamin A malabsorption due to steatorrhoea or bile salt deficiency
Bone pain	Bone tenderness, rickets	Vitamin D and calcium malabsorption
Burning in mouth	Glossitis, stomatitis	Vitamin B deficiencies
Tingling and numbness in feet and hands	Loss of ankle jerks Loss of proprioception	Vitamin B deficiencies
Anaemia	Flat nails, koilonychias Hyperpigmentation	Iron deficiency due to duodenal mucosal disease or blood loss Vitamin B12 deficiency in bacterial overgrowth, ileal disease Folate deficiency due to mucosal disease in upper gut
Amenorrhoea	Delayed secondary sexual characteristics	Secondary hypopituitarism
Stunting	Height for age Z score <-2	Secondary hypopituitarism
Skin lesions	Pellagra, nutritional dermatoses Acrodermatitis Dermatitis herpetiformis	Vitamin and essential fatty acid deficiencies Zinc deficiency Association with coeliac disease

Tropical sprue, also called idiopathic tropical malabsorption, is a disorder characterised by chronic diarrhoea, steatorrhoea, abdominal distension, prominent borborygmi, glossitis and multiple nutrient deficiencies. Tropical sprue occurred as epidemics in south India in the 1960s and 1970s but then disappeared. Sporadic tropical sprue was very common in the 1960s to 1980s but has gradually declined or disappeared in recent years.

Coeliac disease, caused by allergy to gliadin in wheat gluten, is particularly common in Western countries. While it has been reported in Indians since the 1960s, in the last two decades, the incidence of the disease has dramatically increased particularly in the northern states of Punjab, Uttar Pradesh and Delhi where the largest number of cases have been reported. Atypical presentations with anaemia, bone disease, short stature and menstrual disorders are described from India as in other countries.

Parasitic infestations also rank as a common cause of malabsorption in India. Helminth parasites that cause malabsorption include *Strongyloides stercoralis* and *Capillaria philippinensis* and these may affect immunocompetent individuals. Protozoan infections that cause malabsorption include *Giardia intestinalis*, *Cryptosporidium parvum*, *Isospora belli*, *Cyclospora cayetanensis*, *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. The last two are now thought to be fungi rather than protozoans. These usually cause malabsorption only in immunocompromised individuals including those with acquired immunodeficiency syndrome (AIDS) or with congenital immunodeficiencies such as common variable immunodeficiency.

Small intestinal bacterial overgrowth is another cause of malabsorption. Normally, the bacterial population of the small intestine is kept to a minimum by peristalsis. Bacterial overgrowth occurs primarily in conditions where the clearance of bacteria from the gut is impaired as in obstructive strictures due to tuberculosis or Crohn's disease, in diseases where gut motility is impaired such as diabetic autonomic neuropathy or progressive systemic sclerosis, and following surgical bypass of the gut with blind loops.

Infiltrative disorders of the intestine cause malabsorption, but are rarer. These include eosinophilic gastroenteritis, immunoproliferative small intestinal disease which includes the stage of immunoblastic lymphoma, and Whipple's disease.

A variety of other disorders cause malabsorption in infancy and childhood including abetalipoproteinaemia, lymphangiectasia, and disaccharidase deficiencies.

Diagnosis

Initial investigation includes the demonstration of nutrient deficiencies, e.g. anaemia, hypoalbuminaemia, by appropriate testing, along with faecal examination for parasites and occult blood. Detection of the protozoan parasites that cause malabsorption is facilitated by the use of special stains such

as safranin-methylene-blue and modified acid fast stains. Xylose, a pentose sugar that is not metabolised in humans, is given orally and 5-hour urine excretion (greater than 20% of dose ingested) is estimated as a direct measure of small intestinal sugar absorption. Faecal fat (normal <7 g/day) can be measured chemically by collecting stool collectively for three days while ingesting 50 to 100 g/day fat. Breath hydrogen excretion after oral ingestion of a digestible sugar such as lactose may be used as a measure of malabsorption but is fraught with inconsistencies. Breath hydrogen measurement after oral glucose is used to measure bacterial overgrowth in the upper small intestine. Serum iron, ferritin, vitamin B12 and folate, calcium and phosphorus are commonly measured in these patients. If malabsorption has been established, the next step is to image the small bowel by radiology (barium meal follow through or CT enteroclysis) or by endoscopy (enteroscopy) to exclude ulcerative or infiltrative disease. Mucosal biopsies are obtained from the third or fourth part of the duodenum or from the jejunum in order to elucidate the diagnosis.

Tropical sprue is essentially a diagnosis of exclusion, confirmed by the absence of parasites, tuberculosis or inflammatory bowel disease, and negative coeliac serology, with the presence of villous atrophy, crypt elongation and inflammatory cell infiltration of the lamina propria on small bowel biopsy. Coeliac disease diagnosis may be established by the finding of partial or complete villous atrophy and increased intraepithelial lymphocytes on small bowel biopsy, the presence of positive coeliac serology, and clinical and/or histological response to gluten withdrawal. The serological test used most commonly for the diagnosis of coeliac disease is IgA antibody to human tissue transglutaminase (anti-tTG), while anti-endomysial antibody is more specific but also not widely available. Pancreatic insufficiency used to be diagnosed by measuring duodenal trypsin after a fatty meal (Lundh test) but this is given up for tubeless tests such as the pancreolauryl test where fluorescein dilaurate is cleaved by a pancreatic enzyme cholesterol ester hydrolase and fluorescein measured in the urine. Faecal chymotrypsin and elastase are used also as measures of pancreatic insufficiency.

Management

Nutrient deficiencies that need to be urgently corrected include deficiencies of potassium and divalent cations (Ca, Mg) in patients with significant chronic diarrhoea. Megaloblastic anaemia due to vitamin B_{12} or folate deficiency also needs to be urgently treated with the appropriate vitamin given orally or parenterally. Adequate calorie and protein intake, with restriction of long chain triglycerides in patients with symptomatic steatorrhoea, must be maintained. Medium chain triglycerides may be used in patients with malabsorption due to pancreatic insufficiency. Fat-soluble vitamins, A, D and K, need to be given orally or parenterally in patients with significant long-term steatorrhoea.

Specific therapy depends on the nature of the condition causing malabsorption. Tropical sprue is treated with long-term antibiotics, typically tetracycline in a dose of 250 mg four times daily for up to 6 months. Coeliac disease is treated with strict gluten restriction, which has to be explained to the patient and family and monitored. Treatment of parasitic infections causing malabsorption depends on the specific parasite. *Strongyloides* and *Capillaria* infestations may be treated with albendazole or ivermectin, while protozoan infections are treated with co-trimoxazole, ciprofloxacin, or nitazoxanide in appropriate dose. Treatment needs to be for longer periods of time than uncomplicated infection, and in the case of the protozoan parasites it may also involve maintenance therapy since these occur in patients with immunodeficiency. Bacterial overgrowth is treated with periodic administration of antibiotics such as metronidazole, ciprofloxacin or with the non-absorbable antibiotic rifaximin.

13.5 Constipation—Diagnosis and Management

Uday Chand Ghoshal

DEFINITION AND EPIDEMIOLOGY

The daily stool frequency in healthy population differs from thrice a week to twice a day in different geographical and ethnic groups. The Rome II consensus criteria based on western stool frequency, defines constipation as less than three stools per week with straining, excessively hard stool, unproductive urges and feeling of incomplete evacuation. However, many individuals would report themselves as constipated with stool frequency of three or more per week. Therefore, in Rome III criteria, stool frequency has not been given much importance while defining constipation. The stool frequency in India is different from that of the West. Therefore, the definition based on the frequency proposed for Western population does not hold true for Indian population. Hence, Asian consensus on irritable bowel syndrome proposed a definition based on the Bristol stool pattern (**Figure 1**). Passage of type 1 or 2 stool should be considered as constipation.

A second point to consider is difficulty in evacuating the bowel. Patients with this symptom often complain of stool that is hard to pass or pebble-like. This may suggest an outlet obstruction such as an intra-rectal intussusception or anismus. A third pattern is a combination of infrequency and dyschezia. Constipation-predominant irritable bowel syndrome may not fulfil the definition of constipation and has other gastrointestinal and extra-gastrointestinal symptoms in addition.

Constipation is a common symptom at all ages. In a study on 4500 adults from Indian community, 43 (1%) reported passing less than three stools per week. Although the exact frequency of constipation using various definitions in the Indian population is not known, it is likely to be common, but many individuals manage it on their own and do not consult doctors for the same. The perceptions of individuals and doctors about constipation differ, making an exact definition difficult.

AETIOPATHOGENESIS

Of the causes (**Table 1**) and types of constipation, many occur in the elderly. The important practical point is to identify the potentially serious causes. Pathophysiologically, constipation may result from slow colonic transit, faecal evacuation disorders (e.g. anismus or puborectal dyssynergia, rectocoele and perineal descent syndrome) and various combinations of these causes.

CLINICAL FEATURES

A careful history and physical examination usually give adequate pointers to the likely mechanism and type of constipation. Many patients, due to the chronic nature of the disease, tend to take a number of home remedies and seek a medical consultation only when a fresh set of symptoms supervene or the old symptoms get aggravated often due to refractoriness to laxative self-medication. This history is, therefore, important. Some of these fresh symptoms, particularly loss of body weight, rectal bleeding and constipation with spurious diarrhoea, may point to neoplastic disorder. History also helps in classifying the mechanism of constipation, like colonic inertia and functional outlet obstruction. Symptoms predict well colonic transit disturbances, but are relatively insensitive to suspect pelvic floor problems. Digital evacuation, passage of ribbon-like stool, feeling of rectal prolapse, and ability to pass stool in postures different from the usual posture, while pressing in and around the anus and supporting rectovaginal wall with fingers in the vagina may suggest functional disorder of faecal evacuation. A feeling that the

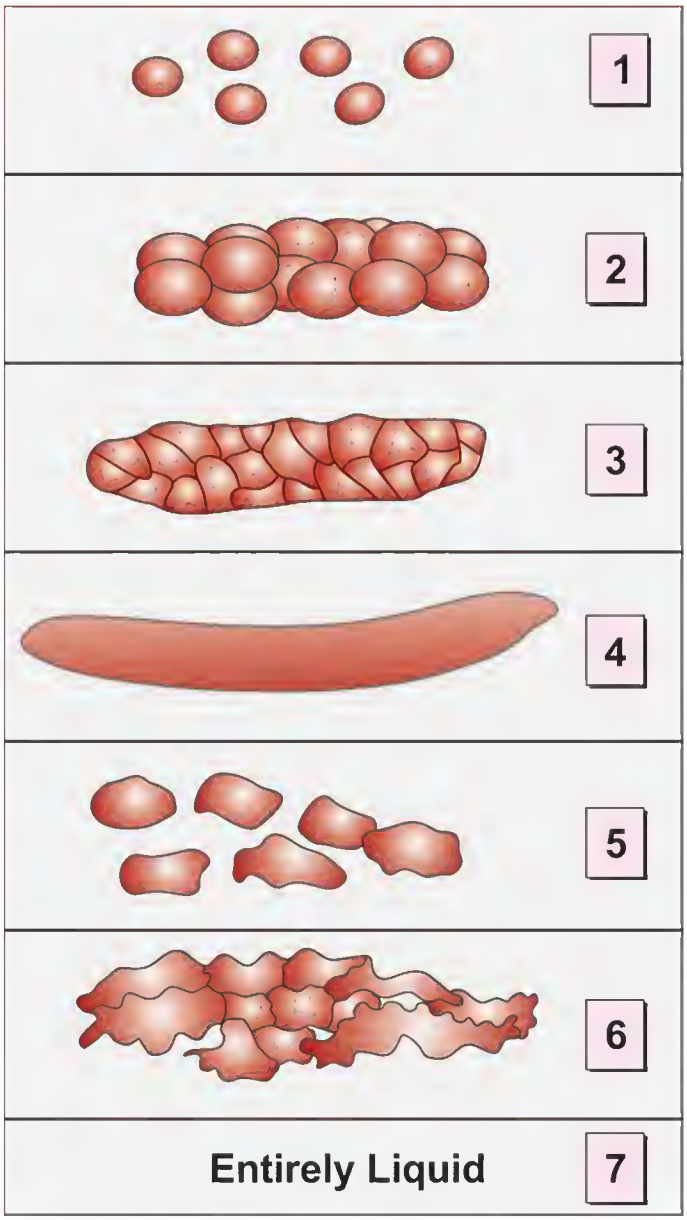

Figure 1: Bristol stool chart.

rectum is loaded with stool with urge to pass and repeated attempt for evacuation and straining at stool may also suggest functional disorder of faecal evacuation. Associated psychosocial disorders are common in these patients.

Table 1: Classification and Mechanisms of Constipation

Classification	Causes
Primary (idiopathic)	
Colonic inertia	Limited to colon or part of a global disorder
Functional outlet obstruction	Anismus Hypertonic internal anal sphincter Solitary rectal ulcer Mucosal intussusception Rectal prolapse
Secondary	
Endocrine/metabolic diseases	Diabetes mellitus Hypothyroidism Hypercalcaemia Porphyria
Neurogenic disorders	Spinal lesions: cauda equina syndrome and tumour Multiple sclerosis Autonomic neuropathy Parkinson's disease Hirschsprung's disease
Rectoanal disease	Anal fissure, haemorrhoids, strictures
Iatrogenic disease	Drugs, surgery
Dietary factors	Low-residue diet

Physical examination: A good physical examination should enable the physician to detect primary diseases like endocrinopathies and neurological disorders leading to constipation. Anorectal examination helps in diagnosing pelvic floor muscle weakness, sphincter disturbances, rectal sensitivity, stool consistency and faecal impaction. Per rectal examination may reveal low resting sphincter pressure due to weakness of the external anal sphincter; this may be related to pudendal neuropathy secondary to stretching of pudendal nerve from long-standing and prolonged straining during defaecation. Unusually high squeeze pressure during per rectal examination and anorectal manometry may suggest anismus, which is best diagnosed by defaecography.

MODALITIES OF DIAGNOSIS

In most patients with mild constipation, not many investigations are required. However, in patients with severe and refractory constipation several tests may be necessary to know the cause. **Table 2** shows the diagnostic tests useful in various forms of constipation and **Figure 2** shows a flow chart to diagnose various causes of constipation. Since a neoplastic disease always looms in the diagnosis of constipation in the elderly, the first investigations should always be proctosigmoidoscopy or if necessary colonoscopy and barium enema. Assessment of colonic transit by radio-opaque markers (**Figures 3A to E**) not only helps in diagnosis of slow-transit constipation but also gives suggestion about faecal evacuation disorder. Balloon expulsion test (**Figure 4**), in which the patient is asked to expel a latex balloon tied on a thin catheter that is placed inside rectum and

Table 2: Criteria for Diagnosis of Functional Anorectal Disorders Causing Constipation

Disorders	Diagnostic criteria
Anismus	Resting anal sphincter pressure >100 mmHg Abnormal balloon expulsion test
Puborectal dyssynergia	Failure of anorectal angle to open by >15° during defaecography between resting and defaecatory position No relaxation or increase in pressure on attempted defaecation Abnormal balloon expulsion test
Perineal descent syndrome	Failure of anorectal angle to open by >15° during defaecography between resting and defaecatory position Descent of perineum >4 cm during defaecation
Rectocoele	Herniation of rectal wall with either preferential filling during defaecography or failure to empty during defaecation
Non-specific syndrome	Symptoms, abnormal balloon expulsion test, but other criteria not fulfilled

Figures 3A to E: (A) Protocol for evaluation of colonic transit using radio-opaque markers (*SG-mark*), in Indian context. (B) sixty hours abdominal radiograph of a patient with constipation studied using such protocol, which shows that most of the markers are retained in the recto-sigmoid segment (RS) suggesting faecal evacuation disorder. Also note that there is retained barium inside rectum from the study done previously, which also suggest evacuation disorder. (C) Anorectal manometry of the same patient showed very high resting and squeeze sphincter pressure and hence, anismus was diagnosed. The patient improved with repeated sessions of biofeedback and osmotic laxative. (D) sixty hours abdominal radiograph of another patient with constipation studied using *SG-mark*, which shows that most of the markers are retained diffusely suggesting slow transit constipation. (E) Defaecography of a patient with constipation, showing a large rectocoele (marked with an arrow). (Reproduced from reference 7).

then filled with 60 mL of water while the patient is lying in the left lateral position, is a good screening test for faecal evacuation disorders. Faecal evacuation disorders are best diagnosed by barium (**Figures 3A to E**) or magnetic resonance defaecography, which helps in picking up intrarectal intussusception, pelvic floor descent, puborectal dyssynergia and rectal prolapse. The other techniques include anorectal ultrasonography for sphincter anatomy, and anorectal manometry. One should also look for systemic disorders causing constipation, such as hypothyroidism, diabetes mellitus, systemic amyloidosis and hypercalcaemia, when indicated.

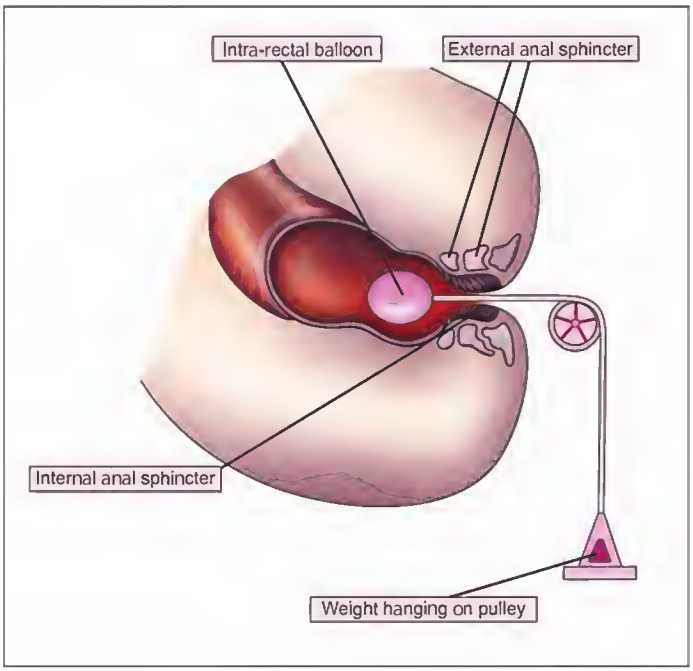

Figure 4: Balloon expulsion test.

TREATMENT

Treatment of primary constipation basically aims at symptom relief and improving quality of life. **Figure 5** outlines treatment protocol for patients with constipation.

Non-Pharmacological Treatment

Adequate diet replete with nutrition, liquids and fibre and physical activity are essential to ensure proper bowel function. Fibre intake must be at least 20 gm/day. It may be necessary to

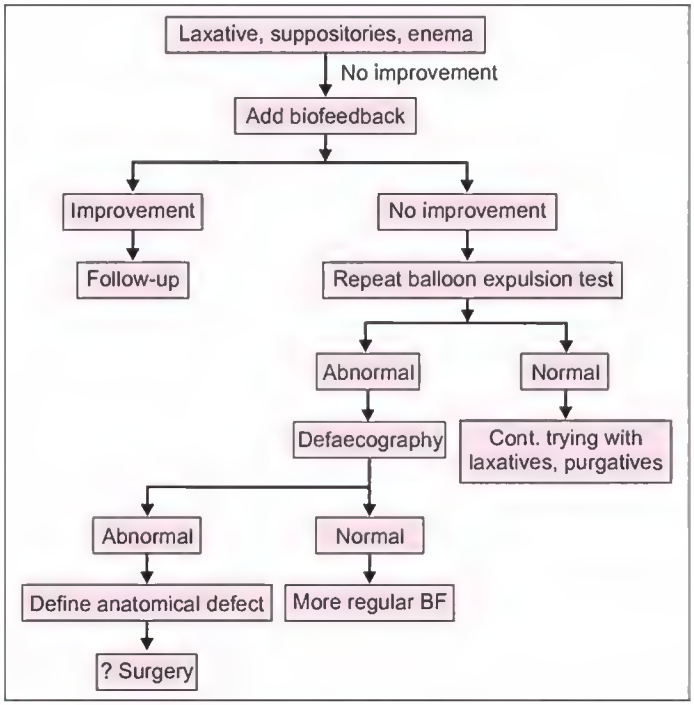

Figure 5: Outline of treatment protocol for faecal evacuation disorders. (Reproduced from reference 7).

BF = Biofeedback.

supplement with fibre-rich food or fibre medication. Physical activity is important to ensure general interest and zest for life, but attention to abdominal wall and pelvic floor muscles may actively help in initiating defaecation. Existing therapy may need to be modified; for instance, if the patient is on opioids for pain, the drug may have to be discontinued.

Pharmacological Treatment (Table 3)

Laxatives are needed in almost all patients with significant constipation. They help in improving the frequency and bulk of stools and thus ease bowel movements. Patients with colonic inertia are best treated with bulking agents like isphagula (15 to 20 gm daily) and methylcellulose (10 gm/day). Bulk laxatives may lead to bloating and excessive gas formation and precipitate intestinal obstruction in those with incipient gut obstruction. Patients with outlet obstruction are best treated with osmotic agents such as magnesium sulphate (15 to 45 mL/day), lactulose (15 to 45 mL/day) or polyethylene glycol (17 to 34 gm/day) (Table 3). These are poorly absorbed osmotically active substances that draw water into the lumen. They modify stool consistency effectively and ease bowel movements. Milk of magnesia is a cheap and safe medication. Other agents are equally effective and safer but more expensive. Stool softeners and stimulants are best avoided because of the danger of cathartic colon or melanosis coli, as with senna. Mineral oil and enemas should be avoided as regular therapy, but may be necessary in some patients infrequently. Mineral oils have a particular problem of depleting fat-soluble vitamins, which should then be supplemented.

Table 3: Commonly Available Agents for the Management of Constipation

Agents	Usual adult oral dose
Ispaghula husk	15 to 20 gm/day
Natural (e.g. psyllium husk)	7 gm/day
Synthetic (e.g. methylcellulose, polycarbophil)	4 to 6 gm/day
Osmotic laxatives	
Polyethylene glycol	8 to 25 gm/day
Lactulose	15 to 30 mL/day
Lactitol	10 to 20 gm/day
Sorbitol (70%)	15 to 30 mL/day
Magnesium hydroxide	2.4 gm (30 mL)
Magnesium citrate	200 mL/day
Stimulant laxatives	
Anthraquinones: Senna	8.5 to 17 mg/day
Diphenylmethanes: Bisacodyl	10 to 15 mg or 10 mg suppository/day

Biofeedback Programmes

Biofeedback has been proved to be useful in faecal evacuation disorders in about half to two-thirds of patients. Its role in the treatment of constipation due to other causes remains to be proved.

Surgery

Surgical treatment may be rarely necessary to correct anatomical problems like stenotic diverticulitis or outlet problems. Patients with colonic inertia due to visceral myopathy may also require surgical treatment such as colectomy in the long run. Surgical treatment, however, is best avoided as long as possible. Injection of botulinum toxin into the puborectal sling has been found to be useful in the treatment of puborectal dyssynergia.

COMPLICATIONS

Most causes of constipation usually do not produce major complications though these impair the quality of life. However, prolonged constipation and straining at stool can be complicated with haemorrhoids, anal fissure and faecal incontinence due to development of pudendal neuropathy. Also, sometimes patients may experience symptoms of large bowel obstruction. Megarectum can also develop due to prolonged constipation. Faecal evacuation disorders may be complicated with solitary rectal ulcer syndrome.

13.6 Gastrointestinal Bleeding

Rakesh Kochhar, Mohd. Talha Noor

Gastrointestinal (GI) bleeding is a common and potentially life-threatening problem. Mortality rate of upper GI bleeding (6% to 10%) has remained unchanged over the years. Lower gastrointestinal bleeding requiring hospitalisation is only one-fifth as common as upper GI bleeding.

GENERAL FEATURES

GI bleeding may manifest in several ways. Haematemesis is defined as vomiting of blood. Gastric acid may alter the colour of the vomited blood. If vomiting occurs shortly after the onset of bleeding, the vomitus appears red. Precipitated blood clots and acid-degraded blood produce a characteristic 'coffee-ground' appearance of the vomitus. Haematemesis usually indicates a source of bleed proximal to the ligament of Trietz. Melaena is black, tarry, foul-smelling stool that results from formation of acid haematin and bacterial degradation of haemoglobin in the gastrointestinal tract. Melaena usually occurs due to bleed proximal to the ligament of Trietz but may at times be due to bleed from the small bowel or ascending colon if gastrointestinal transit time is prolonged. Approximately 60 mL of blood is required to produce a single melaenic stool. Melaena can persist for up to one week after an episode of massive upper GI bleed.

Haematochezia, the passage of bright red or maroon blood per rectum, generally signifies a bleeding source distal to the ligament of Trietz. However, brisk bleeding from a proximal source can also cause haematochezia due to rapid transit. Occult GI blood loss is evidence of blood as identified by laboratory testing of stool. Finally, patients with gastrointestinal blood loss may present with symptoms of blood loss, such as light-headedness, syncope, dyspnoea, angina, or even shock.

Initial Assessment

It is necessary to determine whether bleeding is acute or chronic and whether the patient is haemodynamically stable or not. The presence of GI bleeding should be confirmed by inspection of the stool or nasogastric aspirate. Careful assessment of the vital signs is the best way to judge a patient's stability. Blood loss of less than 500 mL is rarely associated with systemic signs. A postural fall in systolic blood pressure of >10 mmHg usually indicates a 20% or greater reduction in blood volume (**Table 1**). Concomitantly, the patient may have symptoms like light-headedness, syncope, nausea, diaphoresis and thirst. Shock frequently results when the blood loss is more than 25% of the blood volume. Patients may occasionally experience a vasovagal reaction with bradycardia during bleeding episodes. Haematocrit is used to assess the degree of blood loss. However, it does not fall immediately with haemorrhage because of proportionate reduction of plasma and red cell volumes and it reflects the true magnitude of bleed only after a period of 24 to 48 hours. Hence, during this time, the severity of bleeding must not be underestimated. With administration of intravenous fluids as well as entry of extravascular fluid into the vascular space to restore volume, the haematocrit falls. Serial haematocrit measurements are helpful in following a patient's course.

Table 1: Patient's Haemodynamic Status with Degree of Blood Loss

Patient's haemodynamic status	Blood loss %
Resting hypotension	>26
Postural hypotension	10-20
Normal	<10

Resuscitation

Insertion of two large-bore intravenous cannulae is recommended. Saline or lactated Ringer's solution should be infused to stabilise vital signs. Administration of supplemental oxygen may be of benefit in patients with inadequate oxygenation. Airway protection with endotracheal intubation to prevent aspiration should be strongly considered in patients with ongoing haematemesis if mental or respiratory status is altered. Those patients who are in shock have very low haematocrit (less than 20% to 25%), have symptoms related to poor tissue oxygenation (e.g. angina) or those who continue to bleed despite therapy are candidates for transfusion. The target to which the haematocrit value should be raised varies; in elderly it should be 30%; in younger and otherwise healthy patients it should be 20% to 30% and in patients with portal hypertension, it should not exceed 27% to 28%, so as not to raise portal pressure. Transfusion of packed red blood cells is preferred. Warmed blood should be administered to patients who require massive transfusion (i.e. >3,000 mL). Fresh frozen plasma (FFP) or platelets may be required in patients with coagulopathy or severe thrombocytopaenia, and in patients who require ten or more units of blood.

Differentiating Upper from Lower GI Bleeding

After resuscitation, the source of bleeding must be localised to direct further management. A nasogastric lavage must be performed irrespective of the probable site of the bleed. A bloody or a coffee ground aspirate confirms an upper GI source but their absence does not rule it out. A clear aspirate may be seen in up to 10% to 20% of patients with bleeding from a duodenal source. However, the presence of bile in the clear aspirate rules out a duodenal source. Other clues to upper GI bleeding include hyperactive bowel sounds and an elevation in blood urea nitrogen (BUN); the latter results from volume depletion and breakdown of blood proteins in the gut. Patients with lower GI bleed are less likely to present with shock or orthostatic symptoms as compared to patients with upper GI bleed. They have higher haemoglobin levels at presentation and also lower transfusion requirements.

DIAGNOSTIC EVALUATION OF PATIENTS WITH GI BLEEDING

Acute Upper Gastrointestinal Bleeding

History and physical examination

A history of prior episodes of bleeding, illnesses such as ulcers, cirrhosis, cancer or bleeding disorders, prior surgery (such as for peptic ulcer), consumption of excess of alcohol, and medications like nonsteroidal anti-inflammatory drugs (NSAIDs) and anti-coagulants should be elicited. Oesophago-gastric variceal bleed is painless and massive. A bleeding episode preceded by abdominal pain usually indicates underlying peptic ulcer disease. A history of retching and vomiting prior to haematemesis may indicate Mallory-Weiss syndrome. Examination of the skin may reveal cutaneous stigmata of cirrhosis. Rarely, evidence of underlying cancer (e.g. acanthosis nigricans), tumours (e.g. neurofibromatosis, blue rubber bleb nevus). Henoch-Schönlein purpura or vascular anomalies may be found. Skin and musculoskeletal abnormalities of pseudoxanthoma elasticum or Ehlers-Danlos syndrome may be diagnostic. Further clues on systemic examination include lymphadenopathy or abdominal masses, malignancy, abdominal tenderness (peptic ulcers, pancreatitis) and splenomegaly with or without prominent abdominal wall veins (cirrhosis, portal/splenic vein thrombosis).

INVESTIGATIONS

Endoscopy plays a major role in diagnosing the cause of GI blood loss. Other tests that may help include USG abdomen, CT scan of the abdomen and angiography.

Endoscopy

Endoscopy should be performed only after the patient has been haemodynamically stabilised. However, if the patient is bleeding massively and responding to resuscitative measures, endoscopy can be performed at the bedside provided adequate support personnel and with resuscitative facilities. Repeated gastric lavage prior to urgent endoscopy helps in clearing the stomach of blood clots, thereby providing a better field of view. Intravenous erythromycin can help clear the stomach if given half an hour before endoscopy. There is no role of cold saline lavage in controlling gastrointestinal bleeding. At endoscopy, detailed evaluation of the oesophagus, stomach and duodenum is carried out.

A majority of the bleeds occur from peptic ulcers, varices and erosions (**Table 2**). If there is no evidence of any of these, other uncommon lesions, especially vascular malformations should be carefully looked for. Endoscopy is superior to barium studies as it detects more lesions, it permits mucosal biopsy of suspicious lesions; it may act as a therapeutic modality; presence of active bleeding or stigmata or recent haemorrhage can provide prognostic information; and results of endoscopy guides the decision on the level of hospital care, on when to resume feeding and on length of hospitalisation. Endoscopic Forrest classification of peptic ulcer is useful for stratifying patients into high and low risk of rebleeding. Patient with Forrest 1a (active bleeding) and Forrest 1b (oozing vessel) at the time of endoscopy have high risk of rebleeding. Patients with Forrest 2a (visible vessel), Forrest 2b (adherent clot) and Forrest 2c (pigmented base) have moderate risk of rebleeding. Patients with Forrest 3 (clean base) have low risk of rebleeding. Patients in Forrest class 1, 2a and 2b benefit from endotherapy.

Other Diagnostic Tests

Ultrasound of the abdomen can provide evidence of portal hypertension in the form of coarsened liver echotexture, dilated splenoportal axis, presence of collaterals and splenomegaly, it should be carried out in all patients.

Computed tomography (CT) of the abdomen is useful to look for any evidence of pancreatitis, tumour or haemosuccus pancreaticus, CT angiography is useful in the diagnosis of visceral aneurysms.

AETIOLOGY AND MANAGEMENT OF UPPER GI BLEED

The various causes of upper GI bleed and management are given in **Table 2** and **Figure 1**. In India, most common aetiology is oesophageal variceal bleeding, other common causes are duodenal ulcer, gastric ulcer and gastritis.

Table 2: Causes of Upper Gastrointestinal Bleeding

Common causes
Peptic ulcer disease
Oesophageal and gastric varices
Oesophagitis
Gastric erosions
Duodenitis
Mallory-Weiss tear
Gastrointestinal malignancies
Uncommon causes
Angiodysplasia
Dieulafoy lesion
Cameron ulcers
Gastric antral vascular ectasia
Portal hypertensive gastropathy
Gastric polyps
Aortoenteric fistula
Haemobilia
Haemosuccus pancreaticus
Foreign bodies
Iatrogenic-nasogastric tube erosions, endoscopic polypectomy, sphincterotomy

Acute Variceal Haemorrhage

In India, non-cirrhotic portal hypertension (NCPF) account for up to 25% of portal hypertension, and they have a better prognosis than cirrhosis. Oesophageal varices are the site of bleeding in most patients. Bleeding from gastric varices can occur in patients with active as well as thrombosed oesophageal varices. Some patients may bleed from portal hypertensive gastropathy and gastric antral vascular ectasia. Treatment options for bleeding oesophageal varices include pharmacotherapy, balloon tamponade, endoscopic, transjugular intrahepatic portosystemic shunt and surgery. In the emergency room, if clinical suspicion of bleed being variceal is high, patients can be started on intravenous terlipressin 1 mg every 4 to 6 hourly or octreotide 50 to 100 µg bolus, followed by infusion at 50 µg/hour. Continuation of these drugs for 3 to 5 days after endoscopic treatment reduces chances of rebleeding. If the patient is bleeding actively and immediate endotherapy is not possible, an alternative of endoscopic therapy is balloon tamponade with Sengstaken Blakemore tube. It has two balloons, oesophageal and gastric, control of haemorrhage requires inflation of gastric balloon with 250 mL of air, oesophageal balloon is usually not inflated as it is associated with risk of oesophageal rupture. It is very effective in immediate controlling of bleeding in over 80%

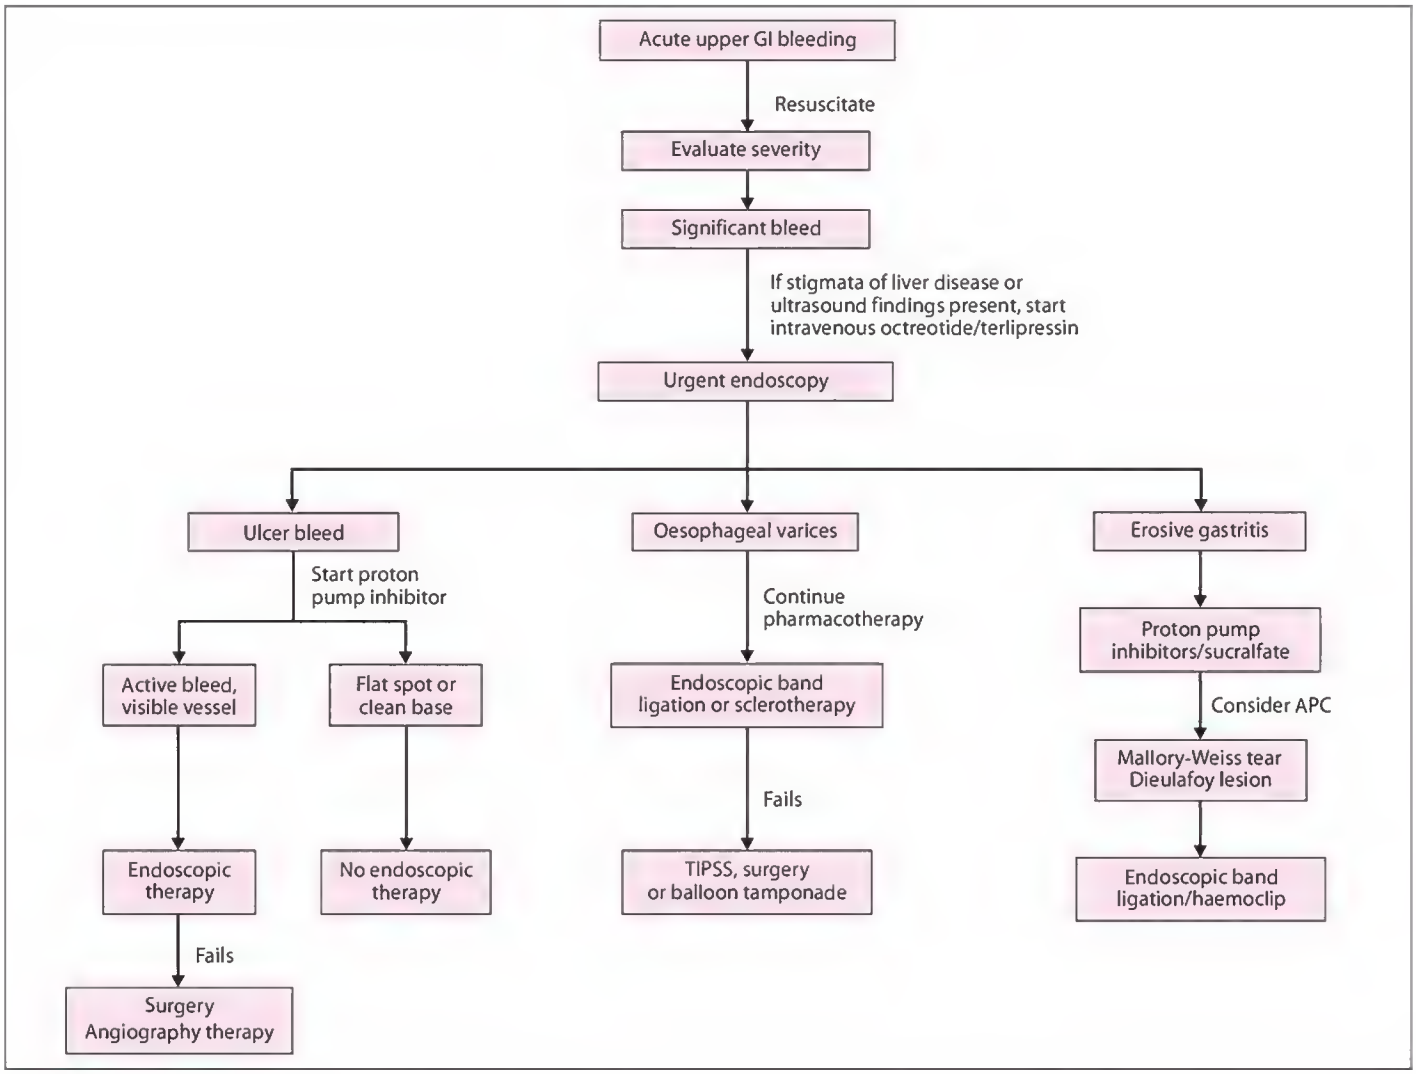

Figure 1: Algorithm for managing acute upper GI bleeding.

TIPSS = Transjugular intrahepatic porto-systemic shunt; APC = Argon plasma coagulation.

of patients. It is associated with 50% rebleeding after deflation of balloon. It is also associated with risk of oesophageal rupture, ulceration and aspiration pneumonia. Though associated with significant complications, balloon tamponade can be instituted even by primary physicians.

Endoscopic treatment options for bleeding oesophageal varices are endoscopic variceal ligation (EVL) and endoscopic sclerotherapy (ES). Both have an efficacy of about 90%. Endoscopic sclerotherapy involves visualisation of the varix during endoscopy, followed by injection of a sclerosing agent into the varix or into the adjacent tissue. Various sclerosing agents include sodium tetradecyl sulphate, polidocanol, sodium morrhuate and ethanol. Variceal obliteration is usually achieved after 3 to 6 sclerotherapy sessions at periodic intervals. Complications associated with ES include retrosternal pain, oesophageal ulcers and oesophageal stricture. EVL was first reported in 1989. The technique involves the placement of rubber bands around a portion of the varix containing oesophageal mucosa. The varix is sucked into a hollow, clear plastic cylinder attached to the tip of the endoscope. Once suctioned into the sheath, a trigger device allows deployment of the band around the varix. The blood flow is completely interrupted, producing ischaemic necrosis of the mucosa and submucosa. Later granulation takes place with sloughing of the rubber rings and necrotic tissue, leaving shallow mucosal ulcerations that heal in 14 to 21 days. Application of the bands is started at the gastroesophageal junction and progresses cephalad in a helical fashion. EVL sessions are repeated at approximately 2-week intervals until varices are obliterated, usually requiring 2 to 4 ligation sessions. Complications are less frequent than with endoscopic sclerotherapy.

Transjugular intrahepatic porto-systemic shunt (TIPSS) is a procedure in which a self-expanding metal stent is placed radiologically between the portal and hepatic veins. It is highly effective in reducing portal pressures and rebleeding and in controlling acute variceal haemorrhage. TIPSS is, however, associated with a risk of encephalopathy and shunt stenosis, although the latter risk is reduced with the use of the newer polytetrafluoroethylene covered stents. Recently a removable self-expanding oesophageal metal stent has also been used effectively in patients with variceal bleeding refractory to other treatment modalities.

Nowadays surgery is rarely needed for variceal bleeding. Surgical options include shunt and non-shunt procedures. The shunts are either total or selective. Total shunts include porta-caval, mesocaval and central splenorenal, selective shunt include distal splenorenal shunt. Non-shunt operations are gastroesophageal devascularisation or disconnection procedures.

For bleeding gastric varices, injection of N-butyl-cyanoacrylate can be made into the varices with good results. This modality can be used in actively bleeding gastric varices as well as to prevent rebleeding; 1 to 2 mL of cyanoacrylate is injected into the varix using a 21 gauge sclerotherapy needle. In refractory cases TIPSS is an effective treatment modality; it controls acute gastric variceal bleeding in over 90% patients. Balloon-occluded retrograde transvenous obliteration (B-RTO) is a new technique; it is highly effective in controlling acute gastric variceal bleeding. Bleeding from portal hypertensive gastropathy and gastric antral vascular ectasia is not massive but difficult to treat. Treatment of portal hypertensive gastropathy is directed towards underlying portal hypertension. First line therapy for gastric antral vascular ectasia (GAVE) is argon plasma coagulation. Recently, endoscopic variceal ligation has also been used for its treatment successfully. Apart from the treatment mentioned above, broad spectrum of antibiotics for a week have been shown to improve survival of these patients.

After control of initial haemorrhage, prevention of variceal rebleeding is an important aspect of the management of portal hypertension. Non-selective beta-blockers reduce cardiac output and cause splanchnic vasoconstriction, reducing portal venous pressure. Several randomised controlled trials comparing propranolol or nadolol with placebo have shown a reduction in rebleeding and mortality with beta blockers. Addition of isosorbide mono nitrate to beta-blockers enhances the efficacy of therapy but offers no survival advantage and reduces tolerance to therapy.

Peptic Ulcer Disease (PUD)

Most ulcer bleeds are from duodenal ulcers, though in patients on NSAIDs, bleeding from gastric ulcers is more common. An ulcer bleeds when it erodes into the lateral wall of a blood vessel. Ulcers located high on the lesser curve of stomach or on the posteroinferior wall of the duodenal bulb are most likely to bleed. *Helicobacter pylori* infection, NSAID use, and stress due to critical illness contribute to the development of ulcers.

Up to 80% of duodenal ulcers are caused by *Helicobacter pylori*, whereas about 50% of gastric ulcers are associated with this infection. NSAIDs constitute the most important cause of PUD after *H. pylori* infection, all patients who have PUD should be carefully questioned about NSAIDs use. NSAIDs induced ulcers may be painless because analgesic properties of NSAIDs can mask the pain of ulcers. Concurrent aspirin and oral anti-coagulant use increase the risk of bleeding. Other risk factors are cardiovascular or cerebrovascular disease and hospitalisation.

Bleeding stops spontaneously in 80% of instances. Patients with ongoing bleed, haemodynamic compromise, and high transfusion requirements mandate urgent endoscopic therapy, which can achieve haemostasis in more than 90% of cases. Surgical intervention is indicated in patients whose bleeding is refractory to endoscopic therapy.

Proton pump inhibitors (PPI) are the mainstay of pharmacological treatment. Proton pump inhibitors elevate the pH, thus, enhancing clot formation and platelet aggregation. PPI should preferably be given intravenously, though oral administration is also shown to be effective. High dose intravenous (IV) omeprazole or pantoprazole (80 mg IV bolus followed by 8 mg per hour for 72 hours) has been shown to reduce rebleeding rate and the need for surgery. Lansoprazole and esomeprazole are the other PPIs available for intravenous use. After the patient's condition stabilises, intravenous PPI therapy may be switched to oral PPI therapy.

Endoscopic therapy is accepted as the most effective method for controlling acute ulcer bleeding and for preventing rebleeding. Depending on the endoscopic appearance of the ulcer, different endoscopic modalities are applied. High risk ulcers are those that are bleeding actively and those with a non-bleeding visible vessel. These patients are shown to benefit the most from endoscopic therapy. Management of ulcers with adherent clots was controversial earlier, but now it has been shown that endoscopic therapy is superior to medical therapy for preventing recurrent haemorrhage in patients with bleeding peptic ulcers with adherent clots. Ulcers with flat pigmented spots or those with clean base have no additional benefit from endotherapy. The most popular endoscopic therapy is injection therapy using epinephrine (1:10,000). Other injection therapies include use of sclerosants, including sodium tetradecyl sulphate, polidocanol or ethanol. Biologic agents like thrombin, fibrin sealant and cynoacrylate glue can also be utilised. The assistant projects the needle, originally designed for injection sclerotherapy, about 5 mm beyond the plastic sheath, injects the solution, multiple injections are given around the ulcer to provide tamponade effect. Thermal methods for controlling bleeding include laser, electrocoagulation and heater probe. These can be combined with injection therapy. Newer techniques include application of metal clips, band ligation, argon plasma coagulation and endoloops. In patients with rebleeding, repeat endoscopy appears to be useful. Presence of hypotension at admission and an ulcer size larger than 2 cm are independent predictors of failure of endoscopic therapy.

Eradication of *H. pylori* and stopping NSAIDS are two factors shown to prevent recurrent bleeding. Relook endoscopy with retreatment in peptic ulcer bleeding significantly reduces the risk of recurrent bleeding, although it does not substantially reduce the need for subsequent surgery or mortality. In summary management of bleeding peptic ulcer include initial resuscitation, pharmacotherapy with proton pump inhibitors, endoscopic therapy and in refractory cases, surgery should be considered. Indications for surgery include failure of endoscopic therapy, large ulcer (>2 cm), massive bleeding and development of complications like perforation. Transcatheter arterial embolisation is reserved for patients who have exceptionally high risks for surgery (e.g. acute myocardial infarction).

Erosive Gastropathy

Erosive gastropathy refers to endoscopically visualised subepithelial haemorrhages and erosions that may account for upper GI bleeding in 15% to 25% of cases. Antacids, H_2 receptor blockers, proton pump inhibitors and sucralfate decrease bleeding from gastric erosions. Endoscopic, argon plasma coagulation has been found to be useful in the treatment of severe bleeding.

Mallory-Weiss Syndrome

Recurrent vomiting or retching can lead to mucosal tears at the gastro-oesophageal junction causing haematemesis. Bleeding

is usually not massive and stops spontaneously. Occasionally injection therapy or haemoclips may be required to control the bleeding.

Dieulafoy's Lesion

Dieulafoy's lesions are prominent submucosal vessels, usually found in the proximal stomach with no surrounding ulceration. These lesions are difficult to identify if they are not bleeding actively during endoscopy. Standard endoscopic injection, thermocoagulation, haemoclip, argon plasma coagulation or band ligation can successfully achieve haemostasis.

Gastrointestinal Malignancies

Endoscopy is used for diagnosis and for taking biopsies but it is usually ineffective in controlling the bleed.

ACUTE LOWER GASTROINTESTINAL BLEEDING

History and Physical Examination

Passage of drops of blood either separately or coating the stool may indicate bleeding from an anorectal source, especially haemorrhoids. Bloody diarrhoea with or without pain occurs in infective colitis or inflammatory bowel disease. Associated weight loss or recent change in bowel habits suggests colorectal cancer. A history of radiation therapy suggests radiation proctitis. The abdomen should be carefully examined to detect tenderness, organomegaly or a mass. A per rectal examination should always be performed to look for prolapsed haemorrhoids, mass polyp or ulcer.

Proctoscopy and Sigmoidoscopy

Patients with presumed lower GI bleeding must undergo early proctoscopy and sigmoidoscopy for the detection of obvious, low-lying lesions such as bleeding haemorrhoids, anal fissure, rectal ulcer, proctitis or rectal cancer.

Colonoscopy

If procto-sigmoidoscopy is not informative, colonoscopy is the next logical investigation. It is superior to barium enema since it can detect vascular lesions and allows biopsies to be taken. As 5% to 10% patients with upper GI lesions present with haematochezia, it is prudent to perform upper GI endoscopy before undertaking extensive investigations. Urgent colonoscopy in lower GI bleeding is safe with high likelihood of making a specific diagnosis (75% to 100%). Performance of colonoscopy requires preparation of the patient with purgatives, polyethylene glycol and sodium phosphate are the commonly used purgatives.

Angiography

Angiography is helpful in detecting the site of bleed in actively bleeding patients. Angiodysplasias are the commonest lesions detected by angiography. It may also show vascular malformations or tumours, even if extravasation of contrast material is not noted.

Radionuclide Scanning

It involves intravenous administration of ^{99m}Technetium tagged sulphur colloid or RBCs followed by imaging with an external gamma camera to detect intestinal extravasation of the substrate. It can detect bleeding even at a slower rate than that detected by angiography.

AETIOLOGY AND MANAGEMENT OF SPECIFIC CAUSES OF LOWER GI BLEED

The various causes and management of lower GI bleed are given in **Table 3** and **Figure 2**.

Table 3: Causes of Lower Gastrointestinal Bleeding

Common causes	Relative frequency in India
Colonic sources	*70% to 90%*
Haemorrhoids	30% to 40%
Inflammatory bowel disease	30% to 40%
Neoplasms	15% to 20%
Arteriovenous malformation, angiodysplasia	2% to 5%
Diverticula	2% to 5%
Small bowel source	*10% to 20%*
Meckel's diverticulum or other diverticula	
Vasculitis	
Ulcers, e.g. typhoid	
Less common causes	*2% to 5%*
Solitary rectal ulcer syndrome (SRUS)	
Infectious enterocolitis	
Ischaemic colitis	
Aortoenteric fistula	
Colonic varices in portal hypertension	
Radiation proctitis	
Lesions associated with use of NSAIDs	

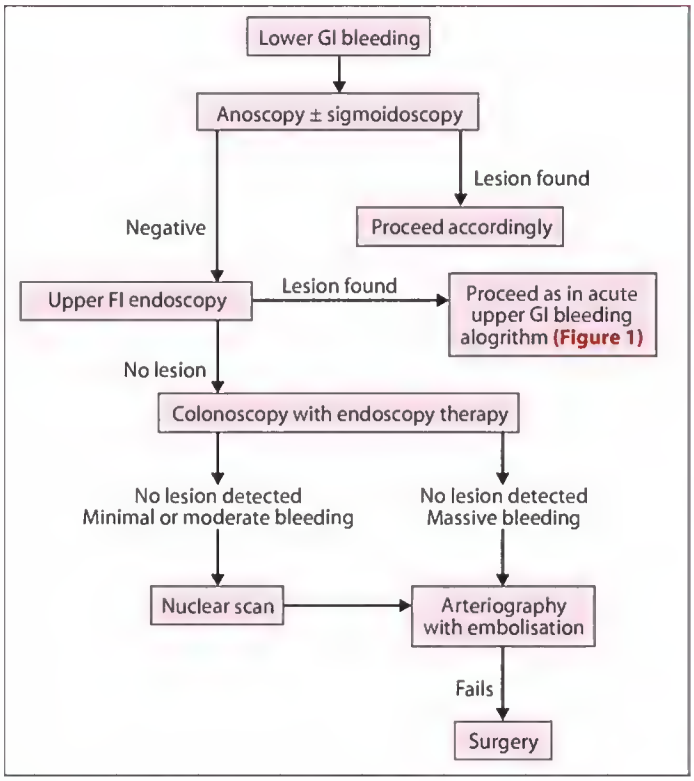

Figure 2: Algorithm for managing acute lower GI bleeding.

Anorectal Lesions

Haemorrhoids are the most common cause of lower GI bleed. Treatment may be in the form of sclerotherapy, banding, and cryotherapy. Surgery is required for large and prolapsed haemorrhoids. Solitary rectal ulcer syndrome (SRUS) is a benign condition in young individuals, which presents as rectal

bleeding, tenesmus and mucous discharge. Sigmoidoscopy with biopsy is essential for diagnosis. Treatment consists of avoiding digital rectal manipulation, laxatives and sucralfate enemas.

Inflammatory Bowel Disease (IBD)

Patients with IBD have a history of recurrent episodes of bloody diarrhoea. Colonoscopy with biopsy is required to differentiate IBD from other forms of colitis. Steroids and 5-aminosalicylic acid usually control the disease. Colectomy is required for massive bleeding not responding to medical management.

Polyps

Adenomatous colonic polyps can present with occult or overt rectal bleeding (if they are larger than 1 cm). Juvenile polyps are hamartomas occurring in the first two decades of life. Colonoscopic polypectomy is the treatment of choice. Bleeding from malignant colonic polyps requires colectomy.

Infectious Enterocolitis

Various invasive organisms viz. *Shigella, Salmonella, Campylobacter,* enteroinvasive *E. Coli, Clostridium difficile* and *Entamoeba histolytica* present with bloody diarrhoea. Diagnosis is usually made by routine examinations and culture of the stool. Treatment is with antibiotics.

Colonic Diverticula

Colonic diverticula are less frequent in the Indian population as compared to the West. However, in elderly patients especially those with complications, diverticular disease should be considered and looked for. Bleeding is abrupt in onset, usually painless and often massive, but ceases spontaneously in 80% of patients. Colonoscopy is required for diagnosis. Vasopressin infusion controls bleed temporarily. Segmental surgical resection is indicated for ongoing bleed.

Angiodysplasia

Angiodysplasia or arteriovenous malformations are also less frequent in Indians as compared to Western population. Bleeding from angiodysplasia is painless, trivial to massive in amount, recurrent and usually resolves spontaneously. Colonoscopic diagnosis and treatment by endoscopic electrocoagulation are generally successful in identification and definitive management of these lesions.

Ischaemic Colitis

Ischaemic colitis usually occurs in the elderly due to occlusion of a major vessel or low cardiac output. It usually presents with sudden, crampy, left lower abdominal pain and passage of bright red or maroon blood mixed with the stool. Bleeding is usually moderate. The splenic flexure, descending colon and sigmoid colon are most commonly affected. Colonoscopy shows segmental haemorrhagic mucosa with or without ulcerations. CT angiography is a non-invasive test which helps in diagnosis. Colectomy is required only if there are signs of bowel infarction.

Radiation Colitis

Symptoms of radiation colitis may occur few months to many years after abdominopelvic radiation usually for cancer of the cervix or prostate. Treatment using laser, argon plasma coagulation or sucralfate enema is effective.

Rectal Varices

Rectal varices are an uncommon cause of lower gastrointestinal bleeding, seen in patients with portal hypertension particularly extrahepatic portal venous obstruction. They can be successfully treated by endoscopic variceal ligation.

Postpolypectomy Bleeding

Postpolypectomy bleeding is the most frequent complication of colonoscopy and is seen in 0.2% to 1.8% cases of colonoscopic polypectomy. Delayed bleeding may occur up to 14 days after polypectomy. Endoscopic clipping is an effective treatment modality.

SMALL INTESTINAL BLEED

Only 3% to 5% of all GI bleeding arises between the second portion of the duodenum and the ileocaecal valve. Bleeding from this site is difficult to diagnose, since the small bowel is relatively inaccessible. Patients present either with chronic occult blood loss or with recurrent episodes of melaena. Repeated endoscopies and barium studies are often negative. Various causes of small intestinal bleed are given in **Table 4**. Vascular ectasias are the commonest cause of small intestinal bleed. Benign small bowel tumours (usually leiomyomas) are the second most common cause. Meckel's diverticulum is the cause of bleeding in two-third of males younger than 30 years presenting with small bowel bleeding. Bleeding is almost always brisk, resulting from ulceration within the diverticulum or the adjoining ileal mucosa.

Table 4: Differential Diagnosis of Occult-GI Bleeding

Mass lesions in colon or small intestine
Carcinoma
Adenoma
Inflammation
Erosive oesophagitis/gastritis
Ulcer (any site)
Coeliac disease
Inflammatory bowel disease
Colitis (non-specific)
Worm infestation (hookworm, whipworm, strongyloidiasis, ascariasis)
Tuberculous enterocolitis
Amoebiasis
Other causes
Drug intake
Haemosuccus pancreatitis
Haemobilia
Vascular disorders (haemangioma, Dieulafoy's lesion)

GASTROINTESTINAL BLEEDING OF OBSCURE ORIGIN

Obscure bleeding is defined as recurrent bouts of acute or chronic GI bleeding for which no definite source has been discovered by routine endoscopic and barium contrast studies. Obscure gastrointestinal bleeding can be overt or occult, depending upon the presence or absence of clinically evident bleeding. Causes of gastrointestinal bleeding that are commonly missed on upper gastrointestinal endoscopy are Cameron's erosion, gastric varices, Dieulafoy's lesion, angiodysplasia, oesophagitis, portal hypertensive gastropathy and gastric antral vascular ectasia. Therefore, upper gastrointestinal endoscopy should be repeated, if it is negative then a cause in the small bowel should be looked

for. The most common cause of obscure GI bleeding is vascular ectasia of the small bowel. Certain lesions are difficult to diagnose because of their rarity or their subtle appearance; and some lesions are detectable only if active bleeding is seen endoscopically (e.g. Dieulafoy's lesion). Tubercular enteritis/colitis is another cause of obscure GI bleed in our country. Worm infestation, especially with hookworms, is a common cause of anaemia in India. With a heavy parasite load, some patients may have continuous ooze from the small intestine and may have positive stool occult blood. Stool examination is diagnostic. An approach to management of obscure gastrointestinal bleeding is given in **Figure 3**.

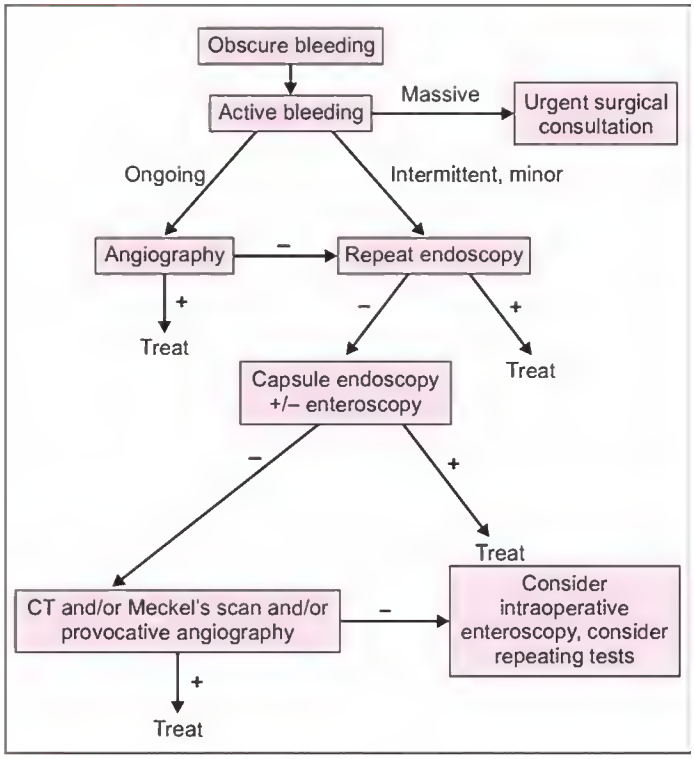

Figure 3: Algorithm for managing obscure gastrointestinal bleeding.

Angiography is performed only if bleeding is likely to be beyond duodenum and is so massive that endoscopy cannot be safely or satisfactorily performed and surgery is contraindicated. Blood loss must be greater than 0.5 mL/min for angiography to detect the site of bleed. Selective mesenteric angiography usually localises the site of bleeding in about 75% of such patients. Radionuclide imaging studies are not useful in the evaluation of upper GI bleeding.

Radionuclide scanning is a sensitive method for detecting gastrointestinal bleeding at a rate of 0.1 mL/min. This technique is more sensitive, but less specific than angiography. The major disadvantages are that nuclear imaging localises bleeding only to an area of the abdomen and the intraluminal blood is moved away by intestinal motility leading to false localisation. For proximal small bowel push enteroscopy permits inspection of the entire duodenum and part of the jejunum.

Capsule endoscopy (CE) was launched at the beginning of this millennium and since then it has had a very important impact on managing obscure gastrointestinal bleeding. Before the advent of CE, small bowel was an organ which was very difficult to explore with available endoscopic, radiological and nuclear medicine techniques. Wireless CE is simple, safe, non-invasive, reliable procedure, well accepted and tolerated by the patient. This technique evaluates with high resolution images, the whole small bowel, avoiding surgery or radiation exposure. In this technique a small capsule camera is swallowed by the patient (capsule enteroscopy). It takes up to 50,000 photographs of the entire small intestine and transmits the images to a data recorder externally, enabling visualisation of areas where the endoscope cannot reach.

Double-balloon enteroscopy is another new technique that allows access to the whole of the small bowel with the added advantage of therapeutic option, like haemoclip application or polypectomy, etc. As inferred from its name, the two inflatable balloons are the crux of the double balloon system. An overtube is backloaded onto the endoscope before intubation. The distal ends of the overtube and of the endoscope are fitted with inflatable/deflatable air-filled latex balloons. When inflated to 45 mmHg, the balloons grip the intestinal lumen, providing traction against the wall without undue pressure. Exploratory laparotomy with intra-operative endoscopy is indicated in patients with severe recurrent or persistent bleeding in whom all other investigative modalities have proved unsuccessful. Scintigraphy and mesenteric angiography can also be done to guide the surgeon in patients prior to exploratory laparotomy.

Faecal Occult Blood

Various causes of occult gastrointestinal bleeding are given in **Table 4**. An important cause of chronic occult bleeding is NSAIDs intake. Other causes are polyps and carcinoma of the colon. Faecal occult blood loss in normal individuals varies from 0.5 to 1.5 mL per day. Faecal occult blood tests are to detect blood not visible overtly. The classic faecal occult blood tests are of guaiac based type. They are based on haemoglobin pseudoperoxidase activity, guaiac turns blue after oxidation by oxidants or peroxidases in the presence of an oxygen donor such as hydrogen peroxide. Various factors influence the result of guaiac test, presence of animal haemoglobin and dietary peroxidases leads to false positivity while presence of vitamin C results in false negativity. Immunological faecal occult blood tests detect human globin epitopes and are highly sensitive for detection of blood. They are more specific than guaiac based tests; their results are not affected by dietary factors. Haem-porphyrin based test relies on spectrofluorometric method to measure porphyrin derived from haem, they provide a highly accurate determination of total stool haemoglobin. Intraluminal degradation of haemoglobin or interfering peroxidase producing substances do not effect the haem-porphyrin assay, although myoglobin, a haem containing protein found in red meats interferes with its result. The initial investigation for evaluation of occult bleeding is colonoscopy which should be followed by an upper GI endoscopy to rule out gastroduodenal pathology. If these tests are unrevealing, small intestinal causes of bleed should be considered.

PROGNOSIS OF GASTROINTESTINAL BLEEDING

Mortality of each episode of variceal bleed in cirrhotics is 30% to 50%. Variceal bleeding in non-cirrhotic causes of portal hypertension, however, carries a good prognosis. Mortality for ulcer bleed is much lower (3% to 10%). Lower GI bleed is usually less life-threatening than upper GI bleed. Risk factors for increased mortality are presentation with shock, active bleeding at presentation, advanced cirrhosis, old age, co-morbid medical illnesses, occurrence of rebleeding and failure of endoscopic methods to control bleed.

FUTURE PROSPECTS

Steady progress in engineering including microelectrical systems will affect the performance of capsule endoscopy. With the advent of robotic capsule in near future, it will be possible to perform drug delivery and tissue sampling, robotic capsule will be equipped with microelectrical system for directed therapy. Natural orifice transendoscopic surgery (NOTES) is a stimulating advancement. Development of endoscopic suturing devices to close gastrointestinal perforations is equally exciting. These techniques will be increasingly adapted to control gastrointestinal bleeding in future.

13.7 Oesophageal Disorders

Shobna J Bhatia, Praveen Mathew

SYMPTOMS

Oesophageal disorders are one of the commonest disorder of the GI tract. The description is given in next chapters. The passage of food through the body of the oesophagus is not sensed by an individual in normal circumstances. The major symptoms of oesophageal diseases are heartburn, chest pain, regurgitation and dysphagia.

Heartburn (pyrosis) is defined as retrosternal burning pain that travels cephalad. It is exacerbated by bending or lying down, and is worse after meals. It is relieved by upright posture, by swallowing of saliva or water, or more reliably by antacids or acid-inhibiting drugs. Heartburn is a characteristic symptom of gastro-oesophageal reflux (GOR), and may be associated with regurgitation.

Regurgitation is described as effortless appearance of acid or a bitter taste in the mouth. It occurs in GOR, and may result in laryngeal aspiration with spells of coughing and choking which awaken the patient from sleep.

It may also result in aspiration pneumonia. Regurgitation of bland food suggests that an obstruction exists in the lower oesophagus; in GOR, bland regurgitation occurs when acid secretion has been inhibited by drugs.

Dysphagia, or difficulty in swallowing, is a sensation of obstruction to the passage of food through the mouth, pharynx or oesophagus due to a significant problem in the anatomy or motility of these organs. Dysphagia could be oropharyngeal (transfer) or oesophageal. Oropharyngeal dysphagia occurs due to neuromuscular or structural abnormalities of mouth, hypopharynx or upper oesophagus; these patients have difficulty in initiating the swallow. Oesophageal dysphagia is classified as mechanical or motor. Mechanical oesophageal dysphagia is initially to solids only. It could be intermittent (webs or Schatzki ring) or progressive from solid to blenderised food and finally to liquids (stricture, malignancy). The severity of dysphagia in mechanical obstruction varies with the degree of luminal narrowing, type of food bolus, and presence of associated oesophagitis. On the other hand, dysphagia due to motor disorders is equal for solids and liquids, may increase with intake of very cold foods and it could be slowly progressive (achalasia cardia) or intermittent (less specific motility disorder). Non-obstructive dysphagia occurs in patients with reflux disease who have oesophageal inflammation associated with a motility disorder.

Odynophagia or painful swallowing is due to mucosal non-infectious inflammation. Causes could be infectious (candidiasis, herpes, cytomegalovirus, Epstein-Barr virus, etc.) or non-infectious like corrosive intake, pill oesophagitis, radiation oesophagitis, severe GOR disease and rarely osesophageal carcinoma.

Chest pain of oesophageal origin described as squeezing or burning sensation, is similar to cardiac angina and may not be related to swallowing. Almost 90% of times it is associated with other oesophageal symptoms. More than 50% of cases of non-cardiac chest pain have GOR disease; other causes are oesophageal spasm, achalasia cardia, nutcracker oesophagus and sometimes panic disorders. Water brash is reflex salivary hypersecretion that occurs in response to GOR. It should not be confused with regurgitation. Globus sensation is a feeling of food stuck at the pharyngeal level, but occurs between meal times.

MOTILITY DISORDERS

Skeletal Muscle Disorders

Pharyngeal paralysis may occur following neuromuscular diseases; laryngeal and orofacial muscles also may be involved. It is characterised by transfer dysphagia, laryngeal aspiration and nasal regurgitation. Barium swallow with cineradiography is the investigation of choice, and reveals poor contraction of pharyngeal constrictors, barium in the valleculae and pyriform sinuses, and nasal and tracheal aspiration. Oesophageal motility studies may reveal reduced amplitude of contraction wave in pharynx and proximal oesophagus, reduction in upper oesophageal sphincter (UOS) resting tone, and incoordination between the pharynx and oesophagus during a swallow.

Patients who have pharyngeal paralysis due to myasthenia gravis or polymyositis respond to treatment of the primary disease. In other patients, swallowing exercises usually help. In patients with a cerebrovascular accident, the extent of impairment of swallowing and its subsequent recovery depend on the type and extent of lesion. In severe cases, a permanent feeding gastrostomy may be required. In patients with UOS spasm, botulinum toxin injection or cricopharyngeal myotomy may be helpful.

Cricopharyngeal achalasia is a disorder of unknown cause, and occurs due to failed relaxation of the UOS and can be associated with Zenker's diverticulum. Dysphagia and choking are the predominant symptoms. On radiography, a prominent bar representing the contracted UOS may be seen. Cricopharyngeal myotomy may be helpful in selected cases, but should not be done in patients with associated GOR, because of increased risk of pulmonary aspiration post-operatively.

Smooth Muscle Disorders

Achalasia cardia

Achalasia cardia is a motor disorder of the oesophageal smooth muscle in which the oesophageal body is aperistaltic, the lower oesophageal sphincter (LOS) may be hypertensive and does not relax completely with swallowing. In addition, because of the non-relaxing LOS, the intra-oesophageal pressure is higher than the gastric pressure.

The underlying abnormality is defective innervation of the smooth muscle portion of the oesophageal body and the LOS.

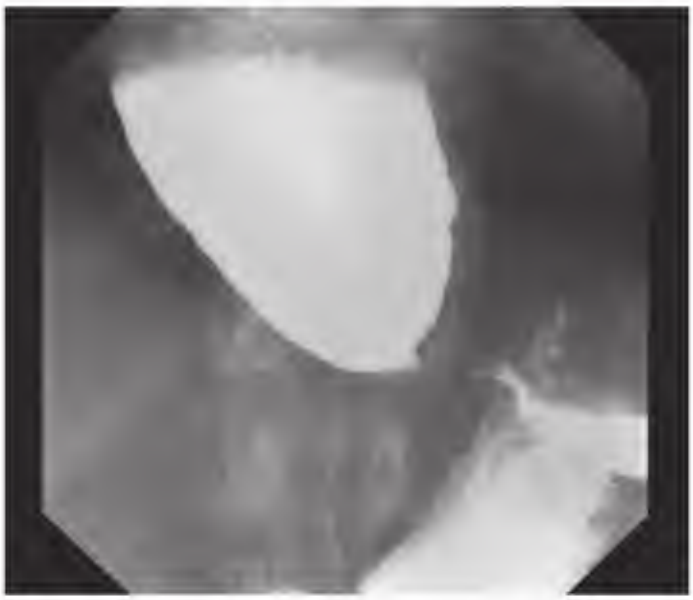
Classic achalasia shows a marked reduction in myenteric neurons. Secondary achalasia may be caused by gastric carcinoma infiltrating the oesophagus, lymphoma, Chagas disease, neuropathic chronic intestinal pseudo-obstruction syndrome, irradiation and certain toxins and drugs.

Dysphagia, chest pain and regurgitation are the main symptoms of achalasia. Dysphagia occurs with both liquids and solids. Various manoeuvres designed to increase intra-oesophageal pressure, including the Valsalva, may help passage of the bolus into the stomach. Regurgitation and pulmonary aspiration occur because of retention of large volumes of saliva and ingested food in the oesophagus. The overall course is usually chronic over months to years.

Chest X-ray may show absence of the gastric air bubble. In advanced cases, an air-fluid level in the mediastinum in the upright position represents retained food in the dilated oesophagus. Barium swallow shows oesophageal dilatation and a persistent beak-like narrowing, representing the non-relaxing LOS, in the lower oesophagus (**Figure 1**).

Oesophageal manometry shows the defining feature of distal body aperistalsis and incomplete or absent swallow induced relaxation of LOS. Other features are hypertensive LOS and low amplitude simultaneous onset oesophageal body contractions. An increased intra-oesophageal basal pressure that exceeds intragastric pressure is commonly seen. High resolution oesophageal manometry with contour plot topographical analysis has found three variants of achalasia (**Figures 2A and B**), type 1—no significant oesophageal pressurisation; type 2—rapidly progressive compartmentalised pressurisation, either localised to distal oesophagus or throughout the whole oesophagus; and type 3—rapidly progressive pressurisation attributable to spastic contractions. This classification is also helpful in prognosticating outcomes with type 2 responding best to therapy; type 3 achalasia does not respond well, and type 1 has intermediate response to any form of treatment.

Endoscopy is helpful in excluding the causes of secondary achalasia, particularly gastric fundal carcinoma.



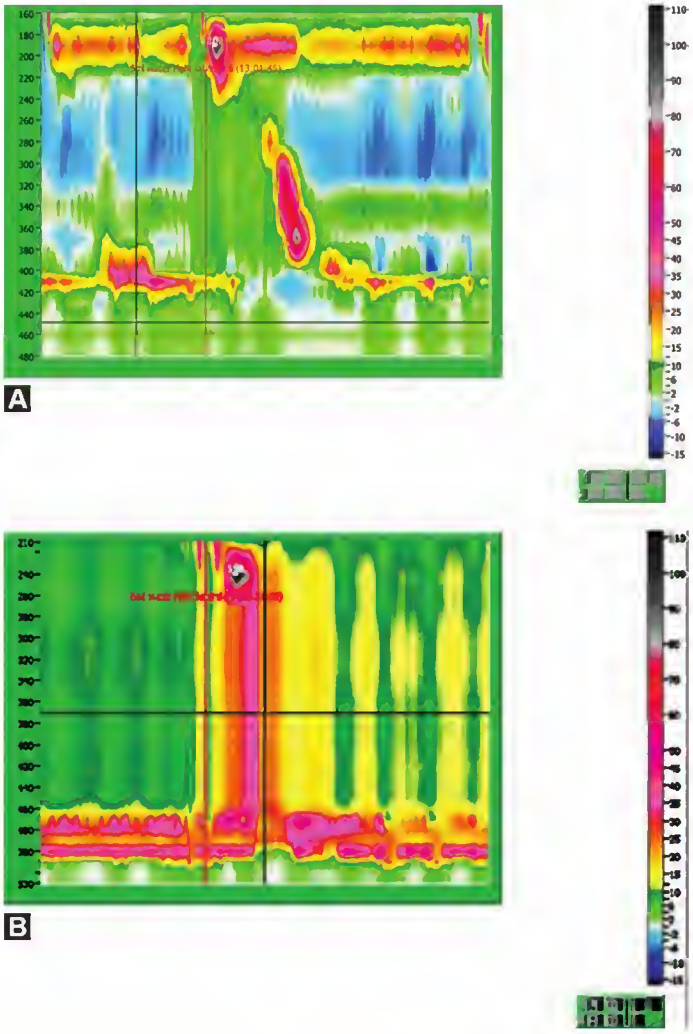


Figure 1: Barium swallow showing dilated oesophagus with bird beak appearance at the lower end and fluid level in the oesophagus, suggestive of achalasia cardia.

Figures 2A and B: (A) High resolution manometry shows normal peristaltic wave after a swallow. (B) Manometry shows aperistalsis in oesophageal body after a swallow with elevated lower oesophageal sphincter pressure suggestive of achalasia.

Medical treatment using nitrates is usually unsatisfactory. Calcium-channel antagonists such as nifedipine have been used with some success; these need to be administered sublingually 15 to 30 min prior to a meal. The best available non-surgical therapy involves endoscopy-assisted balloon dilatation of the LOS; this reduces the basal LOS pressure by tearing muscle fibres. Endoscopic injection of botulinum toxin into the LOS is effective in the short term. Heller's extra-mucosal myotomy of the LOS in which the circular muscle layer is incised, is equally effective. Reflux oesophagitis and peptic stricture may develop after successful treatment of achalasia; this complication is more frequent after surgery than with balloon dilation. Surgery is increasingly being performed laparoscopically; additionally, fundoplication is often done to prevent GOR.

Spastic Disorders of Distal Oesophagus Other than Achalasia

This section includes a spectrum of disorders ranging from diffuse oesophageal spasm, nutcracker oesophagus, non-specific spastic disorders and hypertensive LOS. These are differentiated on the basis of manometry findings (**Figure 3**). They all are present with history of chest pain, occasional dysphagia and rarely regurgitation. Pain is very similar to angina, may occur at rest or after swallowing, and may radiate to the back or neck. These disorders are associated with other functional bowel disorders and have high association with anxiety

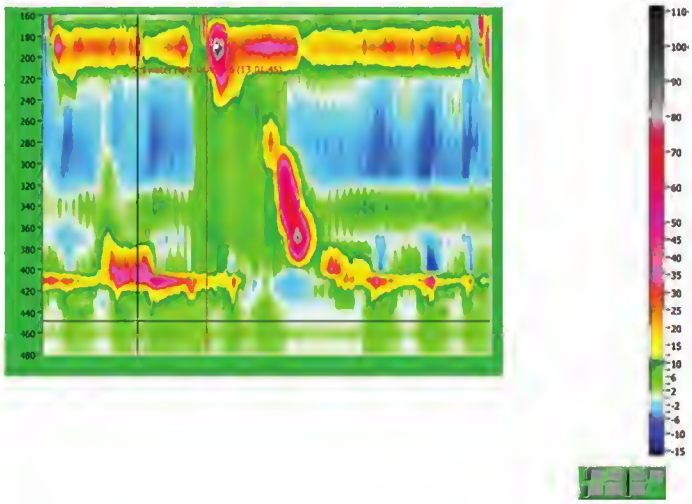

Figure 3: High resolution manometry shows simultaneous and prolonged contraction of oesophageal body suggestive of diffuse oesophageal spasm.

disorders, depression and other psychological abnormalities. The pathogenesis of these disorders is not known, probably functional with no anatomic abnormalities found.

Diffuse oesophageal spasm is characterised by non-peristaltic responses of normal amplitude after 30% or more of swallows with a normally relaxing LOS. Barium swallow may reveal intermittent areas of oesophageal spasm that produce an appearance of a corkscrew oesophagus (**Figure 4**).

Treatment includes ruling out the possibility of ischaemic heart disease; smooth muscle relaxants like nitrates and calcium channel blockers are beneficial in a few cases. Anti-depressants like imipramine, trazodone and sertraline have been found to be useful in a number of patients with chest pain. Pneumatic dilatation of LOS has been found to be beneficial in cases with associated LOS hypertension. In refractory cases, long oesophagomyotomy has been tried with some success.

Figure 4: Barium swallow showing appearance of a corkscrew oesophagus.

Systemic diseases like scleroderma and diabetes mellitus also cause motor disorders of the oesophagus. Scleroderma oesophagus is typically one with a low LOS pressure and aperistalsis. There is atrophy of the smooth muscle. The patient presents with severe gastro-oesophageal reflux disease with complications. Diabetes mellitus, when complicated by autonomic neuropathy, may have associated oesophageal dysmotility. The patients are rarely symptomatic, but may have occasional dysphagia and heartburn. Candidal infection should also be considered; if present, patients may have odynophagia.

GASTRO-OESOPHAGEAL REFLUX DISEASE

Gastro-oesophageal reflux (GOR) is defined as backward flow of gastric contents into the oesophagus. A small amount of GOR occurs in normal individuals. GORD (gastro-oesophageal reflux disease) is defined as a condition which develops when stomach contents cause troublesome symptoms or complications, and adversely affects an individual's quality of life. The typical reflux syndrome is defined by presence of troublesome heartburn and/or regurgitation. GORD is the most common oesophageal disorder, accounting for nearly 75% of all patients with oesophageal disorders. In Western studies, 15% to 20% of the general population suffers from GORD. The prevalence of GORD in Asia is lower (2.3% to 8%), probably due to higher prevalence of *Helicobacter pylori*, lower body mass index, low fat consumption in diet and genetic diversity. Adenocarcinoma of the oesophagus is on the rise in the Western world. Barrett's oesophagus, which is a recognised precursor to adenocarcinoma is strongly associated with GORD.

Pathophysiology

The normal anti-reflux barrier at the gastro-oesophageal junction is a zone whose functional integrity is maintained by the LOS pressure, extrinsic compression of the LOS by the crural diaphragm, the intra-abdominal location of the LOS, integrity of the phreno-oesophageal ligament, and maintenance of the acute angle of His.

Transient LOS relaxation is one of the most important causes for GORD; it is not associated with a swallow. It is more harmful because it is longer in duration (>10 seconds) compared with swallow-induced LOS relaxation, accompanied by relaxation of crural diaphragm and not associated with peristalsis. It is usually stimulated by gastric distension due to food or gas, or rarely fat and stress. Small amount of reflux occurs during swallow induced LOS relaxation. The role of hypotensive LOS seems to be present only in patients with severe oesophagitis.

Hiatus hernia is seen in 60% to 90% of patients with reflux oesophagitis, especially in patients with peptic stricture or Barrett's oesophagus. Hiatus hernia breaches the anti-reflux barrier by displacing the LOS from crural diaphragm. Loss of the intra-abdominal segment of LOS increases transient LOS relaxation and impairs oesophageal acid clearance.

Impaired oesophageal motor function resulting in inadequate volume clearance occurs in oesophagitis; peristaltic dysfunction increases with increasing severity of oesophagitis. The layer of mucous carpeting the mucosa and mucosal bicarbonate also constitute an important line of defence against acid injury.

If acid injury and cell necrosis occur, the rate of regeneration plays a role in determining the severity of lesions.

There is no increase in gastric secretions in GORD patients, but there is a pocket of acid in the distal oesophagus which escapes the buffering action of food; hence the predilection for oesophagitis at this location. Animal and human studies have demonstrated that acid and pepsin are responsible for the mucosal injury. Other factors implicated are duodenogastric reflux, with conjugated bile acids and trypsin as possible culprits. Gastroparesis is found in 6% to 38% of patients with GORD.

Helicobacter pylori infection is currently believed to lower the frequency of GORD. This is backed by epidemiological data of low prevalence of GORD in areas with high prevalence of *H.pylori* and vice versa. Prevalence of more virulent strains of *H. pylori* in developing countries results in corpus or pangastritis, thus reducing gastric acid secretion and resulting in decreased symptoms of GORD.

Pathology

Grossly, the spectrum of oesophageal mucosal appearances varies from normal appearing mucosa (40% to 80%) to mucosal injuries of varying severity-erosions to ulcerations. The earliest finding, seen on electron microscopy, is dilated intercellular spaces, at least three times greater than controls; this is reversible on administering proton pump inhibitors. Light microscopy shows papillary height more than half, and basal zone thickness more than 1/6th of total mucosal thickness. Acute inflammation with neutrophils and eosinophils is seen in up to 40% of cases but is not specific for GORD.

Development of columnar-lined mucosa, with specialised intestinal metaplasia is the defining feature of Barrett's oesophagus, visible on endoscopy when normal squamous mucosa is replaced by salmon pink columnar mucosa. This can progress from low grade to high grade dysplasia, and later to adenocarcinoma of the oesophagus.

Clinical Features

Symptom complex of GORD has been divided into oesophageal and extra-oesophageal syndromes. Oesophageal syndromes include the typical reflux syndrome and reflux chest pain syndromes.

Typical reflux symptoms are heartburn, a burning sensation in the retrosternum and regurgitation—a perception of flow of gastric contents into the mouth or hypopharynx. The prevalence of these is 75% to 98% and 48% to 91%, respectively. GORD can be diagnosed by these two symptoms without the need for endoscopy. Reflux chest pain can be indistinguishable from pain of ischaemic heart disease, but is usually associated with other symptoms of GORD. GORD is the most common oesophageal cause of chest pain. Sleep disturbance is often associated with GORD. In patients with minimal symptoms, exercise has been found to worsen symptoms of GORD.

Dysphagia in a patient with GORD could be a marker of peptic stricture or development of malignancy. Dysphagia may also occur because of reflux oesophagitis and motor functional abnormalities. Barrett's oesophagus is an endoscopic diagnosis (**Figure 5**) confirmed on histology showing specialised intestinal metaplasia. There are no symptoms which herald the development of Barrett's oesophagus. Increasing age, male gender, long duration of GORD symptoms, obesity and smoking are risk factors for Barrett's oesophagus. Adenocarcinoma may develop in patients with Barrett's oesophagus especially high grade dysplasia.

Figure 5: Endoscopy shows evidence of Barrett's metaplasia in the oesophagus. The normal squamous mucosa of the oesophagus is replaced by columnar gastric mucosa.

Extra-oesophageal syndromes are classified as those with established associations and those with proposed associations. Established associations include reflux cough, reflux laryngitis, reflux asthma and reflux dental erosions. These syndromes usually occur with the concomitant manifestation of typical reflux oesophageal symptoms and rarely in their absence. Reflux is rarely the only cause for these extra-oesophageal symptoms. They have been found to respond to treatment of GORD. Other symptoms with proposed associations are sinusitis, pulmonary fibrosis, recurrent otitis media and pharyngitis. The degree of evidence for this last group is minimal, epidemiologically or treatment-response wise.

Investigations

The diagnosis of GORD is made on the basis of clinical history and confirmed by response to medications. Diagnostic testing is done to avert misdiagnosis, to identify complications of GORD and to evaluate the reason for failure of standard therapy. To avert misdiagnosis and identify reflux complications, the concept of alarm symptoms has been introduced; these include gastrointestinal blood loss, involuntary weight loss, dysphagia and anaemia. In these conditions an endoscopy is warranted. In case any lesion is seen, biopsies should be taken from it. Less than 50% of patients with GORD have endoscopic features of oesophagitis; visible breaks in mucosa is the most reliable marker of reflux oesophagitis. This does not correlate with the frequency or severity of reflux symptoms. Reflux stricture seen in less than 5% of GORD patients is defined by a persistent narrowing in the lumen of the oesophagus and manifests as troublesome mechanical dysphagia. If endoscopy is normal, the patient should be treated empirically as GORD, and further investigated if the symptoms do not resolve. Manometry is useful in detecting severe peristaltic dysfunction which is a contraindication for anti-reflux surgery. Investigations to demonstrate excessive oesophageal acid exposure are conventional catheter based pH-metry or wireless capsule pH-metry, and impedence-pH monitoring.

Therapy

Treatment is directed towards decreasing GOR and improving oesophageal clearance. The aim is to alleviate symptoms, heal oesophagitis and prevent complications.

Treatment usually begins with dietary and lifestyle modifications. The patient should be asked to avoid food items that increase reflux (fatty or fried food, caffeinated drinks, chocolate, mint) and decrease intake of acidic foods (citrus fruits, spicy food, carbonated drinks, tomatoes, onions). Lifestyle modifications include weight reduction in those who are obese, elevation of the head end of the bed and avoiding eating within 3 hours of bedtime in those with night time symptoms. Patients with postprandial symptoms are advised to take small frequent meals.

Empirical initial management with acid reduction is the accepted approach currently in patients with uncomplicated heartburn. Evidence suggests that acid reduction helps healing of oesophagitis and relief from symptoms. Meta-analysis of randomised control trials show that proton pump inhibitors (PPIs) are more effective than H_2 receptor antagonists (H_2RAs) in treating oesophagitis and ameliorating symptoms. PPIs as a class (omeprazole, lansoprazole, pantoprazole, rabeprazole and esomeprazole) are all equally effective in standard doses. There does not appear to be any additional benefit of higher dosage/twice daily dosing of PPIs or adding a H_2RA, except in cases of severe oesophagitis. Patients whose heartburn has not responded to twice daily PPIs are considered treatment failures. Preference of a PPI over another is primarily to ameliorate the side-effects of the PPI need earlier. Patients with reflux chest pain can be given a trial of PPI once ischaemic heart disease has been ruled-out. Patients with extra-oesophageal symptoms require high doses.

Maintenance therapy is usually necessary as GORD is a chronic disease, the lowest possible dose of PPI should be titrated for symptom control in patients with definite oesophagitis. PPIs have been shown to reduce the development of reflux strictures, but there is no evidence that they reduce the risk of Barrett's oesophagus or adenocarcinoma. In patients with extra-oesophageal symptoms, maintenance therapy is indicated only to control oesophageal symptoms. Long-term PPI therapy is potentially safe though there is a theoretical risk of hypergastrinaemia, pneumonia, *Clostridium difficile* colitis and hip fractures.

Anti-reflux surgery and PPIs have equal efficacy for control of oesophageal reflux symptoms. Surgery should be offered when an individual is intolerant to PPIs, or when a patient with oesophageal reflux syndrome has troublesome regurgitation. The potential side-effects of anti-reflux surgery include excessive flatulence, inability to belch, dysphagia and recurrence of symptoms post-surgery (30% over 5 years). Patients well controlled on PPIs should not be offered surgery. The surgery recommended is laparoscopic fundoplication.

INFECTIOUS OESOPHAGITIS

Infectious oesophagitis can be due to viral, bacterial and fungal causes. With an increase in the number of patients with immunocompromised states, there has been an increased frequency of oesophageal infections.

Infections of the oesophagus present with acute dysphagia, odynophagia and chest pain. In patients with severe ulceration of the mucosa, bleeding may occur; this is usually self-limiting and small in quantity, but life-threatening haemorrhage may occur.

Viral Oesophagitis

Herpes simplex virus (HSV) type 1 or 2 may cause oesophagitis in immunocompromised individuals. Systemic manifestations like nausea, vomiting and fever may be present. On endoscopy, the oesophageal mucosa has 1 to 3 mm vesicles and small, discrete, punched-out lesions, which may proceed to confluent ulcers and diffuse erosive oesophagitis. These lesions may get superinfected by bacteria or fungi. Biopsy or cytology may show ballooning degeneration, ground-glass change in nuclei with eosinophilic inclusions (Cowdry type A) and giant cell formation. Culture may be positive. Treatment consists of acyclovir 250 mg/m^2 intravenous 8 hourly. As the patient improves, oral therapy may be started with 200 to 400 mg acyclovir 5 times a day. Symptoms resolve within a week. Ulcers take a longer time to heal.

Varicella-zoster virus occasionally produces oesophagitis in children with chicken pox and adults with herpes zoster. The oesophageal lesions are similar to those of HSV, and necrotising oesophagitis may occur in a severely compromised patient. Biopsy from the edge of the ulcer shows findings similar to those of HSV, and differentiation requires culture studies. Acyclovir, in doses higher than for HSV, is required for treatment.

Cytomegalovirus infection occurs only in the immuno-compromised host. Endoscopy shows serpiginous ulcers which are large and deep with surrounding normal mucosa. In the distal oesophagus the ulcers may coalesce. Biopsy should be taken from the centre of the ulcer and reveals intranuclear and small cytoplasmic inclusions in fibroblasts and endothelial cells of blood vessels. Early diagnosis may be made by immuno-histochemistry using monoclonal antibodies to CMV. Ganciclovir is the treatment of choice. Complete healing may take a few weeks to months and treatment should be continued until then.

HIV causes oesophagitis during seroconversion and during inversion of T-cell helper: suppressor ratio. The oesophagitis is self-limiting. Steroids may help in this condition.

Bacterial oesophagitis is very rare. However, patients with AIDS may develop oesophagitis due to *Cryptosporidium* or *P. carinii*.

Tuberculosis of the oesophagus is rare and is almost always due to contiguous spread from the lung or mediastinal lymph nodes.

Fungal Oesophagitis

Candidiasis of the oesophagus occurs in immunodeficiency disorders like diabetes mellitus, chronic renal failure, and AIDS. Individuals receiving steroids or immunosuppressive chemotherapy for malignancy and those with underlying oesophageal diseases that cause stasis of food (achalasia or scleroderma) may also develop candidiasis.

Candida is present in the non-pathogenic form in the oral flora in normal individuals. Patients who develop oesophagitis may be asymptomatic, or may have odynophagia and dysphagia. Rarely, bleeding may occur, and the deep ulcers may perforate or may form a stricture. Systemic invasion from oesophageal candidiasis is also reported.

Oral *candidiasis*, if present, suggests the diagnosis by its white flake's appearance. Endoscopy reveals raised white pseudo-membranous plaques with mucosal erythema. In severe cases, confluent linear and nodular plaques with underlying ulcerations may be present. A smear taken from these plaques may reveal hyphae. Treatment in mild cases is with 10 to 20 mL of oral nystatin (100,000 units/mL) 6 hourly, or oral clotrimazole (10 mg 6 hourly), or fluconazole 100 mg per day for 7 days. If symptoms persist, endoscopic biopsy and culture are

recommended. If anti-fungal resistance is demonstrated, caspofungin may be effective. Narcotics are recommended for patients with severe odynophagia.

Corrosive Injury

Corrosive is any substance which causes tissue injury upon contact. Caustic injury of the oesophagus occurs following ingestion of strong alkali or acid, most often accidentally or with suicidal intent. Sodium hydroxide is the most frequent cause of alkaline injury. Hydrochloric and sulphuric acids are the common acids causing injury. Most corrosives are available as over-the-counter drain cleaners, dish washing detergents, bleaches, battery fluids, button batteries, nail polish removers, etc.

Alkali ingestion provokes liquefaction or saponification necrosis of the oesophageal wall and thrombosis of blood vessels. Acids cause coagulative necrosis. Severity of tissue injury depends upon factors like substance pH, physical state (solids adhere to mucosa and cause more damage), quantity, intention (quantity is usually larger in suicidal cases), tissue contact time and concentration. There is an acute inflammatory response with mucosal necrosis, followed by sloughing of necrotic tissue and ulceration over 4 to 15 days. Risk of perforation is maximum up to 7 days. After 3 to 4 weeks, cicatrisation begins. Significant oesophageal strictures develop when there is circumferential damage.

In the oesophagus, corrosives pool at the post-cricoid area, level of aortic arch, tracheal bifurcation, and lower oesophageal sphincter. These are common locations for strictures. In severe cases, there may be perforation into the mediastinum or pleural cavity or development of a tracheo-oesophageal fistula. The damage is mainly in the antrum in the fasting stomach, and in the gastric corpus if the patient has ingested a meal prior to corrosive ingestion.

Symptoms include burning pain in the mouth and throat, odynophagia, excessive salivation, stridor, hoarseness, dysphagia and chest pain. Gastric involvement leads to abdominal pain and vomiting, and occasionally symptoms and signs of perforation. There may be oedema and ulceration of the lips, tongue and pharynx. Airway obstruction from severe epiglottic and laryngeal oedema may occur. As the acute inflammatory reaction subsides, odynophagia and dysphagia decrease; with the development of oesophageal stricture, dysphagia gradually returns, usually within 1 to 3 months after the accident. Mortality rate is of 1%, usually due to mediastinitis or peritonitis resulting in multi-organ failure.

The aim of therapy in the acute phase is resuscitation and supportive care. Assessment of the severity of damage is most important after resuscitation of the patient. Clinical features do not correlate with severity of damage. X-ray films of chest and abdomen are taken to check for perforation, pneumo-mediastinum or pneumoperitoneum, which if present can be confirmed by CT scan. If there is evidence of perforation, patient should be referred for surgery (oesophagectomy or gastrectomy). Flexible endoscopy should be done at the earliest or up to 96 hours of corrosive ingestion, after ruling out a perforation and is the best way to assess the severity of mucosal damage. Endoscopic grading is helpful in management and prognostication. Patients who have minimal injury can be started on oral liquids by 48 hours and can be discharged early; they also have a low risk of complications. In patients with advanced damage, a nasojejunal tube can be placed over a guide wire during endoscopy; this serves as a route for maintaining nutrition and also provides a lumen for dilatation in future as these patients are prone to develop strictures. Measures which have shown to be of no use or are harmful are administration of activated charcoal, pH neutralisation or dilution, by inducing emesis, and intravenous steroids. Antibiotic therapy is required only if secondary infection sets in.

Early dilatation of the oesophagus has been associated with a high-risk of perforation, and is therefore not recommended. Stricture of the oesophagus is the major long-term complication. Caustic strictures are often extensive and multiple, involving most of the lower oesophagus. They respond to repeated dilatation, and the frequency of dilatation may decrease over time. Recently, self-expandable plastic stents have been placed at the site of stricture for 6 to 8 weeks, with good results. Oesophageal resection with colon or gastric tube replacement may be necessary in cases where the lumen is too small for dilatation, or in cases of extensive damage. Oesophageal squamous cell carcinoma is a potential long-term complication of corrosive injury.

Pill-Induced Oesophageal Injury

Pill-induced oesophageal injury results from damage due to ingestion of certain medications which cause injury by either production of caustic solution, hyperosmolar solution or direct drug damage. Drugs commonly implicated are tetracycline, doxycycline, potassium chloride, nonsteroidal anti-inflammatory drugs, alendronate, ferrous sulphate, theophylline, quinidine, etc. The injury is more common in individuals with anatomic or motility abnormalities of oesophagus. It could be predisposed by taking inadequate water or assuming recumbent posture immediately after taking the pill. Symptoms include severe chest pain, odynophagia and dysphagia. Endoscopy may reveal an ulcer, diffuse oesophagitis or pseudomembrane at the site of damage. Withdrawal of the offending medication, viscous lignocaine solution, adequate hydration, and use of PPIs to reduce acid exposure results in healing of the lesion. Rarely there can be perforation, oesophago-respiratory fistula or a chronic stricture at the site of the ulcer. The disorder is preventable in most cases.

Eosinophilic Oesophagitis

Eosinophilic oesophagitis (EO) is a disease characterised by eosinophilic infiltration of the oesophageal mucosa. Identified in 1978, the incidence of EO has been increasing in the Western world. Familial clustering and seasonal variation have been noted in patients with EO. Almost 80% of children and 40% to 60% of adults have history of allergies. It is postulated to be IgE or non-IgE mediated. Sensitisation could be via food or inhaled allergens. EO appears to be a Th2 mediated immune response; IL-5 and IL-13 appear to play a key role in pathogenesis.

The pathognomonic feature of EO is eosinophilic infiltration of ≥15 eosinophils/HPF in the oesophageal mucosa; eosinophils should be counted in the most densely inflamed part of the biopsy (X 400). Other features are eosinophilic micro-abscesses, superficial infiltration of eosinophils in the upper half of mucosa, basal zone hyperplasia and papillary lengthening.

Most of the patients are men with a male to female ratio of 3:1, in the third or fourth decade of life. Presentation varies from dysphagia (60% to 90%), food impaction (50% to 60%), heartburn

and regurgitation (24% to 50%), refractory GORD, chest pain, abdominal pain, diarrhoea and weight loss. Children present with poor feeding, vomiting, regurgitation and failure to thrive.

Endoscopic findings include oesophageal rings (felinisation or trachealisation), raised white specks, longitudinal furrows, whitish exudates and a friable mucosa which may tear by passage of endoscope. Normal mucosa can be seen in up to a third of the patients. Strictures could be seen in any part of the oesophagus. Multiple (>5) biopsies from different levels of the oesophagus should be taken. Oesophageal pH monitoring should be done in difficult cases to rule-out GORD, or biopsies should be repeated after 6 weeks of PPI treatment. Barium swallow may reveal strictures, Schatzki's ring or a diffuse narrowing of the oesophagus. Allergic testing by skin prick, skin patch test or food specific radioallergosorbent testing can be done.

Treatment

Treatment is to control the inflammation using systemic steroids, prednisolone 1 to 2 mg/kg, tapered over 6 weeks in patients with severe dysphagia, weight loss and refractory oesophageal strictures. Steroids should not be used for maintenance therapy. Other steroids used are swallowed topical fluticasone propionate (440 to 500 µg/day) twice daily for 6 weeks, swallowed budesonide mixed with sucralose and beclomethasone have also been used. Symptoms recur in 50% of patients when treatment is stopped and can be managed with reintroduction of same therapy or, use of steroid-sparing drugs like azathioprine. Leukotriene receptor antagonist montelukast 10 to 40 mg/day has been used with some success. Endoscopic dilatation of strictures should be preferably limited to patients after a trial of medical therapy, because of the risk of perforation. Dietary therapy by eliminating foods like dairy, peanuts, soy, fish, eggs wheat and other foods identified by allergic testing has been found to be successful in 70% of paediatric cases. Because of poor tolerability, dietary therapy should be used in individuals not responding to medical and endoscopic treatment. Studies with targeted therapies to IL-5 are underway.

Hiatus Hernia

Herniation through the oesophageal hiatus occurs in two forms: axial or sliding type in which both the distal oesophagus and a varying portion of the stomach (i.e. the entire oesophago-gastric junction) are situated above the diaphragm, and para-oesophageal or rolling type in which the lower most oesophagus and the oesophago-gastric junction retain their position below the diaphragm, while a portion of the proximal stomach protrudes into the thorax alongside the oesophagus.

The size of the sliding hernia alone does not predict the presence or severity of symptoms; larger, long-standing hernias are more likely to be associated with symptomatic GOR.

In the less common para-oesophageal or rolling hernia, the less-than-atmospheric intrathoracic pressure is transmitted directly through the pleura to the peritoneal sac. With positive intra-abdominal pressure exerting an upward push, this hernia tends to enlarge progressively. The typical para-oesophageal hernia is rarely associated with GOR; however, it can get incarcerated and strangulation or bleeding may occur.

The management of symptomatic sliding hiatus hernia is similar to that of GORD. Para-oesophageal hernia needs surgical correction to avoid complications.

OESOPHAGEAL WEBS, RINGS AND DIVERTICULA

Oesophageal webs usually occur in the upper oesophagus, but may occur in the mid or lower oesophagus as well. They are thin horizontal membranes of stratified squamous epithelium, usually protrude from the anterior wall, rarely complete and are best demonstrated on the lateral view in the barium swallow. They are usually acquired, but webs in the upper third may be congenital in origin (**Figure 6**). A syndrome of cervical oesophageal web, anaemia and platonychia, which occurs mainly in middle-aged women, is called the Patterson-Kelly or Plummer-Vinson syndrome.

Figure 6: Barium swallow shows a web in upper oesophagus.

Oesophageal rings are found near the lower oesophageal sphincter (LOS). They are of 2 types. Type A is a muscular ring, 4 to 5 mm thick and is the hypertrophied upper portion of LOS. Type B ring, or Schatzki ring, is a mucosal ring at the squamo-columnar junction; its upper surface is squamous epithelium and undersurface is columnar. It is usually associated with GORD or rarely EO.

Rings and webs present with intermittent dysphagia to solid food. Rarely, dysphagia progresses to a severe state. Treatment consists of breaking the web or ring by dilatation; webs may rupture even during a diagnostic endoscopy. The underlying disorder like anaemia or GOR needs appropriate treatment.

Diverticula are outpouchings of the oesophageal wall from an area of muscular weakness. Zenker's diverticulum occurs due to weakness in the posterior hypopharynx; patients present with dysphagia and regurgitation. Treatment consists of cricopharyngeal myotomy. Epiphrenic diverticula occur in the distal oesophagus and are associated with oesophageal motility disorders.

13.8 Diseases of the Stomach and Duodenum

Pankaj Dhawan

The stomach is a J-shaped organ continuous with the oesophagus proximally and the duodenum distally. It is divided from the proximal to distal end into the cardia, fundus, body or corpus, antrum and pylorus (pyloric channel). The duodenum is the first part of the small intestine and is in continuity with the pylorus of the stomach proximally and the jejunum distally. It forms a C-shaped loop around the head of the pancreas.

The arterial blood supply of the stomach is derived from the coeliac artery and its major branches, the common hepatic, splenic and left gastric arteries while the duodenum receives additionally from the superior mesenteric artery. The venous drainage is into the portal vein or its tributaries, the superior mesenteric and splenic veins. The lymphatic drainage of the stomach is to the coeliac lymph nodes. The autonomic innervation stems from both the sympathetic (coeliac plexus) and the parasympathetic (right and left vagus nerves) nervous systems. The latter synapses with ganglion cells in the submucosa (Meissner's plexus) and myenteric plexuses (Auerbach's plexus). From these plexuses fibres are distributed to secretory components including cells and glands as well as to the gastric smooth muscle.

MOTOR PHYSIOLOGY

The motor function of the gastrointestinal (GI) tract is controlled at 3 levels. The first is the extrinsic neural control from the parasympathetic pathways via the vagus nerve and the sympathetic supply through the coeliac ganglion. The second level is provided by the enteric nervous system, which constitutes the complex network of ganglion cells in the layers of the gut wall. The third level of control of GI motility is in the excitable smooth muscle cells. Specific receptors in the cell membrane of the smooth muscle bind to amines, peptides, and other transmitters that reach the smooth muscle membrane via neurocrine, endocrine and paracrine routes. The main transmitters involved in excitation of the gastric muscle are acetylcholine and tachykinins, such as substance P and substance K. The main inhibitory transmitters are nitric oxide and vasoactive intestinal peptide (VIP).

GASTRIC SECRETION

The human stomach secretes water and electrolytes (H^+, Na^+, K^+, Cl^- and HCO_3^-), enzymes (pepsins and gastric lipase) and glycoproteins (intrinsic factor and mucins). The gastric exocrine secretions have a variety of functions.

Acid Secretion

The most important secretion of the stomach is gastric acid, secreted from parietal cells in the fundus and body of the stomach. Parietal cells have on their basolateral membrane receptors for 3 stimulants: histamine (H_2) receptor for histamine released from ECL cells and possible mast cells, a muscarinic (M_3) type of cholinergic receptor for acetylcholine released from post-ganglionic neurons and a cholecystokinin (CCK) receptor for gastrin released from pyloric and duodenal G cells.

Hydrogen ions are generated in the parietal cell from water. The corresponding hydroxyl ions combine with cellular carbon dioxide (CO_2) to form HCO_3. This reaction is catalysed by carbonic anhydrase. HCO_3 ions are exchanged at the basolateral membrane for Cl^- ions, which are ultimately secreted by the parietal cells. Hydrogen ions are exchanged for K^+ catalysed by the magnesium dependant H^+-K^+ ATPase pump. The H^+-K^+ ATPase is inhibited by covalent antagonists such as the substituted benzimidazoles (e.g. omeprazole). The apical membrane of the parietal cell is impermeable to H^+ and Cl^- and hence, it does not diffuse back from the lumen into the cell.

Other Secretions

The other important gastric secretion is pepsinogen (PG). This is a proenzyme S which gets activated to pepsin in the gastric lumen by the gastric acid. Two types of pepsinogen are PG I and PG II.

The gastric mucosa also secretes bicarbonates through the surface cells that are rich in carbonic anhydrase. Under most conditions, luminal HCO_3 is overwhelmed by luminal H^+ and is converted to CO_2. Therefore, HCO_3 is not ordinarily present in gastric juice. The other secretory products are gastric mucin and intrinsic factor. The role of intrinsic factor in vitamin B12 absorption is discussed elsewhere.

GASTRITIS

Gastritis is acute or chronic inflammation of the stomach and is most often diffuse. It is usually diagnosed on upper GI endoscopy and can be confirmed and classified histologically by performing a gastric biopsy. A detailed system for classification (Sydney system) has been adopted recently.

Acute Gastritis

This is also called erosive or haemorrhagic gastritis. Of these, the most common cause is use of aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs). These agents cause gastric mucosal damage by inhibiting prostaglandins, gastric bicarbonate and mucous, disrupting epithelial tight junctions and altering gastric mucosal micro-circulation. The mucosal damage can result in either slow upper GI bleeding which can be detected as positive faecal occult blood test or can manifest as massive upper GI bleeding. In some patients, epigastric discomfort, anorexia and nausea may be present. Treatment includes omission of the offending agent, acid-suppressive agents such as H_2 receptor antagonists and proton-pump inhibitors, prostaglandin analogues such as misoprostol (more useful for prevention) and cytoprotective agents, such as sucralfate.

Chronic Gastritis

Chronic gastritis progresses over years in three stages. In chronic superficial gastritis, there is infiltration of lymphocytes and plasma cells in the lamina propria; however, the mucosal thickness is normal. In atrophic gastritis, there is reduction in the gastric glands (parietal and chief cells) along with infiltration of plasma cells and lymphocytes. When there is associated polymorphonuclear cells infiltration, gastritis is termed active. In gastric atrophy, glands are lost, mucosal thickness is reduced, infiltration of lymphocytes and plasma cells is minimal and there may be foci of intestinal metaplasia.

The two main types of chronic gastritis are autoimmune (formerly type A) and *H. pylori*-associated (formerly type B). Autoimmune gastritis involves the gastric body and spares the antrum. Parietal cell and intrinsic factor antibodies are serum markers of autoimmune chronic gastritis. Patients present with pernicious anaemia (megaloblastic anaemia with absolute achlorhydria) and features of vitamin B_{12} deficiency. Also, autoimmune chronic gastritis is a pre-malignant condition and can progress to gastric cancer. *H. pylori*-associated chronic gastritis usually involves the antrum but over a period of time may involve the body as well (*see Infection Section*).

An uncommon cause of chronic gastritis is Menetrier's disease (hypertrophic gastritis). The most common presentation is in middle age with features of protein-losing enteropathy. On upper GI endoscopy, enlarged rugal folds in the fundus and body are evident. Histologically, gastric pits and glands are elongated and tortuous and the parietal and chief cells are replaced by mucous-secreting glands. Treatment with proton-pump inhibitors may decrease protein loss. However, in patients who do not respond, gastric resection may become necessary.

PEPTIC ULCER DISEASE

Peptic ulcers are defects in the GI mucosa that result when injury occurs due to the effects of acid and pepsin in the GI lumen. Although the term 'peptic ulcer' is commonly used to describe ulcers in the stomach (**Figure 1**) and duodenum (**Figure 2**), peptic ulcers can develop in any portion of the GI tract exposed to acid and pepsin such as the oesophagus, Meckel's diverticulum or site of gastrojejunostomy (**Figure 3**). In the early part of the 20th Century, stress and diet were thought to be important pathogenetic factors. During the 1980s, it was established that most peptic ulcers were related to either *H. pylori* infection or due to consumption of NSAIDs. This revolutionised the management of peptic ulcer disease.

Figure 1: Benign gastric ulcer at incisura.

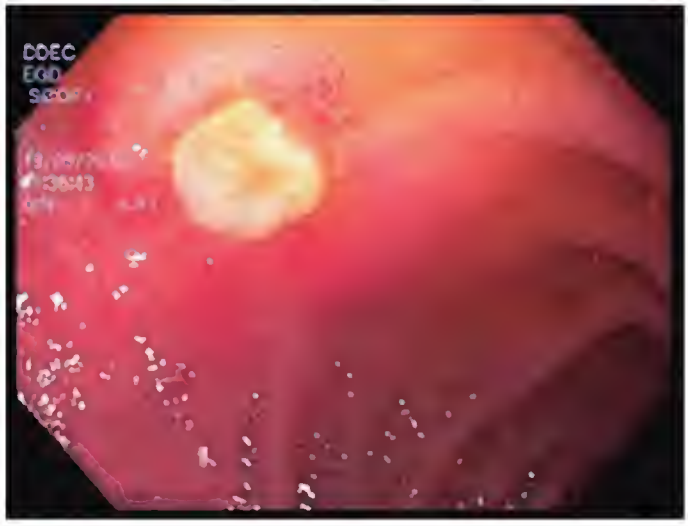

Figure 2: Duodenal ulcer in first part of duodenum.

Figure 3: Barium meal showing an anastomotic ulcer at the gastro-jejunostomy site.

Pathophysiology

Peptic ulcer occurs when the deleterious effects of acid and pepsin overwhelm the ability of the mucosa to resist these effects.

Defence Mechanisms

The mechanisms that normally enable the mucosa to resist acid-peptic attack can be divided into three components: pre-epithelial, epithelial and post-epithelial defence mechanisms.

Pre-epithelial defence mechanisms

A prominent coat of mucous and a layer of unstirred water rich in bicarbonate constitutes this component. Within the mucous layer glycoprotein form a physical barrier to the diffusion of pepsin. Mucous also contains phospholipids which protect the mucosa by forming a hydrophobic layer.

Epithelial defence mechanisms

The apical cell membranes and the tight junctional complexes between the surface cells limit the diffusion of hydrogen. Excess hydrogen ions can be removed actively by ion pumps in the basolateral membrane, such as Na^+/H^+ exchanger and Cl^-/HCO_3^- exchanger. Mucosal cell restitution regulated by growth factors (epidermal and fibroblast growth factors) also plays a part.

Post-epithelial defence mechanisms

Mucosal blood flow comprises the post-epithelial defence mechanism.

Abnormalities in Gastric Acid Secretion, Acid Homeostasis and Gastroduodenal Motility

In 1910, Schwarz proposed his famous dictum 'no acid, no ulcer'. This followed numerous studies on abnormalities in acid homeostasis in peptic ulcer. After the discovery of *H. pylori* it has been shown that many of these abnormalities may not be the primary defects but reversible consequences of infection with *H. pylori*.

Abnormalities associated with duodenal ulcer

Studies have shown these patients to be hypersecretors of gastric acid with an increase in the number of parietal cells. This may be related to *H. pylori* induced increases in cytokines such as tumour necrosis factor which stimulates gastrin release from G cells and *H. pylori* mediated decrease in somatostatin, a peptide which suppresses gastric release. Also an increased rate of liquid gastric emptying with increased acid burden in duodenum has also been described.

Abnormalities associated with gastric ulcer

Whereas the mucosa of the fundus and body is acid secreting (oxyntic) mucosa with abundant parietal cells, the gastric antrum is normally lined by a columnar epithelium that does not secrete gastric acid. The majority of gastric ulcers occur in the non-acid secreting epithelium at or near its junction with oxyntic mucosa. Long standing gastritis as occurs in *H. pylori* infection can cause atrophy of oxyntic mucosa with development of intestinal metaplasia and extension of the non-acid secreting epithelium into the proximal stomach. Patients who have gastric ulcers in the proximal stomach have chronic gastritis, substantial gastric atrophy and low gastric acid outputs.

Helicobacter pylori

H. pylori is associated with more than 80% of duodenal ulcers and more than 60% of gastric ulcers patients. Host factors as well as bacterial virulence factors (such as cagA positive *H. pylori*) may determine disease predisposition in those who are *H. pylori* positive.

Nonsteroidal Anti-Inflammatory Drugs

A large number of peptic ulcers not related to *H. pylori* are related to NSAIDs use. Typically NSAIDs-induced ulcers are asymptomatic, but may cause symptoms as well as complications such as, bleeding, perforation and obstruction. Asymptomatic ulcers can be endoscopically documented in 15% to 45% of patients receiving chronic NSAID therapy. However, 1% to 4% of patients receiving NSAIDs for 1 year will experience serious GI complications.

The major mechanism of NSAIDs-induced injury appears to be due to its topical effects leading to ulcers, erosions and sometimes acute haemorrhages. Most NSAIDs are weak organic acids that in acidic gastric juice become unionised, and thus, are freely lipid soluble. These diffuse across the gastric epithelium into the cytoplasm. Uncoupling of oxidative phosphorylation resulting in decreased mitochondrial energy production, reduction in cellular integrity and increase in cellular permeability. Attenuation of the gastric mucous gel layer also occurs. Enteric coated NSAIDs produce considerably less acute topical erosive injury than non-enteric coated formulations over short term (1 to 2 weeks) usage.

Injury also occurs through its systemic effects. Peptic ulcers will develop after intravenous or rectal suppository further supporting a systemic effect. Cyclo-oxygenase (COX) is the rate limiting enzyme for prostaglandin synthesis. Most NSAIDs (excepting the specific COX-2 inhibitors) reduce mucosal prostaglandin. A small dose of 10 mg of oral aspirin can decrease gastric prostaglandin levels by 60% and can cause gastric ulcers. Levels do not recover till 5 to 8 days. Animal experiments indicate that for gastric ulcers to occur both COX-1 and COX-2 must be inhibited. Hence, theoretically, COX-2 specific inhibitors are associated with improved GI toxicity profile.

Besides COX inhibition NSAIDs increase gastric acid secretion, decrease gastric mucosal blood flow, decrease mucous production and duodenal bicarbonate. Nitric oxide (NO) protects the GI mucosa from NSAIDs-induced injury. Nitric oxide donating NSAIDs or COX inhibiting nitric oxide donating drugs (CINODs) exhibit reduced GI toxicity in animal and human trials.

Other Ulcerogenic Drugs

Besides NSAIDs the other ulcerogenic drugs are 5-fluorouracil, potassium chloride, mycophenolate mofetil, and bisphosphonates (alendronate and risedronate).

Hypersecretory Conditions

These should be considered in any patient who has peptic ulcer not associated with *H. pylori* or NSAIDs. Other clues include severe complicated disease, ulcers in the post-bulbar duodenum and diarrhoea. Hypersecretory conditions include gastrinoma, systemic mastocytosis and myeloproliferative disorders with basophilia, and antral G cell hyperfunction.

Epidemiology

It has been observed that there is a declining prevalence of peptic ulcer disease, in part related to falling prevalence of *H. pylori*. In contrast ulcer related complications as well as hospitalisation is on the rise, particularly in elderly due to increased use of NSAIDs.

Cigarette smoking is a risk factor for peptic ulcer disease and its complications. It slows healing and predisposes to relapses. However, if *H. pylori* is eradicated, smoking does not influence relapses.

As far as alcohol is concerned, wine and beer are potent acid secretagogues but its importance in pathogenesis of peptic ulcer is dubious. There is no study which has clearly demonstrated a link between diet and peptic ulcer disease. Coffee (both caffeinated and decaffeinated), tea and colas are potent acid secretagogues. Amongst the diseases associated with peptic ulcer are alcoholic cirrhosis, chronic pulmonary disease and chronic renal failure. Despite popular belief, there is no role of emotional stress and peptic ulcers. Some studies have suggested that genetics may predispose to peptic ulcer disease.

Clinical Features of Uncomplicated Peptic Ulcer Disease

The main symptom of peptic ulcer disease is abdominal pain. Patients with duodenal ulcer describe burning or gnawing epigastric pain. Pain occurs 2 to 3 hours after a meal and is relieved after food or with antacids. Pain may occur in the night. Anorexia and weight loss are uncommon. Patients with gastric ulcers may have pain indistinguishable from duodenal ulcer. Peptic ulcers may be asymptomatic. Symptoms are neither specific nor sensitive for diagnosing peptic ulcers. If peptic ulcer is suspected, investigations must be carried out. Increase in severity of pain, radiation of pain to the back, pallor, vomiting or bleeding should point to the development of complications. It should be remembered that the symptoms of gastric cancer may be very similar to those of peptic ulcer. Presence of alarm signs like increased severity of pain, pallor, weight loss, vomiting, high ESR and presence of occult blood in stool should prompt investigations. In uncomplicated peptic ulcer the clinical examination will be unremarkable or the only sign will be tenderness in the epigastrium or slightly to the right of the midline in the upper abdomen.

Diagnostic Tests

Upper GI endoscopy has become the gold standard for diagnosis of peptic ulcer. Barium-meal is a far less sensitive investigation. Also endoscopy allows an opportunity for mucosal biopsy. Studies of acid secretion have little role in the diagnosis of peptic ulcer. However, these are useful in the work up of hypergastrinaemia, and to assess the completeness of vagotomy in recurrent ulcer. In patients with refractory peptic ulcer, serum calcium and fasting serum gastrin are indicated.

Treatment

The treatment of peptic ulcer has dramatically changed over the years. From bed rest and prescription of 'bland diets' came the era of antacids. The discovery of H_2 receptor antagonists and later of proton pump inhibitors (PPIs) achieved greater ulcer healing rates. The real revolution occurred, however, with discovery of the link between *H. pylori* and peptic ulcer.

Acid lowering drugs

These are not routinely required for patients with uncomplicated *H. pylori* ulcers in whom the bacterium has been successfully eradicated. However, anti-ulcer drugs are important for healing of large ulcers, management of complicated ulcer disease such as bleeding, reducing the risk of ulcer relapse in patients on NSAIDs and treating idiopathic ulcers.

Antacids: Besides increasing the gastric pH, antacids have a variety of cytoprotective effects. At present, they are used mainly for relieving symptoms. Side-effects include diarrhoea (magnesium containing) or constipation (aluminium containing). Antacids must be used cautiously in patients with renal insufficiency.

Histamine (H_2) receptor antagonits

These include cimetidine, ranitidine, famotidine, roxatidine and nizatidine. These agents competitively inhibit histamine stimulated acid secretion. All of them decrease basal as well as meal stimulated acid output. These agents are well absorbed after oral dosing and are not affected by food. All of them are eliminated by a combination of renal excretion and hepatic metabolism. H_2 receptor antagonists are remarkably safe and well tolerated. Overall incidence of side-effects is less than 4% and serious side effects are very uncommon. A variety of central nervous system symptoms have been rarely reported; these include headache, dizziness, depression. Drug interactions (inhibiting elimination of theophylline, phenytoin, lidocaine, quinidine and warfarin) have been reported due to binding of hepatic cytochrome P450 (CYP) system. Tolerance appears to develop quickly and frequently.

Proton pump inhibitors

These agents decrease gastric acid by inhibiting the H^+/K^+ ATPase pump of the parietal cell. Currently five PPIs are available; omeprazole, lansoprazole, pantoprazole, rabeprazole and esomeprazole. They are all substituted benzimidazoles and are weak bases. They are prodrugs and are acid labile. PPIs are most effective when administered immediately before meals. If the dose is once daily, it is preferable to administer immediately before breakfast. Single dose may inhibit gastric acid secretion for more than 24 hours. Newer PPIs inhibit H^+/K^+ ATPase more rapidly than omeprazole. PPIs are remarkably safe. Common side-effects are headache and diarrhoea. No dose adjustment is required in patients with renal or hepatic impairment. Elevation of gastric pH can interfere with absorption of drugs such as ketoconazole (decrease) and digoxin (increase). Drug interactions are uncommon. Potential interactions may occur since PPIs are metabolised by CYP system. One such example is reduction in the effect of clopidogrel. Although PPIs cause hypergastrinaemia, there is no human report of development of gastric carcinoid tumours. Tolerance to the anti-secretory effects of PPIs is not seen. There is no need for routine *H. pylori* eradication prior to initiating treatment with PPIs.

Mucosa protective agents

Sucralfate: This is a complex metal salt of sulphated sucrose and aluminium hydroxide. When exposed to gastric acid, the aluminium hydroxide dissociates, leaving sulphate anions that can bind electrostatically to positively charged proteins in damaged tissue. It forms a protective layer over the ulcer craters. Other beneficial effects include increase in mucosal prostaglandins, stimulation of mucous and bicarbonate secretions, binding of bile salts and promotion of angiogenesis. It is effective in promoting healing when given in a dose of 1 g four times a day. Since it is not absorbed, there is no systemic toxicity.

Bismuth: The two commonly used preparations are colloidal bismuth subcitrate and bismuth subsalicylate. The bismuth component forms complexes with mucous and coats the ulcer

craters. Also bismuth has anti-microbial action against *H. pylori*. Bismuth is unabsorbed if given over a short duration and systemic toxicity is rare.

Prostaglandin E analogues: Prostaglandin E2 regulates mucosal blood flow, epithelial cell proliferation, epithelial restitution, mucosal immunocyte function, mucous and bicarbonate secretion, and basal acid secretion. Misoprostol, a prostaglandin analogue is used for prevention of NSAIDs-induced ulcer disease. It is well absorbed after oral administration. Dose related diarrhoea is observed in nearly one-third of the patients. It is contraindicated in pregnant women.

Ulcers associated with H. pylori

Peptic ulcer management was revolutionised after discovery of *H. pylori*. It is well established that *H. pylori* eradication not only heals ulcers but also prevents relapses. *H. pylori* is associated with 70% to 90% of duodenal ulcers and 40% to 70% of gastric ulcers. For uncomplicated duodenal ulcers, additional anti-secretory treatment is not required. For large gastric ulcers additional anti-secretory treatment may promote ulcer healing. For large gastric ulcers, biopsy must be taken to exclude malignancy. After successful eradication, maintenance therapy with anti-secretory agents is not required.

Ulcers associated with NSAIDs

In this situation NSAIDs should be discontinued, if possible. PPIs are more effective than H_2 receptor antagonists or misoprostol for healing of NSAIDs-induced ulcers. There is little role of substituting a selective COX 2 inhibitor in place of conventional NSAIDs once an ulcer develops. *H. pylori* needs to be eradicated if present in these patients.

Prophylaxis of NSAIDs ulcers

H_2 receptor antagonists reduce the risk of duodenal ulcers but not gastric ulcers. Misoprostol reduces the risk of NSAIDs-induced gastric and duodenal ulcers. Higher dose (800 µg/day) of misoprostol reduced ulcer complications. PPIs are very effective in reducing the risk of NSAID-induced gastric and duodenal ulcers. COX 2 inhibitors induced fewer ulcers than conventional NSAIDs. New data suggest that a combination of non-selective NSAIDs with PPI is as effective or better than using selective COX 2 inhibitors in prevention of NSAIDs-ulcers. Also studies have shown increased serious cardiovascular events with the use of COX 2 inhibitors. If *H. pylori* is present, it needs to be eradicated. This is also recommended for patients on long-term, low-dose aspirin. In patients with risk factors for ulcer complications (**Table 1**), co-therapy with a PPI is recommended.

Table 1: Risk Factors for NSAIDs-Induced Ulcer Complications

History of peptic ulcer complication
Increasing age
Use of steroids
Use of anti-coagulants
Use of combination NSAIDs
Co-morbid diseases
Smoking

Refractory Peptic Ulcers

Most peptic ulcers heal with 8 to 12 weeks of anti-secretory therapy. If this does not occur, consider the following: lack of compliance, failed *H. pylori* eradication, ongoing NSAIDs, smoking, hyper-secretory condition and other aetiologies (neoplastic, infective).

Complications

The complications of peptic ulcer are penetration, perforation, haemorrhage and obstruction.

Penetration refers to the extension of the ulcer through the bowel wall into the adjacent structures without producing free perforation into the peritoneal cavity. The ulcer can penetrate into the pancreas, biliary tract, omentum or colon. Perforation into the colon leads to gastro-colic fistula. Symptoms of penetration vary depending on the organ involved. It manifests as increase in severity and duration of pain and failure of pain relief with antacids or food.

Bleeding from peptic ulcer is a life-threatening complication. The patient may present with melaena, haematemesis or both. When the bleeding is massive haematochezia will be present. Old age, shock at the time of admission and massive bleeding necessitating transfusion of more than five units of blood indicate poor prognosis, and surgery should be considered in these situations. The first step in the management is resuscitation of the patient by replacing the blood volume and managing haemodynamic instability. Upper GI endoscopy should be done as soon as the patient is stable. This will show the site of bleed. Active bleeding or the presence of high-risk lesions—visible vessel or adherent clot (**Figure 4**)—call for endoscopic management. Injection of saline or dilute adrenaline (**Figure 5**), application of heater probe, endoscopic application of clips (**Figure 6**) can all arrest the bleeding. Anti-secretory treatment (intravenous, continuous infusion of PPI) should be started.

Figure 4: Duodenal ulcer with stigmata of recent bleed (black base).

Perforation of peptic ulcer is an emergency. The patient presents with sudden onset of abdominal pain; peritonitis and free gas in the peritoneum are present. Patients who present late and those who develop perforation while in the hospital have a poor prognosis. Surgical treatment, which involves closure of the perforation with an omental patch is the procedure often employed. Effective treatment of *H. pylori* infection and strong acid suppressants are available now, and

Figure 5: Injection sclerotherapy being done for bleeding duodenal ulcer with stigmata of recent bleed (visible vessel).

Figure 6: Haemoclips applied to base of bleeding ulcer.

hence, a definitive surgical treatment may not be necessary in selected patients; small leaks into peritoneum can be managed conservatively.

Obstruction in peptic ulcer may be due to fibrosis, inflammation or spasm. It is the pyloric channel ulcers or ulcers in the first part of duodenum that develop gastric outlet obstruction. Gastric outlet obstruction (pyloric stenosis) (**Figure 7**) presents with post-prandial bloating, fullness and vomiting. Vomiting brings out food consumed several (>6) hours ago. Foul smelling eructations may be present. Examination reveals a visibly dilated stomach, visible peristalsis or succussion splash. Barium meal shows a dilated stomach with delayed emptying. Endoscopy should be performed after thorough cleaning of the stomach. Carcinoma of the stomach should be excluded in every patient with gastric outlet obstruction as malignancy is seen in about half of such cases. Management includes gastric lavage to remove food debris, correction of fluid and electrolyte disturbances and metabolic consequences of prolonged vomiting and loss of gastric acid. Anti-secretory drugs should be administered parenterally since absorption is poor. *H. pylori* infection and NSAID intake should be looked for and managed. If the symptoms fail to respond, surgery is indicated. Endoscopic balloon dilatation of the narrowed segment has also been used successfully (**Figure 7**).

Figure 7: Endoscopic balloon dilatation for pyloroduodenal stenosis.

Ulcers in the lower end of the oesophagus may in the long run lead to peptic strictures and dysphagia. Endoscopic balloon dilatation gives symptomatic relief to these patients. Fibrosis during healing of gastric ulcers may result in rare deformities of the stomach like 'tea-pot stomach' or the 'hour-glass stomach'.

Recurrent ulcer is the term used for recurrence of ulcers after surgical treatment of duodenal ulcer. Incomplete vagotomy and retained antrum are the most common causes.

Duodenal ulcer does not turn malignant. *H. pylori* is implicated as an aetiological agent in carcinoma stomach. In spite of the high prevalence of *H. pylori* in persons with peptic ulcer, duodenal ulcer is not a risk factor for the cancer of the stomach or of the duodenum. However, persons who had undergone surgery (partial gastrectomy) for duodenal ulcer are at increased risk of developing cancer in the post-operative stomach.

GASTRIC VOLVULUS

Twisting of the stomach upon itself leads to gastric volvulus which can present clinically either acutely or as chronic volvulus. Three types have been described—organoaxial volvulus is the most common; in this type the stomach twists along its long axis (cardiopyloric line); mesenteroaxial volvulus is one in which the stomach falls on itself along an imaginary line drawn from the mid-point of the lesser curvature to the mid-point of the greater curvature and is the least common of the three; mixed gastric volvulus is a combination of organoaxial and mesenteroaxial types. Anatomical anomalies such as ligamentous laxity, paraoesophageal hiatus hernia, eventration of the diaphragm, extrinsic compression from adjacent organs or submucosal tumours of the stomach can cause gastric volvulus.

Patients with acute gastric volvulus present as an acute abdomen with the classical triad of violent retching and little vomiting, severe epigastric pain and inability to advance a nasogastric tube into the stomach. In patients with chronic volvulus the major symptoms are epigastric pain, bloating and eructations.

Barium-meal examination usually demonstrates the twisted stomach. Acute volvulus is an emergency and usually requires an emergent laparotomy although endoscopic derotation of the

volvulus is sometimes successful. Recurrent symptoms in patients with chronic volvulus need surgical treatment wherein the stomach is fixed to the anterior abdominal wall by performing a gastropexy. Recently, percutaneous endoscopic gastrostomy has been found to be an alternative to surgical gastropexy.

BEZOARS

These have been classified into two main groups: hair or trichobezoar and plant or phytobezoars. Other materials such as chemical concretions, food boluses and foreign bodies may also cause bezoars. For phytobezoars, hypochlorhydria, gastroparesis and incomplete mastication are important predisposing factors. In patients with trichobezoar, underlying neuropsychiatric disturbances may be present. Bezoars present with pain in the upper abdomen, periodic attacks of nausea and vomiting and a lump in the abdomen. Complications such as gastric ulcer, perforation and peritonitis may occur. Plain X-ray abdomen in the standing position occasionally demonstrates a mass invading the gastric air bubble. Barium-meal examination demonstrates a barium shell coating an irregular large filling defect. In most cases upper GI endoscopy is diagnostic. For treating phytobezoars, endoscopic internal fragmentation using forceps and polypectomy snares may be tried. Chemical dissolution using papain, cellulase and acetylcysteine is sometimes successful. If these methods fail, surgical removal needs to be done. In most cases of trichobezoars, surgery is required.

DUODENAL DIVERTICULUM

It is usually single and present along the medial wall of the duodenum. It is acquired as an outpouching of the duodenal mucosa at the point of maximum weakness. Most often this diverticulum is asymptomatic and incidentally detected during a barium-meal examination or Upper GI endoscopy (**Figure 8**). Rarely, duodenal diverticulum may perforate retroperitoneally, cause upper GI bleeding or obstruct the bile duct or pancreatic duct. The treatment of a complicated duodenal diverticulum is surgical.

Figure 8: Barium-meal examination showing duodenal diverticulum along medial wall.

13.9 Diseases of the Pancreas

V Balakrishnan, G Rajesh

ACUTE PANCREATITIS

Acute pancreatitis (AP) is an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems.

Mild acute pancreatitis consists of minimal or no organ dysfunction and an uneventful recovery. Severe pancreatitis manifests as organ failure and/or local complications such as necrosis, abscess, or pseudocyst (**Table 1**). Overall, about 20% of patients with acute pancreatitis have a severe course, and 10% to 30% of those with severe acute pancreatitis die.

Table 1: Criteria of Severe Acute Pancreatitis

Organ failure
Shock: Systolic blood pressure of <90 mm Hg
PaO_2 <60 mmHg
S. Creatinine >2 mg/dL
Gastrointestinal bleed of >500 mL in 24 hours
And/Or local complications
Necrosis
Abscess
Pseudocyst
Unfavourable prognostic signs
>3 Ranson's signs
>8 APACHE II points

Aetiopathogenesis

The gallstone disease and alcohol are the two most common causes for AP (**Table 2**). The initial step in the pathogenesis of acute pancreatitis is conversion of trypsinogen to trypsin within acinar cells. Trypsin, in turn, catalyses conversion of pro-enzymes, including trypsinogen and inactive precursors of elastase, phospholipase A_2, and carboxypeptidase, to active enzymes. Active enzymes autodigest the pancreas and initiate a cycle of releasing more active enzymes. Factors that may initiate gallstone pancreatitis include reflux of bile into the pancreatic duct or obstruction of the pancreatic duct at the ampulla by a stone(s) or oedema resulting from the passage of a stone. The pathophysiology of acute pancreatitis includes microcirculatory injury, leucocyte chemoattraction and release of cytokines, oxidative stress, and bacterial translocation.

Clinical Features

Abdominal pain is present at the onset, but the timing of abdominal pain is variable. Biliary colic may herald or progress to acute pancreatitis. Alcohol-related acute pancreatitis frequently occurs 1 to 3 days following drinking. The pain radiates to back and is associated with nausea and vomiting. Its onset is rapid and reaches maximal intensity in 10 to 20 minutes. Occasionally, pain takes several hours to reach maximum intensity. It is steady and moderate to very severe in intensity.

Physical findings depend on the severity of an attack. Patients with mild pancreatitis may not appear acutely ill and have mild abdominal tenderness. In severe pancreatitis, patients look severely ill and often have abdominal distention, especially epigastric, which is due to gastric ileus or dilatation of the transverse colon. Bowel sounds are reduced and may be absent.

Table 2: Aetiology of Acute Pancreatitis

Gallstones
Biliary sludge and microlithiasis
Alcohol
Mechanical obstruction of ampulla
Metabolic: Hypertriglyceridaemia and hypercalcaemia
Infections: Mumps, HIV, CMV, EBV, Clonorchiasis, and Ascariasis
Toxins: Scorpion venom, organophosphorous insecticides
Trauma
Post ERCP
Pregnancy
Post-operative
Hereditary
Ischaemia
Drugs: Pentamidine, didanosine, salicylates, sulindac, frusemide, thiazides
Sulphasalazine, mesalamine, L-asparaginase, azathioprine, valproic acid, ACE-inhibitors

Diagnosis

Acute pancreatitis can be diagnosed by the presence of typical clinical features along with corroborative laboratory findings of elevated serum enzymes (amylase/lipase) and/or imaging features. It needs to be differentiated from other abdominal causes which may present as an acute abdomen.

Investigations

Blood investigations

The white blood cell count is usually elevated, markedly so in severe pancreatitis. A raised haematocrit, indicative of haemo-concentration, may indicate severe disease.

Serum amylase is the most frequently ordered test. However, hyperamylasemia can also occur in other conditions. In acute pancreatitis, the serum amylase concentration is usually more than three times the upper limit of normal. Measurement of serum lipase is performed less frequently. Amylase levels tend to return to normal faster than lipase levels, so that measurement of the latter is particularly useful in patients who present several days after the onset of pain. An increase in serum alanine aminotransferase (ALT) 3 to 4 times the base-line level suggests gallstone-induced pancreatitis.

Imaging

There can be localised ileus of a segment of small intestine ('sentinel loop') or the colon cut-off sign on a plain radiograph of the abdomen. Thirty per cent of patients with acute pancreatitis have abnormalities in chest radiograph in the form of elevation of a hemi-diaphragm, pleural effusion(s), basal or

plate-like atelectasis secondary to limited respiratory excursion, and pulmonary infiltrates.

Transabdominal ultrasonography is the best initial imaging modality. It is used during the first 24 hours of hospitalisation to search for gallstones, dilatation of the common bile duct due to choledocholithiasis and ascites. Pancreas is usually diffusely enlarged and hypoechoic.

A contrast enhanced computed tomography (CECT) scan of the abdomen is the most important imaging test for the diagnosis of acute pancreatitis and its intra-abdominal complications and is also used to assess the severity of the disease.

Magnetic resonance imaging (MRI) shows the pancreas as well CT scan. In addition, it has certain advantages over the latter. It does not carry the potential nephrotoxicity of the contrast required to perform CECT, better than it avoids the radiation exposure of CT scan and finally, it shows a greater ability than CT scan to distinguish necrosis from fluid.

Endoscopic ultrasound (EUS) helps in timely diagnosis of common bile duct (CBD) or ampullary stones in the setting of acute gallstone pancreatitis; hence it can be used instead of diagnostic endoscopic retrograde cholangio-pancreatography (ERCP) to identify patients who would likely benefit from therapeutic ERCP.

Treatment

The algorithm for treatment of acute pancreatitis is outlined in **Figure 1**.

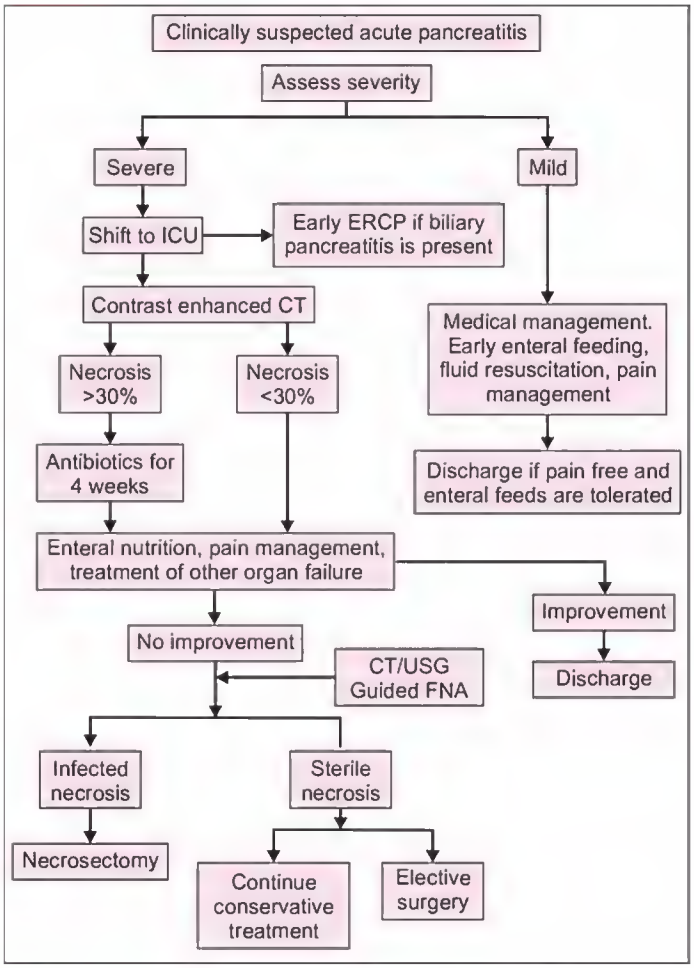

Figure 1: Algorithm for management of pancreatitis.

Mild acute pancreatitis

The prognosis of mild pancreatitis is good and can be managed in a regular hospital ward with fluid administration, bowel rest and analgesics. Fluid resuscitation is important to replace low intravascular volume due to vomiting, diaphoresis, and third-space losses. Abdominal pain is treated with parenteral analgesics. Most patients require no further therapy and recover within a week.

Severe acute pancreatitis

Patients with signs of severe acute pancreatitis should be identified early and admitted promptly to an intensive care unit. The goal is to provide supportive care and treatment of complications when they develop. Maintaining adequate intravascular volume may require 5 to 10 litres of fluid daily for the initial few days. Hypoxaemia (oxygen saturation <90%) requires oxygen, ideally by nasal prongs or by facemask. If nasal oxygen fails to correct hypoxaemia or if there is fatigue and borderline respiratory reserve, endotracheal intubation and assisted ventilation are required early. Nutritional support via nasojejunal feedings should be initiated. Hyperglycaemia may present during the first several days of severe pancreatitis but usually normalises as the inflammatory process subsides. Blood sugar levels can be variable, and insulin should be administered cautiously.

Sterile pancreatic necrosis is managed conservatively. Bacterial infection of pancreatic and peripancreatic tissues develops usually after one week in approximately 30% of severe acute pancreatitis. Three approaches to decrease bacterial infections in acute necrotising pancreatitis are used; they are selective decontamination of the gut with non-absorbable antibiotics, prophylactic systemic antibiotics, and enteral feeding to avoid catheter-related infections associated with a central line, to maintain gut barrier integrity, and to decrease bacterial translocation.

Infected pancreatic necrosis should be suspected in patients with worsening of symptoms after initial improvement; and in those who develop new fever, marked leucocytosis, positive blood cultures, or other evidence of sepsis. The important organisms causing infection in necrotising pancreatitis are from the gut (*Escherichia coli*, *Pseudomonas*, *Klebsiella*, and *Enterococcus* species). Standard regimens include imipenem 500 mg intravenously three times a day; pefloxacin (fluoroquinolone) 400 mg intravenously two times a day; or metronidazole 500 mg three times a day for 10 to 14 days. Infected pancreatic necrosis usually requires minimally invasive debridement via endoscopic or surgical approaches.

Urgent therapeutic ERCP should be performed in patients with suspected or proven biliary pancreatitis, who satisfy the criteria for predicted or actual severe pancreatitis; or when there is cholangitis, jaundice, or a dilated common bile duct.

Adequate supply of nutrients plays an important role early in management. Enteral feeding is safe and as effective. However, total parenteral nutrition may be necessary for patients who cannot obtain sufficient calories through enteral nutrition or in whom enteral access cannot be maintained; but carries an increased risk of infection.

Prognostic indicators

These include use of single markers like C-reactive protein (CRP), trypsin activation peptide (TAP), procalcitonin, etc. as well as

scoring systems like Ranson's score, Glasgow score, acute physiology and chronic health evaluation (APACHE) II, among others (**Tables 3 and 4**). A new prognostic scoring system, the bedside index for severity in acute pancreatitis—BISAP (blood urea nitrogen >25 mg/dL, impaired mental status, systemic inflammatory response syndrome (SIRS), age >60 years, and pleural effusions) was comparable to existing scoring systems.

Table 3: Complications of Acute Pancreatitis

Local
- Pseudocyst
- Necrosis
- Abscess
- Gastrointestinal bleed due to ulcerations, gastric varices and pseudoaneurysm rupture

Systemic
- Shock
- Coagulopathy
- Respiratory failure
- Renal failure
- Metabolic: Hyperglycaemia, hypocalcaemia
- Subcutaneous nodules
- Retinopathy
- Psychosis

Table 4: Ranson's Criteria for Assessing Severity of Acute Pancreatitis

	Non-gallstone pancreatitis	Gallstone pancreatitis
On Admission		
Age (years)	>55	>70
WBC (/cmm)	16000	18000
Glucose (mg/dL)	>200	>220
LDH (IU/L)	>350	>400
AST (IU/L)	>250	>250
Within 48 hours of admission		
Haematocrit fall	>10	>10
BUN rise (mg/dL)	>5	>2
Calcium (mg/dL)	<8	<8
PO_2 mmHg	<60	—
Base deficit (mEq/L)	>4	>5
Fluid deficit	>6L	>4L

CHRONIC PANCREATITIS

Chronic pancreatitis (CP) is characterised by pancreatic inflammation and fibrosis, the end point of which is destruction of pancreatic parenchyma with eventual loss of exocrine and endocrine function.

Aetiology

The aetiologic risk factors associated with chronic pancreatitis is given in **Table 5**.

Alcohol

The most common cause of chronic pancreatitis in the Western world and in Japan is excessive alcohol consumption. In most patients, at least five years of alcohol intake exceeding 80 g/day is required prior to the development of chronic pancreatitis.

Tropical pancreatitis

Tropical pancreatitis (TCP) remains an important form of chronic pancreatitis in certain areas of India. The exact aetiopathogenesis of TCP remains unknown. Nutritional deficiencies, especially of micronutrients and antioxidants or/and dietary toxins such as cyanogenic glycosides (cassava or tapioca), have been considered as likely aetiological factors.

Hereditary pancreatitis

Hereditary pancreatitis is a rare autosomal dominant disorder with approximately 80% penetrance. It presents typically in childhood or early adulthood with abdominal pain and recurrent acute attacks of pancreatitis.

Table 5: Aetiologic Risk Factors Associated with Chronic Pancreatitis: TIGAR-O Classification System

Toxic-metabolic

Alcohol, tobacco smoking, hypercalcaemia (hyperparathyroidism), chronic renal failure, medications (phenacetin), toxins (organotin compounds, e.g. DBTC)

Idiopathic

Early onset, late onset

Tropical (tropical calcific pancreatitis, fibrocalculous pancreatic diabetes)

Genetic

Autosomal dominant (Cationic trypsinogen codon 29 and 122 mutations)

Autosomal recessive/modifier genes (CFTR mutations, SPINK1 mutations

Cationic trypsinogen codon 16, 22, 23 mutations, α1-antitrypsin deficiency)

Autoimmune

Isolated autoimmune chronic pancreatitis

Syndromic autoimmune chronic pancreatitis (Sjögren syndrome-associated chronic pancreatitis, inflammatory bowel disease-associated chronic pancreatitis

Primary biliary cirrhosis—associated chronic pancreatitis)

Recurrent and severe acute pancreatitis

Post-necrotic (severe acute pancreatitis), recurrent acute pancreatitis, vascular diseases/ischaemic, post-irradiation

Obstructive

Pancreatic divisum, sphincter of Oddi disorders, duct obstruction (e.g. tumour)

Pre-ampullary duodenal wall cysts, post-traumatic pancreatic duct scars

Obstructive chronic pancreatitis

Obstruction of the main pancreatic duct by tumours, scars, cysts, or stenosis of the papilla of Vater or minor papilla can produce chronic pancreatitis in the parenchyma upstream of the obstruction. Blunt and penetrating trauma to the pancreas can also lead to pancreatic duct strictures.

Autoimmune pancreatitis

This is characterised by presence of autoantibodies, elevated levels of immunoglobulins especially IgG4, enlargement of the pancreas (diffuse or focal), pancreatic duct strictures, and pathologic features of a dense lymphocytic infiltrate. A common presentation is that of a pancreatic mass mimicking cancer. It is often steroid responsive. Low dose steroids or immunomodulators may be needed to maintain remission.

Idiopathic chronic pancreatitis

Idiopathic chronic pancreatitis accounts for 10% to 30% of all cases of CP in the West and 40% to 60% in India, and appears to occur in two forms, early onset and late onset type.

Pathophysiology

The pathophysiology of CP remains incompletely understood. Four major theories include toxic-metabolic, oxidative stress, stone and duct obstruction, and necrosis-fibrosis.

Pathology

In early CP, areas of interlobular fibrosis are seen, with the fibrosis often extending to the ductal structures. Infiltration of the fibrotic area and lobules with lymphocytes, plasma cells, and macrophages is seen. In affected lobules, acinar cells are replaced by fibrosis. As the disease progresses, fibrosis within the lobules and between lobules becomes more widespread. The pancreatic ducts become more abnormal, with progressive fibrosis, stricture formation, and dilation. Protein plugs may calcify and obstruct major pancreatic ducts.

Clinical Features

The cardinal symptom of CP is abdominal pain. Fat malabsorption leading to steatorrhoea and weight loss is common in CP. Steatorrhoea does not occur until pancreatic lipase secretion is reduced to less than 10% of normal. Diabetes in CP is considered as a secondary form of diabetes mellitus. Weight loss is most commonly due to decreased intake in episodes of acute exacerbation. Weight loss may also occur owing to the development of small bowel bacterial overgrowth, malabsorption, uncontrolled diabetes or pancreatic or extrapancreatic malignancy.

Physical examination might show evidence of nutritional deficiencies. Complications of common bile duct obstruction or a pseudocyst may produce physical findings of jaundice, or a palpable swelling in the epigastrium. Ascites may rarely follow a leak from a ruptured pancreatic duct. A palpable spleen may be seen following thrombosis of the splenic vein (**Table 6**).

Diagnosis

Serum amylase or lipase may be found to be elevated only during acute exacerbations. A full diabetic work-up should be done for all patients with suspected pancreatitis. A prediabetic stage has been well described.

Imaging

The demonstration of pancreatic calcification on imaging is pathognomonic of CP. Diagnosis is difficult in early cases of pancreatitis where the patient may have typical symptoms but lack diagnostic imaging features on ultrasonography (USG)/CT. In such cases, an endoscopic retrograde pancreatography (ERP) or a EUS may be helpful.

Pancreatic calcifications are most common in alcoholic, late-onset idiopathic, hereditary and especially in tropical pancreatitis and may be detected on abdominal radiograph.

Ultrasonography findings indicative of CP include dilation of the pancreatic duct, pancreatic ductal stones, gland atrophy or enlargement, irregular gland margins, pseudocysts and changes in the parenchymal echotexture.

CECT scan of the abdomen is superior to USG. The sensitivity of CT for CP is 75% to 90% and specificity 85% or more.

ERCP is considered the most specific and sensitive test of pancreatic structure. The sensitivity of ERCP is between 70% and 90%, with a specificity of 80% to 100%.

Magnetic resonance cholangiopancreatography (MRCP) agrees with ERCP in 70% to 80% of findings. MRCP is non-invasive, avoids ionising radiation and contrast administration, and does not routinely require sedation, making it a diagnostic procedure of choice in some groups of patients, particularly children.

EUS is the best among currently available tests for the detection of early changes of CP. Typical findings in CP include parenchyma features like hyperechoic strands, hyperechoic foci, lobularity, cysts; and ductal features like stones, main duct irregularity, hyperechoic main duct, visible side branches, main duct dilatation.

Table 6: Complications of Chronic Pancreatitis

No.	Complication	Signs and Symptoms	Treatment
1.	Pseudocyst	Increased abdominal pain, nausea, vomiting, jaundice, palpable mass, bleeding, increase in amylase and lipase	Endoscopic drainage (transmural or transpapillary) Surgical drainage (cyst-gastrostomy or cyst-jejunostomy) Percutaneous drainage
2.	Biliary obstruction	Jaundice, biliary pain, cholangitis, pruritus	Drainage of obstructing pseudocyst Endoscopic decompression Surgical decompression Surgical biliary bypass, either with a cholecystojejunostomy or choledochojejunostomy
3.	Gastric outlet obstruction	Abdominal pain, early satiety, nausea and vomiting	Drainage of pseudocyst Surgical gastrojejunostomy
4.	Pancreatic adenocarcinoma	Increased pain, weight loss, jaundice, elevated Ca 19-9	Whipple's or modified Whipple's surgery Palliation if advanced disease
5.	External pancreatic fistula	Consequence of surgical or percutaneous therapy for chronic pancreatitis or pseudocyst	NPO, parenteral nutrition, octreotide and endoscopic stent placement Surgical treatment includes pancreatic resection (if the fistula is in the tail) or a fistulojejunostomy, in which the fistula tract is 'capped' with a defunctionalised limb of jejunum
6.	Pancreatic ascites	Increased abdominal girth, high ascitic fluid amylase typically greater than 4000 units/L	Endoscopic stent placement, total parenteral nutrition
7.	Pleural effusion	Shortness of breath, high amylase in pleural fluid typically greater than 4000 units/L	Therapeutic thoracentesis, endoscopic stent placement, total parenteral nutrition
8.	Splenic vein thrombosis	Bleeding from gastric varices	Splenectomy

Treatment

Continued alcohol abuse hastens the development of pancreatic dysfunction and continued alcohol abuse, along with smoking, increases mortality. Moreover, smoking is one of the risk factors for the progression to pancreatic cancer. There are good reasons, therefore, to encourage patients to stop drinking and smoking.

Relief of pain

Analgesics like acetaminophen for mild pain or non-narcotic agents for moderate to severe pain are usually used. If non-narcotic agents fail, it is useful to begin with the less potent opioid agents like propoxyphene napsylate or tramadol before starting morphine. Pancreatic enzyme preparations, particularly those with high protease content and antioxidants may also help to relieve pain. Failure of medical management necessitates use of interventions like coeliac plexus block, extra-corporeal shock wave lithotripsy (ESWL), endoscopic therapy or surgery.

Correction of maldigestion

Pancreatic enzymes (~ 30,000 units of lipase) have to be given along with each meal. The enzyme activity tends to be degraded by the gastric acid, especially in case of non-enteric coated preparations; hence it is better to also administer proton pump inhibitors or H_2 receptor antagonists.

Management of diabetes

A few newly detected diabetics in CP can be controlled with diet and regular exercise. The majority can be managed with oral hypoglycaemic agents for varying periods. A large group will require insulin for glycaemic control.

Endotherapy

The general goal of endoscopic therapy is to improve drainage of the pancreatic duct by relieving obstruction. Patients with a solitary stone or a few small stones in the head region with a dilated proximal duct are the ideal candidates. Sphincterotomy, with pancreatic duct stenting, sometimes undertaken after ESWL to crush the stones, is the usual procedure.

Surgery

Surgery is indicated for intractable abdominal pain that has failed medical therapy. Other indications for surgery include complications involving adjacent organs (duodenal, splenic vein, or biliary obstruction), pseudocysts failing endoscopic or radiologic management, internal pancreatic fistulas, and suspected or proven malignancy. Surgical options for pain can include pancreatic ductal drainage, resection of all or part of the pancreas, or both. If there is suspicion of a malignancy in the head, a pancreaticoduodenectomy should be undertaken.

PANCREATIC CANCER

Pancreatic cancer remains a leading cause of death with 5-year survival rates of less than 5%. Despite advances in diagnosis and staging, most cancers are diagnosed in an advanced stage and are suitable only for palliative treatment.

Pathophysiology

Approximately 75% of all pancreatic carcinomas occur within the head or neck of the pancreas, 15% to 20% occur in the body of the pancreas, and 5% to 10% occur in the tail. It is a very aggressive neoplasm. At the time of diagnosis, 80% will already have metastasised.

Clinical Features

The presenting symptoms of pancreatic carcinoma are generally non-specific. Cancer that originates from the head of the pancreas can produce obstructive jaundice, epigastric pain and weight loss. The presence of pain is a late symptom and back pain typically signifies advanced disease. Jaundice is usually progressive and associated with pruritus, which can often be severe. Dyspepsia and early satiety may be present due to delayed gastric emptying (gastroparesis). Vomiting may be present if the tumour has invaded or compressed the second portion of the duodenum, creating a partial or complete intestinal obstruction.

The patient is usually jaundiced and may be anaemic or cachectic. There may be an epigastric mass or an irregular, enlarged liver because of metastases. There may be a palpable gallbladder secondary to common bile duct obstruction. Other findings include left supraclavicular lymphadenopathy (Virchow's node) and superficial thrombophlebitis (Trousseau's sign).

Investigations

The lesion may have a variable appearance on ultrasonography; it may be hypoechoic, isoechoic, or hyperechoic as compared to normal pancreas. Pancreatic ductal dilatation and biliary ductal dilatation are easily demonstrated in patients with a tumour in the head of pancreas. Lymphadenopathy, relation of the tumour to peripancreatic vessels, and the tumour margins are demonstrated less reliably with sonography.

CECT scan of abdomen using a pancreas protocol is the most useful and widely used imaging modality especially when some intervention is planned. Features on CT scan include: alterations in morphology of the gland with abnormalities of CT attenuation values, obliteration of peripancreatic fat, loss of sharp margins with surrounding structures, involvement of adjacent vessels and regional lymph nodes, pancreatic ductal dilatation, pancreatic atrophy, and obstruction of the common bile duct. Tumours less than 1 cm are readily visualised with EUS.

ERCP has a sensitivity of 95% and a specificity of 85% for pancreatic malignancy. MRCP is a non-invasive alternative to ERCP.

Serum carbohydrate antigen (CA) 19-9 has an overall sensitivity of approximately 80% and specificity of 90%.

Treatment

Surgery is the mainstay of treatment, but it is of value only if the primary tumour is less than 3 cm, free of major blood vessels and if there is no metastatic spread (**Tables 7 and 8**). Suitable patients undergo Whipple's procedure, which involves excision of the head of the pancreas, the distal common bile duct, the gall bladder, the duodenum and distal stomach, followed by anastomosis of the pancreatic duct, the common hepatic duct, and the distal stomach to a loop of jejunum. Perioperative mortality is less than 5% in experienced hands. Modified Whipple's procedure involves preservation of the distal stomach and pylorus, which may have long-term nutritional benefits. Distal pancreatectomy may be suitable for carcinoma of the body or tail.

Table 7: American Joint Committee for Cancer (AJCC) Staging of Carcinoma of the Pancreas (2002)

T stage
TX – Primary tumour cannot be assessed
T0 – No evidence of tumour
Tis – Carcinoma *in situ*
T1 – Tumour limited to the pancreas, 2 cm or less in greatest dimension
T2 – Tumour limited to the pancreas, more than 2 cm in greatest dimension
T3 – Tumour extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
T4 – Tumour involves the coeliac axis or the superior mesenteric artery (unresectable primary tumour)

N Stage
NX – Regional lymph nodes not assessed
N0 – No regional lymph node metastasis
N1 – Regional lymph nodes involved

M stage
MX – Distant metastases cannot be assessed
M0 – No distant metastases
M1 – Distant metastases present

Table 8: TNM Staging of Pancreatic Cancer

Stage	Classification	Clinical classification	5-year survival rate
0	Tis, N0, M0	Resectable (7.5%)	15.2%
1A	T1, N0, M0		
1B	T2, N0, M0		
IIA	T3, N0, M0		
IIB	T1-3, N1, M0	Locally advanced (29.3%)	6.3%
III	T4, any N, M0		
IV	Any T, any N, M1	Metastatic (47.2%)	1.6%

Palliative Treatment

Jaundice is palliated by stenting the biliary stricture. Both plastic and self-expandable metal stents (SEMS) have been used for palliation of jaundice. When endoscopic biliary drainage is unsuccessful or contraindicated, percutaneous transhepatic biliary drainage is done.

Pain requires graded use of analgesic agents. Coeliac plexus block (percutaneous or EUS guided) and splanchnectomy are useful interventions for palliation of pain.

Gemcitabine is the standard chemotherapeutic agent used for pancreatic cancer. Other drugs are capecitabine, 5-fluorouracil, cisplatin and oxaliplatin.

13.10 Functional Gastrointestinal Disorders

Philip Abraham

The term 'functional gastrointestinal disorders' is used for a group of conditions with clinical manifestations in the absence of obvious organic disease in gastrointestinal (GI) tract. These disorders constitute the most common gastrointestinal cause for consultation. The characterisation and classification of these disorders is based on predominant symptoms (which may suggest region of origin in the GI tract), because no single aetiological factor or investigative pattern has been identified in any subgroup.

CLASSIFICATION

For the sake of convenience, the disorders have been broadly classified as due to upper or lower GI disturbance. Although each subgroup has distinct features, many subjects have overlapping symptoms, suggesting that the disorder may be more diffuse than implied by the predominant symptom. Thus, patients with the irritable bowel syndrome (IBS), a predominantly lower GI disturbance, often have dyspeptic symptoms in addition. Also, in IBS, what is considered abnormal bowel frequency by the patient may overlap what is considered normal by a segment of the general population, suggesting visceral hypersensitivity in the patient.

The Rome III criteria for functional bowel disorders (**Table 1**) are an attempt to improve on several previous classifications.

FUNCTIONAL DYSPEPSIA

(Synonyms: Idiopathic, essential or non-ulcer dyspepsia)

Functional dyspepsia is a chronic or recurrent heterogeneous symptom complex that has its origin in the upper gastrointestinal tract, is localised to the upper abdomen, and is generally meal-related. The Rome III criteria identifies two primary symptom groups, namely, epigastric pain or burning (the epigastric pain syndrome) and meal-related early satiety or postprandial fullness (the postprandial distress syndrome).

The diagnosis of functional dyspepsia ideally requires that organic conditions with similar symptoms (peptic ulcer disease, gastro-oesophageal reflux disease, giardiasis, pancreatic and biliary diseases) be excluded first. In clinical practice, however, a normal upper gastrointestinal endoscopy is generally taken as adequate evidence, unless the suspicion of pancreatic or biliary disorder is strong enough to merit investigation. The likelihood of endoscopy detecting an organic lesion is low if it is undertaken as a regular practice.

Aetiopathogenesis

Recent data implicates phenotypic changes in acid secretion; alterations of fundic accommodation, antro-duodenal motility and gastric emptying; gastric hypersensitivity triggered by chemo- or mechanoreceptors; and hormonal disturbances; as the possible causes of dyspepsia, but each of these is present in only a proportion of the patients. A possible role of alpha-adrenoceptor gene polymorphism has also been suggested.

Table 1: Rome III Diagnostic Criteria for Functional Bowel Disorders

Functional Dyspepsia

At least 3 months, with onset at least 6 months previously, of one or more of the following:

- Bothersome postprandial fullness
- Early satiation
- Epigastric pain
- Epigastric burning
- No evidence of structural disease (including an upper GI endoscopy) that is likely to explain the symptoms

This is subclassified into:

Epigastric pain syndrome

At least 3 months, with onset at least 6 months previously, with all of the following:

Pain and burning that is:

- Intermittent
- Localised to the epigastrium of at least moderate severity, at least once per week,
- And not:
  - Generalised or localised to other abdominal or chest regions
  - relieved by defaecation or flatulence
  - Fulfilling criteria for gall bladder or sphincter of Oddi disorders

Postprandial distress syndrome

At least 3 months, with onset at least 6 months previously, of one or more of the following:

- Bothersome postprandial fullness occurring after ordinary-sized meals at least several times a week

or

- Early satiation, which prevents finishing a regular meal and occurs at least several times a week

Cyclic vomiting syndrome

At least 3 months, with onset at least 6 months previously, of:

- Stereotypical episodes of vomiting regarding onset (*acute*) and duration (*less than 1 week*)
- Three or more discrete episodes in the prior year
- Absence of nausea and vomiting between episodes

Supportive criteria: History of migraine headaches or a family history of migraine headaches

Chronic idiopathic nausea

At least 3 months, with onset at least 6 months previously, of:

- Bothersome nausea, occurring at least several times per week in the last 3 months
- Not usually associated with vomiting
- Absence of abnormalities at upper endoscopy or metabolic disease that explains the nausea

Irritable Bowel Syndrome

At least 3 months, with onset at least 6 months previously, of recurrent abdominal pain or discomfort* associated with two or more of the following:

- Improvement with defaecation; *and/or*
- Onset associated with a change in frequency of stool; *and/or*
- Onset associated with a change in form (appearance) of stool

** Discomfort means an uncomfortable sensation not described as pain.*

It is generally agreed that *Helicobacter pylori* has a poor or irrelevant role in the pathophysiology. Gastric acid secretion is normal in most patients although acid-related symptoms may be present. Non-painful dyspeptic symptoms are suggestive of motor disorder. Post-prandial fullness and vomiting have been associated with delayed gastric emptying of solids, and early satiety to postcibal impaired accommodation of the gastric fundus. Many patients with this condition implicate particular articles of diet as cause of symptoms. Higher anxiety and neuroticism scores have also been described.

Investigations

Investigations are mandatory in the following situations ('alarm' or 'red flag' features): recent onset, late age at onset of symptoms (>40 years), weight loss, no response to adequate standard therapy, and any abnormality on physical examination.

The utility of routine laboratory testing is debated. Haematocrit, stool examination (including test for occult blood in the elderly), and liver and renal profiles are used as screening tests. Diagnostic oesophago-gastroduodenoscopy with or without biopsy-based testing for *H. pylori* should be considered with the slightest suspicion of organic disease. The most common finding is antral gastritis; its relevance in the absence of *H. pylori* infection is not clear. Ultrasound screening for biliary and pancreatic diseases is done when suspicion exists.

Specialised tests (antro-duodenal manometry, electro-gastrography, radionuclide evaluation of gastric emptying) are confined to the research setting.

Management

Simple dietary precautions may go a long way in alleviating symptoms. Regular meal timings; having unhurried meals; not habitually sipping fluids during meals; avoidance of excessively spicy and fatty food; restricting intake of caffeinated and aerated beverages may all be helpful to the patients. 'Avoid what you cannot tolerate' is a better advice than a blanket ban on food items; this also leaves the patient feeling in charge of himself. Tobacco in any form, and immoderate alcohol consumption, should be avoided.

The most common medication used is antacid; since most of the commercial preparations are antacid-antiflatulent combinations, they may alleviate a wide range of symptoms. When this is not effective (its long-term use is also not desirable), a histamine H_2-receptor antagonist (ranitidine, famotidine) can be substituted in patients with acid-peptic symptoms. More powerful acid suppressants (proton pump inhibitors) are seldom required.

In patients with symptoms of gastroduodenal dysmotility (bloating, early satiety) a prokinetic agent (metoclopramide, domperidone, mosapride, itopride, levosulpiride) may be beneficial; cisapride may be preferred when the patient has additional lower gastrointestinal symptoms (constipation, incomplete evacuation); its use is, however, restricted by fears of cardiotoxicity. There is no evidence to show that treatment for *H. pylori* is indicated.

Other distinct functional upper gastrointestinal conditions with features suggesting dysmotility have been described, but these are uncommon in clinical practice. These include:

Idiopathic gastroparesis

As the term implies, these patients have defective gastric contraction and emptying. While this may be a consequence of systemic diseases, e.g. diabetes mellitus, acute viral infections, or of drug therapy (beta-adrenergic agonists, dopamine D2 agonists such as bromocriptine, levodopa and opioids), in some cases no cause is identified.

These patients may present with dyspepsia-like symptoms (early satiety, bloat, nausea and occasional vomiting) acutely over months or years.

The diagnosis rests on documenting delayed gastric emptying by radionuclide scan or other appropriate techniques. More frequent small meals, liquids or soft solids, and prokinetic drugs are the mainstay of therapy.

Aerophagia and belching syndrome

Aerophagia is the semivoluntary swallowing of abnormal amounts of air while eating or drinking. When this results in increased intragastric air volume, belching occurs. Patients with the syndrome voluntarily aspirate air into the oesophagus, and then expel it loudly. Frequent swallowing is an accompanying feature. Some of them push the air further into the stomach and present with bloat and discomfort. Anxiety may aggravate the condition, which takes on the nature of a compulsive tic. Gastric hypomotility has been documented in such subjects, but whether this is a cause or effect is not known. Management is empirical, and should include a search for psychological factors.

Cyclic vomiting syndrome

This condition is characterised by stereotypic episodes of vomiting, with absence of nausea and vomiting in between episodes. Sometimes it is confused with other functional gastrointestinal syndromes because abdominal pain is not uncommon when episodes occur. The causes remain unclear, but some investigators have considered it to represent a migraine variant.

Antral hypomotility and delayed emptying have been recorded in some patients. Nutritional compromise may occur in the long term. Available evidence suggests poor response to prokinetics. Anti-depressants work in some individuals, suggesting a central origin for the symptoms.

Rumination syndrome

Rumination is a process by which food from the stomach is brought back into the mouth; some of the food is chewed and re-swallowed, and the process is repeated. Contraction of abdominal muscles and simultaneous relaxation of the lower oesophageal sphincter seem to occur as an effortless, semivoluntary action. A psychological element seems to be underlying. Apart from erosion of tooth enamel and bad breath (halitosis), this condition may also lead to nutritional deficiencies because patients tend to be withdrawn. Psychological support and physical training to overcome the muscle activity may be helpful.

IRRITABLE BOWEL SYNDROME (IBS)

The terms spastic colon, mucous colitis, irritable colon, among others were used to describe this condition earlier. While each of them reflected the predominant symptom or the

understanding of the condition at that time, they all reflect the recognition that the symptoms arise primarily in the colon.

Patients with IBS report with abdominal pain and altered bowel habits. The earlier criteria laid down by Manning *et al* for its diagnosis have been supplemented by the recent Rome III symptom criteria (**Table 1**). These identified pain or discomfort as an overwhelming symptom and introduced a time factor for diagnosis.

It is accepted now that a positive clinical diagnosis of IBS can be made and the condition need not be a diagnosis established by absence of evidence for structural disease. The presence of certain 'alarm' features (**Table 2**), however, requires that the patient be investigated.

Table 2: Features Against Diagnosis of IBS

History
- Late age (>40 years) at onset of symptoms
- Large-volume diarrhoea or steatorrhoea
- Frequent nocturnal symptoms
- Blood in stools (except from anal lesions, e.g. haemorrhoids, fissure)
- Fever, dehydration
- Significant weight loss
- Progression of symptoms or development of new symptoms

Physical examination
- Abdominal mass
- Signs of malabsorption, bowel obstruction, thyroid dysfunction
- Extraintestinal manifestations (arthritis, skin lesions)

Laboratory findings
- Occult blood in stools

Epidemiology

About 15% of the general population have symptoms that justify a diagnosis of IBS; however, only about 20% of these will seek medical opinion, prompting a suggestion of hypersensitivity in them. IBS is the most common single reason for referral to gastroenterologists. In Western series, female patients predominate; in South Asia and in India, most reporting patients are young men. The reason for this difference is not known.

Clinical Features

Pain (or discomfort) is an important feature of IBS, and is localised to the periumbilical region or lower abdomen, especially the left side. Altered bowel habit is the other symptom. While Indian patients generally do not have the alternating diarrhoea and constipation pattern described from the West, whether diarrhoea or constipation predominates varies regionally within the country. Abdominal pain and other accompanying features like gas bloat are usually relieved temporarily by defaecation.

In patients with constipation, sense of incomplete evacuation is a particularly distressing symptom; since these patients actually have increased attempts at defaecation, they may wrongly be labelled as having diarrhoea and are treated accordingly, with worsening of symptoms. Some of them attempt digital evacuation of the anal canal; these patients often have a profusion of mucous, and may develop ulcers in the anal canal or lower rectum (solitary rectal ulcer syndrome). Many patients with straining at stools as their only complaint may actually have an evacuation disorder.

Stool consistency may vary from small-quantity semisolid or liquid with mucous in those with diarrhoea, to hard, pellet-like with mucous in constipated subjects. Blood in stools may take the form of streaks or fresh drops after defaecation; the former are due usually to anal fissures and the latter to haemorrhoids, two conditions these patients are predisposed to.

Though the predominant symptoms arise from the colon, up to one-third of patients have accompanying upper gastrointestinal symptoms like dyspepsia, heartburn and bloat. Extraintestinal symptoms like dysmenorrhoea, dyspareunia, urinary frequency and headache are also common in female patients. Abnormal psychological features have been reported in over 70% of patients; stressful life events are also reported with increased frequency. However, a cause and effect relationship is not certain.

Pathophysiology

The pathophysiology of IBS is considered to be multifactorial, generated by interplay between genetic, psychosocial and environmental factors. These produce abnormalities in central nervous system processing as well as in the periphery, where they generate abnormal motility and possibly abnormal secretory activity. No consistent anatomic, physiological or microbiological abnormality has, however, been demonstrated; it is unlikely there is a single unifying explanation. Alterations in bowel motility and transit, as a consequence of abnormal myoelectric rhythm, are the most common features identified.

In a subgroup of patients the onset of symptoms follows an episode of infective diarrhoea (post-infective IBS). These and other patients with documented bacterial overgrowth may benefit from short courses of antibacterial treatment. This response to drugs, including a nitroimidazole, has often led to a wrong label of 'chronic amoebiasis', especially when this is associated with incidental stool detection of amoebae.

As stated earlier, a proportion of individuals from the general population have symptoms overlapping those of IBS, but do not consult a physician. Whether this represents a non-complainant group, or suggests that visceral hypersensitivity plays a role in distinguishing 'patient' from 'normal', is an open question.

Investigations

The diagnosis is generally based on history with normal physical examination (at most, tenderness in the lower abdomen, especially on the left side). Finding anal fissures or haemorrhoids on proctoscopic examination confirms the source of local pain and bleeding. Twenty four hours stool weight is recorded to rule out causes of large-volume (small intestinal or pancreatic) diarrhoea; stool weight in normal Indian subjects and those with IBS is less than 350 g/24 hours. Routine stool examination is done for amoebae and giardia. Sigmoidoscopy or colonoscopy is done when features against the diagnosis of IBS exist (**Table 2**). Recent Western studies suggest that routine investigation of all patients with diarrhoea predominance may identify a small number with unsuspected coeliac disease, bacterial overgrowth syndrome, or inflammatory bowel disease.

Management

The most important component of management is reassurance and psychological support. Cancer phobia is often the reason for medical consultation, and some investigations may become necessary if only to allay this fear. Despite the lasting discomfort and morbidity, patients should be assured that no complications arise out of IBS. Tranquilisers or anxiolytics may be required in the highly apprehensive patients (**Table 3**). Non-pharmacological relaxation modalities like yoga and biofeedback may also help.

Dietary advice should include restriction on items known to aggravate symptoms. Thus, milk and spicy food may need to be restricted in those with diarrhoea; milk, legumes and cabbage in those with gas bloat. Patients often report relief by eliminating meat from the diet. Obviously, advice will have to be individualised.

High-fibre diets are most effective in patients with constipation; when adequate fibre is already being consumed in the diet with no relief (as often happens in Indian patients), fibre supplementation may be tried. Commercially available isaphgol husk preparations can be taken with meals; usually 1 to 2 teaspoons of the refined preparations are given with breakfast and dinner, to ensure an additional 15 to 20 g fibre/day. These hydrophilic agents bind water and so prevent stool dehydration and add bulk. They may also help in patients with diarrhoea. One side-effect of fibre supplementation that is particularly distressing to patients with IBS is bloat. Relief can be obtained by combining this with preparations of simethicone or methylpolysiloxane. An alternative is the fibre substitute calcium polycarbophil.

Drugs that have the potential for use in the treatment of IBS are listed in **Table 3**. Tegaserod, a specific serotonin ($5\text{-}HT_4$) agonist, can improve symptoms in patients with IBS and constipation. Lactulose, lactitol and oral solutions containing polyethylene glycol (PEG) have been associated with improvement in stool frequency and consistency. Bowel retraining may improve bowel regularity.

Patients with diarrhoea may benefit from a morning dose, or if necessary thrice-daily doses, of the anti-diarrhoeal agent loperamide; milder symptoms may be controlled with racecadotril. Abdominal pain may require anti-spasmodics (e.g. mebeverine, dicyclomine).

Table 3: Drugs with Potential for Use in Treatment of IBS

Predominantly centrally acting drugs
- Selective serotonin-reuptake inhibitors (SSRIs)

Centrally and peripherally acting drugs
- Neurokinin-receptor antagonists
- Serotonin-receptor (mainly 5-HT3 and 5-HT4) modulators: alosetron, tegaserod, prucalopride
- Drugs with opioid (mu, kappa, delta) action: diphenoxylate, loperamide
- Neurotrophins
- Corticotrophin-releasing factor (CRF) antagonists
- Somatostatin analogues

Predominantly peripherally acting drugs
- Antibiotics (rifaximin) and probiotics
- Selective chloride-channel activators: lubiprostone
- Cholecystokinin (CCK) antagonists
- Peripheral receptor modulators: guanylate cyclase

FUNCTIONAL ABDOMINAL PAIN SYNDROME

Many of these patients are young women with other features to suggest psychological problems, including somatisation. Where suspicion is strong, investigation for the rare metabolic cause, e.g. porphyria, or poisoning (lead) should be done. The more common metabolic causes of abdominal pain (diabetes mellitus, uraemia) usually have other characteristic features present. The diagnosis of functional abdominal pain should be entertained only after organic causes are eliminated with reasonable certainty.

Management includes reassurance, psychologic support measures, anxiolytics if necessary, and spasmolytics, antacids, analgesics or other similar drugs depending on the type of pain described by the patient.

13.11 Abdominal Tuberculosis

Govind K Makharia

INTRODUCTION

About 20% of patients with tuberculosis (TB) have extra-pulmonary TB and 7% to 10% of them have abdominal TB. While abdominal TB continues to be a common problem in the developing countries including India; increasing population migration, epidemic of acquired immunodeficiency syndrome (AIDS) and use of more potent chemotherapeutic agents led to resurgence of this disease in regions where TB had previously been largely controlled. Reliable epidemiologic data on abdominal TB from India is lacking. Of all hospital admissions, nearly 0.8% is reported to be due to intestinal TB. Three per cent to twenty per cent of all intestinal obstruction and 5% to 7% of intestinal perforation are due to intestinal TB in India.

In the abdomen, TB infection can involve many organs including gastrointestinal (GI) tract, peritoneum and many others (**Table 1**). In an analysis of 6 reports including 596 patients, Marshall *et al* reported that 42%, 50% and 8% had peritoneal, GI and lymph node TB, respectively and only a minority had combined peritoneal and GI TB.

Table 1: Classification of Abdominal Tuberculosis

- Gastrointestinal tuberculosis
  - Intestinal (both small and large)
  - Gastroduodenal tuberculosis
  - Oesophageal tuberculosis
- Peritoneal tuberculosis
  - Acute tuberculosis peritonitis
  - Chronic peritoneal tuberculosis
    - Ascitic form
    - Encysted (loculated) form
    - Dry type
- Tuberculosis of the solid viscera
  - Hepatobiliary
  - Spleen
  - Pancreas
- Tuberculosis of the abdominal lymph nodes
  - Tubercular mesenteric lymphadenitis
  - Tubercular retroperitoneal lymphadenitis
- Genitourinary tuberculosis

INTESTINAL TUBERCULOSIS

Site of Involvement

While any part of GI tract may be involved by the TB infection, the most common site of involvement is ileocaecum (ileum, ileocaecal valve and caecum). Other common sites of involvement are the colon (where the frequency decreases segmentally from the ascending colon to the rectum), appendix, jejunum, stomach, duodenum and oesophagus. The preferential location of ileo-caecum is because of a number of reasons including: the abundance of lymphoid tissue, relative physiologic stasis, higher electrolyte and water absorption, and minimal digestive activity, permitting greater contact time of the acid-fast bacilli (AFB) with the mucosal surface.

Pathogenesis

The mycobacterial infection can develop primarily within the intestinal tract or secondary to a focus elsewhere in the body. There are 4 possible ways by which an infection can reach GI tract: direct invasion by the ingested mycobacteria, transport by the way of infected bile, extension from adjacent diseased organs or tissues and spread through mycobacterial bacteraemia. Animal studies have shown that intestinal TB can result from ingestion of food containing tubercle bacilli, especially milk. With widespread pasteurisation of milk, milk is not a significant cause of TB. Secondary infection of the GI tract may arise from contamination of enteric chyme by bacteria from another site, usually the lungs, through swallowing of infected sputum. Intestinal involvement is probably related to the number and virulence of the ingested organisms and the nutritional status of the patient. Invasion of the intestine does not seem to occur when there is TB involvement of the peritoneum. Generalised tuberculous peritonitis is usually not associated with intestinal TB other than as a consequence of the extension of the infectious process transmurally or from an infected, ulcerating lymph node to the serosal surface.

Pathology

Traditionally, intestinal TB is described as of three types—ulcerative, hypertrophic and ulcero-hypertrophic. The ulcerative form of the disease is mainly due to deprivation of blood supply, because of endarteritis. In GI TB, ulcerogenesis is relatively slow, and an inflammatory wall develops ahead of the advancing ulcer. Thus, most perforations are confined. There is an accumulation of collagenous tissue during the process of ulcer healing that subsequently contracts and cause circumferential stricture of the intestinal lumen. The diseased segment is moderately indurated and the serosa is studded with nodules. The mesenteric lymph nodes are usually enlarged. The mucosal surface may show single or multiple ulcers, and skip areas may be present with normal appearing mucosa between involved segments. The ulcers are characteristically transverse and circumferential, but may be round, stellate, or longitudinal. The ulcers are deep, these however, generally do not penetrate the muscularis propria. In the acute phase, there may be a functional stenosis of the involved segment because of the spasm. In the more chronic phase, circumferential strictures may develop. The hypertrophic form of the disease, there is a marked inflammatory fibroblastic reaction in the submucosa and subserosa of the involved segment mostly ileocaecum.

Caseating granulomas (**Figure 1**) are the histologic hallmark of TB. The granulomas in intestinal TB are usually larger (>200 µm), multiple in number (>5/section) and confluent (**Figure 1**). Careful scrutiny should be made of acid-fast stained tissue for

tubercle bacilli. The ulcers usually do not penetrate beyond the muscularis and are lined by non-specific inflammatory granulation tissue. It must be emphasised that the histologic features of intestinal TB may be altered and may remain undiagnostic in patients who have received anti-tuberculosis drugs earlier or where tissue specimen is small.

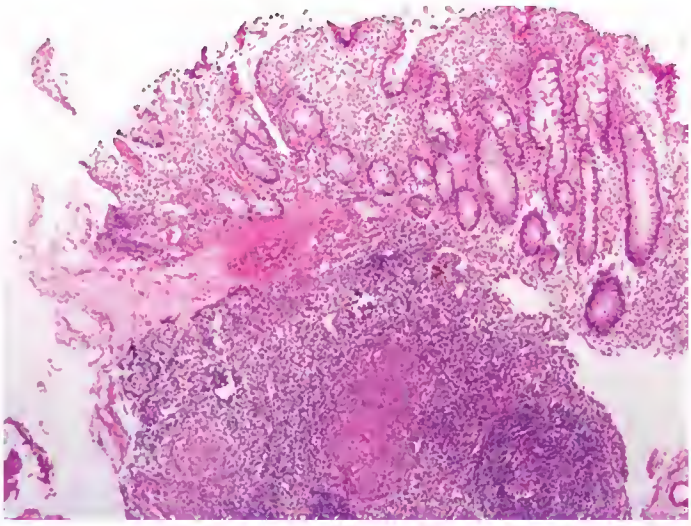

Figure 1: Photomicrograph showing caseating granuloma, multiple submucosal large (> 200 μm diameter) epitheloid cell granuloma with lymphocytic cuffing. Focally, the granuloma show central necrosis and presence of Langhan's giant cells (Haematoxylin and Eosin x 40).

Clinical Features

The most common age of patients with intestinal TB is between 20 to 40 years it, however, can occur in any age. Intestinal TB may have symptoms arising from the (a) intestinal ulcero-constrictive disease (intestinal colic, abdominal distension, nausea, vomiting, constipation, bleeding manifestations); (b) symptoms due to chronic inflammatory process (fever, weakness, weight loss, night sweats); (c) symptoms due to associated adjacent tissue involvement (ascites, lymph node enlargement or tubo-ovarian symptoms); and (d) coincident pulmonary TB (chronic cough, expectoration, haemoptysis).

The symptoms of GI TB will depend upon the site(s) of involvement of the GI tract and also the type of lesions it produces. As discussed earlier in the pathogenesis, ileocaecal area is the most common site of involvement in patients with intestinal TB, and most of the lesions are ulcerative or ulcero-constrictive. Abdominal pain is the most common manifestation and occurs because of stricture of the lumen, stretch on the surrounding tissue, mesenteric inflammation and peritoneal involvement. While the pain arising from the intestine is mostly colicy in nature, the pain arising from mesentery or peritoneum is diffuse and dull ache. As disease advances with time, the severity and frequency of pain increases. Therefore, the patient may initially present with occasional episodes of intestinal colic only, which may be disregarded by a physician as an episode of GI infection. As the stricture advances, the patient may develop partial intestinal obstruction (abdominal distension, gurgling in the abdomen, partial or complete cessation of flus, vomiting or movement of ball of wind in the abdomen). Diarrhoea is seen in 20% to 30% of patients and can be because of both small and large intestinal involvement. Malabsorption results from: (a) decreased small intestinal mucosal surface, (b) lymphatic obstruction, (c) fistula formation between the small and large intestine, (d) deconjugation of bile salts secondary to bacterial overgrowth, and (e) decreased bile salt pool because of impaired active absorption in the distal ileum. Bleeding per rectum is seen in 10% to 15% of patients with intestinal TB and occasionally massive bleeding. Almost half of patients have constipation. Constitutional symptoms in the form of fever, malaise, night sweats, anorexia, and weight loss are reported by 40% to 70% of patients with intestinal TB. A few patients may have active TB elsewhere especially lungs.

On examination, there are no characteristic signs. Most patients appear sick, poorly nourished and febrile. Doughy consistency of abdomen (due to extensive fibro-adhesive inflammation) is infrequent and non-specific. Abdominal tenderness is frequently present in the right lower quadrant. Palpable mass, which is a conglomerate of adhered bowel loops, lymph nodes and sometimes mesentery, may be observed in 10% to 20% patients.

Complications

The complications of intestinal TB are partial or complete intestinal obstruction, lower GI bleeding, intra-abdominal abscess, malnutrition and at occasions intestinal perforation. Intestinal obstruction occurs due to contraction of intestine following healing of circumferential tuberculous ulcers, bowel wall thickening, kinking of the intestine by intra-peritoneal adhesions, retraction of the mesentery and obstruction at the ileocaecal junction (due to changing the angle of entrance of the ileum into the colon of 90° to nearly 180°). Malnutrition occurs because of anorexia, inadequate food intake (because of sitophobia and poverty), and malabsorption.

Investigations

The haemogram in patients with intestinal TB shows a mild-to-moderately severe normochromic, normocytic anaemia, thrombocytosis and a normal white cell count with relative lymphocytosis. The erythrocyte sedimentation rate is almost always raised. Mantoux test is positive in over 70% of patients but high prevalence of Mantoux positivity in developing countries (≈ 60%) limits its usefulness. False-negative result is often seen in the elderly, malnourished, immunosuppressed, or in patients with disseminated disease. Pulmonary lesions on chest radiograph may be noted in a quarter of subjects; recognition of active pulmonary disease reduces the cost and expedites the diagnosis. Plain radiograph abdomen should be done in those who present with intestinal obstruction and may reveal air-fluid level and dilated bowel loops. One should review the radiograph properly to see other suggestive evidences, such as calcified lymph nodes, calcified granuloma in the spleen, liver and pancreas and enteroliths.

The aims of the investigations in patients suspected to have intestinal TB are detection of lesion, site and extent of the lesion, type of lesion, detection of any associated complication, histological diagnosis, microbiological confirmation and detection of TB either active or healed elsewhere, most commonly lungs. Intestinal imaging includes: luminal imaging (endoscopic, barium studies), and imaging of the wall and extra-intestinal extent which is detected by cross sectional imaging, such as CT scan and MRI. Both these techniques may be combined in one, such as CT-enteroclysis or MR-enteroclysis.

Endoscopic Investigation

Since ileocaecal area is involved in the majority of the patients with intestinal TB, colonoscopy with retrograde ileoscopy is the investigation of choice. Colonoscopic examination provides an opportunity to visualise the lesion directly and one can obtain biopsies from the lesions at the same time. The morphological appearance of intestinal TB depends upon the stage of the disease. The lesions may vary from mild lesions, such as loss of vascular pattern, erythema, small ulcerations and superficial ulcerations, to more advanced lesions including deep ulcerations, nodularity and strictures. One should realise that the evolution of intestinal TB takes from months to years. The classical morphological features described in the textbooks are seen in advanced cases. Some of the patients may present in early stages of evolution of the disease, thereby one may not find classical lesions and instead finds minute lesions. The wisdom lies in identifying these minute lesions so that the progression of the disease can be prevented. Common colonoscopic features of intestinal TB include deep ulcers (50% to 80%), nodules (30% to 60%) and strictures (**Figure 2**). One should take multiple biopsies from the lesion for not only histological examination but also for *M. tuberculosis* culture, PCR and AFB staining.

For small intestinal lesions, newer endoscopic techniques such as single and double balloon enteroscopic examination can be done. Capsule endoscopic examination is generally not done for those patients where obstructive lesion such as intestinal TB is suspected.

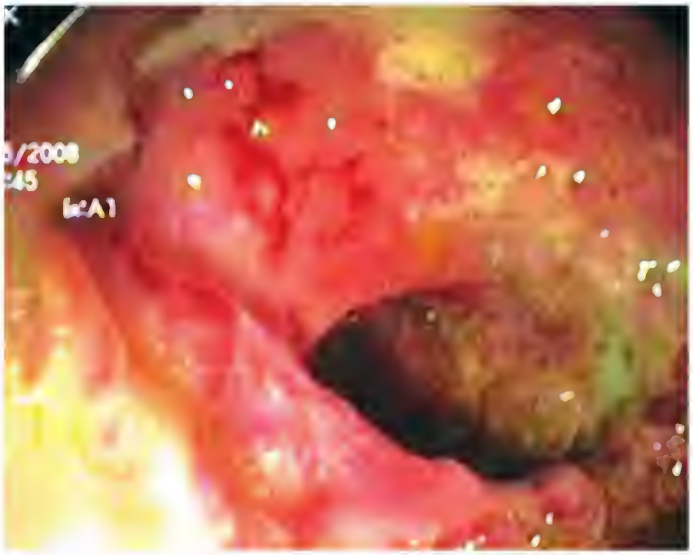

Figure 2: Colonoscopic picture showing ulceration of the ileocaecal valve in a patient with intestinal tuberculosis.

Radiological Investigations

Although there are many suggestive features on radiological investigations, none however is diagnostic of intestinal TB. The radiological features depend upon the stage of the disease, site of involvement and severity of the disease. In the early stage of mucosal invasion and ulceration, barium findings of ileocaecal TB are non-specific and include spasm and hyper-motility of the intestinal segment, oedema of the ileocaecal valve and mucosal thickening. Tubercular ulcers are circumferential or transverse in orientation. With progression of the disease, the ulcers become confluent. In patients with TB, barium findings in the advanced stage of fibrosis are more definitive. There is a thickening of the ileocaecal valve with narrowing of the terminal ileum (Fleischner or inverted umbrella sign). In further advanced disease, the characteristic deformity include symmetric, annular stenosis with obstruction, and shortening of the intestine and the colon. The caecum classically becomes conical, shrunken, and pulled up from the iliac fossa due to contraction of the mesocolon. There may be a loss of the normal ileocaecal angle (**Figure 3**). A localised narrowing opposite the ileocaecal valve with a rounded smooth caecum and a dilated terminal ileum is termed as 'purse string stenosis'. Spasm of the distal ileum and the ascending colon with contraction of the caecum (Stierlin sign) may be seen in association with shrunken ascending colon. The ileocaecal valve classically becomes incompetent, rigid and fixed with an irregular outline. Tubercular strictures are typically short and multiple separated by unaffected segments. Enteroliths may form proximal to the

Figure 3: Barium-meal follow through study showing contracted and pulled up caecum with narrowing of the ileocaecal junction and loss of the normal ileocaecal angle. The terminal ileum appears suspended and hanging from the caecum.

strictures and may vary from a single large lamellated calculus to multiple small stones visible on the radiograph.

CECT or CT-enteroclysis/MR-enteroclysis is essential for the evaluation of extra-luminal, peritoneal, nodal and visceral involvement. CT is more accurate than ultrasonography in detecting most of these manifestations including peritoneal and intestinal involvement. CECT/CT enteroclysis may show intestinal wall thickening (unifocal or multifocal), stricture with proximal dilation of the intestine, and regional lymphadenopathy. The pattern of lymphadenopathy in TB may vary widely, including increased number of normal sized nodes, mildly enlarged nodes to large confluent nodal masses. The involved lymph nodes typically show hypodense centre and peripheral enhancement in 40% to 70% cases; which reflects central necrosis (**Figure 4**).

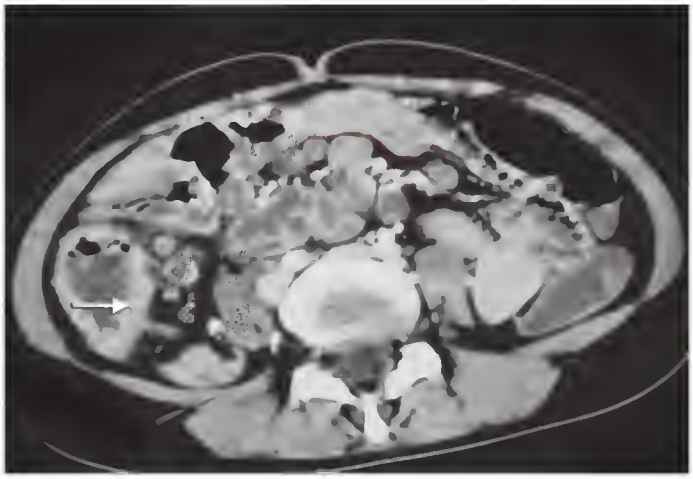

Figure 4: A contrast enhanced computerised tomography showing enlarged mesenteric lymph nodes with central hypodensity and thickening of the caecum (arrow) in a patient with abdominal tuberculosis.

Microbiological Tests

Isolation of *M.tuberculosis* using culture is the most specific method for diagnosis of active TB. It can detect 10-100 bacilli per mL of the sample. The most commonly used solid media is the Lowenstein-Jensen medium, on which it usually takes 4 to 6 weeks to grow. Radiometric (BACTEC) method and MGIT culture system can grow *M. tuberculosis* in shorter period of time, however, these are expensive. PCR using *M. tuberculosis* specific primer shows a positivity varying from 20% to 65%. Identification of acid-fast bacilli (AFB) on microscopy is presumptive for TB infection as saprophytic mycobacteria may give false-positive result.

Serological Tests

Although enzyme-linked immunosorbent assay (ELISA) using semi-purified antigens has sensitivity of 80% in abdominal TB; however, it fails to distinguish active from the past infection and it has high false positive rate. At present, there is no role of commercially available ELISA in making diagnosis of TB. One should not base one's decision of starting anti-tuberculous treatment (ATT) on ELISA report unless there are enough clinical, endoscopic and histological evidences.

Diagnostic Criteria for Tuberculosis

At least one of the following criteria must be met:

1. Culture of tissue (colonic biopsy, lymph nodes) resulting in growth of *M. tuberculosis.*
2. Histological demonstration of typical ATB.
3. Histological evidence of necrotising granuloma.
4. Definite response to ATT in a patient with probable TB based on clinical, endoscopic, histological features (Logan's modification).

Differential Diagnosis

Crohn's disease (CD) and intestinal TB are granulomatous diseases of the intestine. The clinical, morphological and histological features of intestinal TB and Crohn's disease are so similar that it becomes difficult to differentiate between these two entities. In geographical regions like Asia where both Crohn's disease and intestinal TB are prevalent, differential diagnosis between the two may be challenging. In Asia, intestinal TB is common, but CD is also being increasingly reported from all over Asia. Natural history of CD is quite different from that of intestinal TB. While intestinal TB gets cured by appropriate ATT, CD has a remitting/relapsing or persistent course and usually stays lifelong. Because of similarity in the clinical presentation and morphology of these two entities, at times such patients are treated empirically with anti-tuberculous drugs. The clinical, endoscopic and histological features which can differentiate these two diseases are summarised in **Table 2**.

Table 2: Clinical, Endoscopic and Histological Differentiation between Intestinal Tuberculosis and Crohn's Disease

Variables	Intestinal Tuberculosis	Crohn's Disease
Symptoms		
Chronic diarrhoea	20 to 40%	60 to 80%
Blood in the stools	10 to 20%	50 to 70%
Abdominal pain	90%	60 to 80%
Constipation	50%	10 to 30%
Partial intestinal obstruction	50 to 60%	20 to 30%
Peri-anal disease	5%	30 to 80%
Fever	40 to 70%	30%
Loss of appetite	40 to 80%	40 to 60%
Weight loss	60 to 90%	50 to 60%
Extra-intestinal manifestations	10%	20 to 50%
Involvement of the Intestine		
Anal canal	<5%	15 to 50%
Rectum	10 to 20%	40 to 60%
Sigmoid colon	5 to 10%	10 to 50%
Descending colon	5 to 10%	10 to 50%
Ascending colon	40 to 60%	50 to 70%
Ileocaecal area	70 to 90%	60%
Ileum	10 to 20%	20 to 40%
Endoscopic Features		
Aphthous ulcers	5 to 10%	30 to 50%
Linear ulcers	5%	20 to 30%
Deep ulcers	50 to 70%	30 to 40%
Nodularity	50%	20%
Cobblestoning	None	15 to 20%
Histological Features		
Granuloma	30 to 60%	30%
Necrosis in the granuloma	10 to 30%	None

PERITONEAL TUBERCULOSIS

The peritoneum is another common extra-pulmonary site for TB infection. Tuberculous peritonitis frequently complicates patients with underlying end-stage renal or liver disease. The disease can present in three different forms which are: the ascitic form (wet

type), encysted (loculated) form and dry type. All of them have almost similar clinical manifestations except for abdominal distension which does not occur in the dry type tuberculous peritonitis. Abdominal pain (60% to 70%) is a common presenting symptom and frequently accompanied by abdominal distension. It is usually non-localised and vague in nature. The pain is largely due to the tuberculous inflammation of the peritoneum and mesentery. Less often, it could be due to involvement of intestine as described in the above segment. Tenderness on palpation is common in tuberculous peritonitis and occurs in almost half of patients. Rebound tenderness is rare as the presence of ascitic fluid prevents approximation of the parietal with the visceral peritoneum. A smaller percentage of patients (5% to 10%) present with the classical 'doughy' abdomen. This is described as the dry or plastic type of tuberculous peritonitis.

The ascitic fluid is usually straw coloured. Although, red blood cells (RBCs) are frequently seen on microscopic examination, frank haemorrhagic, however, is uncommon. The ascitic fluid white blood cells (WBC) in tuberculous peritonitis varies widely from <100 cells/mm^3 to 5000 cells/mm^3. However, most patients have cell counts between 500 and 1500 cells/cmm. The WBCs are predominantly lymphocytes with the possible exception of patients with underlying renal failure where, for unknown reasons, the cells are mostly neutrophils. The protein content of ascitic fluid is high (> 2.5 g/dL) and have low glucose. The serum ascites albumin gradient (SAAG) has more diagnostic yield than ascitic fluid total protein measurement. It is calculated by measuring both serum and ascitic fluid albumin on the same day and subtracting the ascitic albumin from the serum albumin concentration. While tuberculous peritonitis has low SAAG (<1.1 g/dL), a high SAAG (>1.1 g/dL) suggests portal hypertension.

Adenosine deaminase (ADA) is an enzyme that converts adenosine to inosine and its activity is more in activated T lymphocytes than in B lymphocytes. There is an increase in number of activated T-cells in closed cavity infection, such as tubercular ascites or pleural effusion. With attrition of these lymphocytes, ADA along with other enzymes and end products are released in the closed compartment and, therefore, there is an increase in the ADA levels. A high value of ADA in any fluid cavity is not diagnostic of TB infection; in fact it is a reflection of high T-cell activity. An ADA value more than 32 IU/L in ascitic fluid has been reported to have high sensitivity and specificity for the diagnosis of tubercular ascites. High ADA may be seen in malignant ascites and even ascites due to cirrhosis. Interferon-γ (IFN-γ) has also been reported to be higher in tubercular ascites compared with malignant and cirrhotic ascites. The clinical significance and utility of estimating IFN-γ in ascitic fluid for diagnostic purposes is not very clear. While at least 5000 bacilli/mL of specimen is required for a positive smear, only a few bacilli/mL may be sufficient for a positive culture and for detection by PCR. Ziehl-Neelsen staining of the ascitic fluid for mycobacterial detection has a very low yield (3% to 5%) in proven patients with tuberculous peritonitis. In order to increase the yield, it is recommended that a larger volume of ascitic fluid should be sent to the laboratory and the fluid should be centrifuged before staining. There is a lack of reliable data on the sensitivity of PCR in tuberculous peritonitis, however, PCR is expected to show a higher yield.

Direct inspection and biopsy of the peritoneum are perhaps the most effective method of diagnosing peritoneal TB. The laparoscopic examination can show thickened, hyperemic peritoneum with ascites and whitish miliary nodules (<5 mm) scattered over the parietal peritoneum, omentum and intestinal loops in two-third of patients. The diagnostic yield of laparoscopic examination is very high. Peritoneal carcinomatosis, and sarcoidosis may have same features such as that seen in tuberculous peritonitis. Therefore, one should always take peritoneal biopsy during laparoscopic examination. In a patient with lymphocytic, exudative ascites with low SAAG and high ADA; tuberculous peritonitis is the most likely cause. However, one should remember the possibilities of fungal peritonitis, and malignant ascites.

OESOPHAGEAL TUBERCULOSIS

TB of the oesophagus is uncommon. Oesophageal involvement in TB occurs usually due to direct extension of infection from adjacent affected structures, such as mediastinal lymph nodes or the lung. Less frequently, oesophageal involvement occurs in the absence of TB elsewhere in the body. Upper part of the oesophagus is more often involved than the lower part. The main presenting features are dysphagia, odynophagia, chest discomfort, and systemic symptoms. Some of these patients may develop trachea-oesophageal or broncho-oesophageal fistula. The lesion can be seen by endoscopic examination and the diagnosis can be achieved by histological and microbiological evaluation of the biopsies. The endosonographic examination can help in imaging the mediastinal lymph nodes and one can obtain the fine needle aspiration from these nodes using endosonography. One can also do a CECT of the chest to look for the extent of involvement including mediastinal lymph nodes.

GASTRODUODENAL TUBERCULOSIS

Because of acidic environment, stomach and duodenum are generally spared by TB infection. The TB lesion produces ulcerations and stricture in the duodenum and rarely in the stomach. Therefore, symptoms include abdominal pain, nausea, vomiting, GI bleeding, fever and weight loss. Once there is obstruction to the lumen because of the lesion, the patient presents with obstructive features such as copious vomiting of stale food (food eaten four hours earlier). Endoscopic examination is the best investigation wherein one can see the lesion and obtain appropriate biopsies. If the lesion is out of reach of a routine upper GI endoscope, one can still see the lesion using enteroscope, if available. Otherwise radiological investigations such as barium-meal or barium-meal follow through can be done. Many patients respond to ATT and to endoscopic dilation of stricture while some may require surgery for obstructive symptoms.

HEPATOBILIARY TUBERCULOSIS

Liver is involved in TB infection in two forms. More commonly liver is involved in TB as part of miliary or disseminated disease. There may not be any specific signs or symptoms related to the liver except the hepatomegaly and liver biopsy may show presence of granuloma. The second form, which is seen less often, is localised form of TB involving liver and biliary ducts. Localised hepatobiliary tuberculosis occurs as: (i) localised

solitary or multiple nodules, tuberculoma and tuberculous hepatic abscess without bile duct obstruction; (ii) and bile ductal epithelium involvement producing inflammatory strictures with obstructive jaundice; and (iii) enlarged lymph nodes at porta causing obstruction to the bile duct. Obstructive jaundice is more common in those who have biliary system involvement. Most patients have an increase in alkaline phosphatase and gamma glutamyl transferase in addition to a mild rise in serum transaminases. Ultrasonography and subsequently CECT are required for complete imaging. In suspected patients, the bile ductal abnormality (stricture, unifocal or multifocal; ductal irregularity) can be seen by MRCP or ERCP.

SPLENIC TUBERCULOSIS

As liver, spleen can also be involved by TB infection in two ways mostly as a part of disseminated or miliary form of the disease and occasionally as isolated splenic TB. Most of these patients are immunocompromised; splenic TB, however, has been reported in otherwise immunocompetent individuals. Most of the cases of splenic TB are recognised on imaging and sometimes as surprise on operated splenectomy specimen. In those with disseminated form of the disease, there are enough clinical clues in other organs; there is no specific feature in isolated splenic TB to suggest a clinical diagnosis of splenic TB. Fever, left upper quadrant abdominal pain, weight loss, splenomegaly and or hepatomegaly are usual features. On imaging (US or CT), spleen may be enlarged and there may be one or multiple lesions. The treatment is similar as elsewhere except that a splenectomy may be required in a few patients where spleen is studded with TB abscesses.

PANCREATIC TUBERCULOSIS

Pancreatic TB is uncommon. Pancreatic TB is most often the result of lymphatic or haematogenous dissemination or direct spread from other adjacent organs. The involvement of pancreas by TB infection can occur as part of miliary or disseminated form of TB or as isolated pancreatic TB. The usual lesion in such patients is a pancreatic mass and, therefore, symptoms depend upon the type and site of the mass. As other sites, anorexia, malaise, low-grade fever, weight loss, night sweats are seen in majority of the patients. The specific symptoms include abdominal pain and obstructive jaundice if pancreatic head is involved. The imaging shows mass in the pancreas which is a conglomerate of lesions in the pancreas and peri-pancreatic lymph nodes. Therefore, pancreatic TB mimics pancreatic malignancy. A fine needle aspiration cytology and a guided biopsy helps in differentiating TB from pancreatic malignancy. One must always should culture the tissue for *M. tuberculosis*. The other differential diagnosis include pancreatic lymphoma, chronic pancreatitis, and sarcoidosis.

TREATMENT OF TUBERCULOSIS

Medical Treatment

All patients with abdominal TB should be treated with standard anti-tuberculous drugs. The treatment of TB includes multiple drugs for a prolonged duration. Treatment using more than one drug is based on two principles: preventing acquired drug resistance and enhancing efficacy. Tubercle bacilli undergo random chromosomal mutations that make them resistant to drugs used to treat TB. Fortunately, these mutations are infrequent. Because they are unlinked (in terms of chromosomal location or function) and specific to a drug or drug class, spontaneous generation of an organism with multi-drug resistance is extremely uncommon. Acquired drug resistance for TB is almost always caused by inadequate treatment. Most of the guidelines on the treatment of TB suggest that short course treatment for 6 months is sufficient for extra-pulmonary TB except for bone TB and tuberculous meningitis. Despite these recommendations, many physicians treating abdominal TB use ATT for 9 months, sometimes even 12 months without any scientific justification. In a randomised controlled trial, Balasubramaniam *et al* showed almost equal efficacy of ATT given for 6 months (99%) versus 12 months (94%) in the treatment of abdominal TB.

The role of corticosteroid treatment in patients with abdominal TB is not well-established and these should not be routinely-administered to all patients.

Surgical Treatment

Surgery is required only in small number of patients with intestinal TB and other solid organ TB. The indications for surgery in intestinal TB are generally for the complications of the disease such as free perforation, confined perforation with abscess or fistula formation, intestinal obstruction not responding to usual conservative measures, and massive haemorrhage. A subset of patients despite effective ATT continue to have episodes of intestinal obstruction. This may occur because of two reasons: failure of ATT or residual tight fibrotic strictures. In such cases, the stricture is required to be removed. Stricturoplasty or resection of the diseased segment with end-to-end anastomosis is the routinely done procedure. Surgical procedures such as bypass surgery (entero-enterostomy, ileo-transverse colostomy) are not recommended for obstructive lesions as these procedures may facilitate the formation of blind loops leading to obstruction, malabsorption, or both. Strictures at ileocaecal region may be treated by limited ileocaecal resection with a 5 cm margin from a visible abnormal tissue or a limited right hemicolectomy and end-to-end anastomosis. Perforating ulcers are treated by excision of the perforated segment with primary anastomosis. Wherever appropriate, elective surgery should be performed after four to six weeks of ATT. Even after surgery, the course of medical treatment for TB should be completed.

13.12 Inflammatory Bowel Disease

Ajit Sood, Vandana Midha

INTRODUCTION

Chronic inflammatory bowel disease (IBD) includes ulcerative colitis (UC), a disorder in which inflammation affects the mucosa and submucosa of the colon, and Crohn's disease (CD), in which inflammation is transmural and may involve any or all segments of the gastrointestinal tract. Patients who have features of IBD but cannot be clearly categorised into any of these two diseases are labelled as having indeterminate colitis (IC).

EPIDEMIOLOGY

Both UC and CD are worldwide disorders, although the precise incidence varies considerably in different countries. The United States, Northern Europe and Scandinavian countries have higher rates compared to countries in Southern Europe, South Africa and Australia. In Asia, the disease was thought to be uncommon, but recent reports have highlighted the increasing incidence of the disease. The rapid changes in incidence and prevalence in Asia may point to environmental changes associated with the so-called 'Westernisation' of lifestyle (e.g. dietary changes, smoking, etc.) as potential risk factors.

IBD typically affects young people, but may have a bimodal incidence with a second peak in later life. Crohn's disease is frequently diagnosed in late adolescence or early adulthood, with a median age of diagnosis in the third decade. Men are slightly more likely to be affected with UC whereas women with CD.

AETIOPATHOGENESIS

Despite improved understanding of the mechanisms of intestinal inflammation, the aetiology and pathogenesis of IBD remain obscure. The pathogenesis involves an interplay of genetic, environmental, microbial and immune factors, which in combination result in chronic intestinal inflammation.

The most firmly established risk-factor for developing IBD is a positive family history. The incidence of IBD among first-degree relatives of IBD patients is 30 to 100 times that of the general population. Approximately 15% of patients with IBD have a first-degree relative suffering from either UC or CD; the risk being higher in patients with CD. Other factors suggesting genetic susceptibility are higher concordance amongst monozygotic than dizygotic twins, and ethnic differences in disease prevalence. However, no clear cut Mendelian pattern of inheritance has been established. Genome scans reveal that IBD is a complex genetic disorder with several predisposing genes. Linkage analyses have identified 16 susceptibility loci, of which those on chromosomes 1, 5, 6, 12, 14, 16 and 19 are important. The actual identification of NOD2/CARD15 within the IBD gene locus is an important breakthrough in genetic research for unraveling the aetiology of CD. The major histocompatibility complex or HLA genes on chromosome 6 have a greater role in modifying the IBD phenotype than overall disease susceptibility.

A dramatic rise in the incidence in recent decades points to environmental factors as potential risk factors for disease occurrence. Westernisation of lifestyle, such as changes in diet and variance in exposure to sunlight, pollution, and industrial chemicals, has been postulated to be responsible for the rising incidence. It is postulated that improved hygiene alters the intestinal flora by decreasing exposure to certain bacteria. This may explain the higher frequency of both UC and CD in higher socioeconomic groups. Studies seeking to link diet and IBD are generally inconclusive. There is some evidence that a higher intake of fatty acids increases the risk of IBD. Similarly, frequent fast-food intake confers a 3- to 4-fold greater risk of IBD. It has been observed that smoking is protective against UC while patients with CD who smoke are more likely to have frequent relapses. Appendicectomy has been reported to be a potential protective factor for UC. Other factors that may have a role in pathogenesis or precipitation of relapse are use of drugs like oral contraceptives, nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics and seasonal variation and mental stress.

Over the past decades, various pathogenic agents have been implicated including *Mycobacterium paratuberculosis*, *Listeria monocytogenes*, *Chlamydia trachomatis*, cytomegalovirus, measles virus, *Saccharomyces cerevisiae* and certain strains of *Escherichia coli*, *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*. However, these data have not been confirmed and antibiotics have not been effective in treating IBD. It has been postulated that the normal local flora may play an important role in the development and perpetuation of the disease. This is supported by the observation that surgical exclusion of small bowel loops resulting in loss of contact of bowel contents, can lead to disappearance of inflammatory changes in these bowel segments. On re-establishing the continuity, recurrence of inflammatory changes occur. In most animal models for experimental colitis, animals do not develop inflammation when they are maintained free of bacteria.

Unlike in healthy individuals, the equilibrium between pro- and anti-inflammatory cytokines is significantly deranged. This dysregulation of the immune reaction leads to excessive activation of pro-inflammatory cytokines. Excessive and prolonged activation of bowel-associated immune system may result in causation of IBD.

CLINICAL FEATURES

Symptoms suggestive of IBD include watery stools, blood or mucus in the stool, diarrhoea persisting for more than 4 weeks, crampy abdominal pain, nocturnal defaecation and fever. Weight loss is significant. Anal fissures, anal fistulae, frank bleeding per rectum and abdominal masses can occur. Symptoms are generally recurrent. Ulcerative colitis is a recurrent inflammatory disease of the colon and rectum

characterized by mucosal inflammation and ulceration. The disease starts in the rectum and spreads to a variable extent in a proximal direction. The inflammation is continuous and affects the entire circumference of the mucosal membrane. Pathological and histological features include diffuse inflammation of the mucosal membrane with ulceration, crypt abscesses, infiltrates and reduced number of goblet cells. The terminal ileum is rarely involved (backwash ileitis). The disease activity is categorised as active colitis or flare (active disease), remission (quiescent phase) or chronic continuous disease (partially active disease). The disease extent is variable and can be confined to the rectum (proctitis), rectum and sigmoid colon (proctosigmoiditis), may reach upto the splenic flexure (left-sided colitis) or may involve the transverse colon or beyond (pancolitis). Disease severity is categorised as mild, moderate or severe according to Truelove-Witts criteria (**Table 1**).

Crohn's disease is segmental, non-continuous, subacute or chronic inflammation that can affect any part of the digestive tract from the mouth to the anus, with a predilection for the distal ileum and colon. The inflammation is transmural and this can lead to internal abscesses and fistulae. The fistulae can be entero-enteric, entero-cutaneous, entero-vesical or entero-vaginal. The deeper layers of the intestinal walls may be more severely affected. Creeping fat around the diseased part of the intestine is very suggestive of CD.

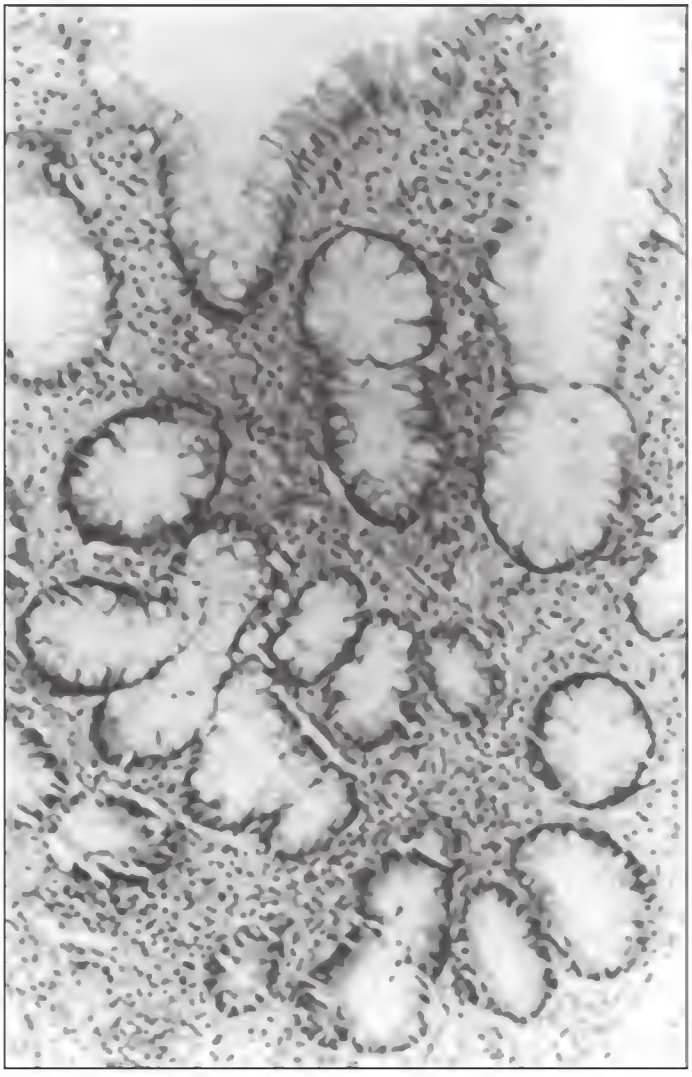

Figure 1: Microphotograph showing cryptitis, crypt abscess, crypt distoration and crypt branching along with villiform surface (x 550).
Courtesy Dr Ritambhara Nada.

Pathological and histological features include segmental transmural inflammation with micro-erosions, fissures, ulcerations, granulomas, infiltration, and dilated lymph vessels (**Figure 1**). The disease is most common in distal ileum and colon (50% of patients), small intestine only (25% to 30%), colon only (20% to 25%), rectum (10% to 15%) or gastroduodenal (3% to 5%). Anorectal disease like anal fistulae, anal fissures, perianal abscess can occur in 30% to 40% of patients. Comparative features of UC and CD are shown in **Table 2**.

Table 1: Severity of Ulcerative Colitis (Based as Truelove-Witts Criteria)

Features	Mild	Moderate	Severe
Bowel frequency	<4/day	4-6/day	>6/day
Rectal bleeding	Intermittent	Usual	Common
Fever	No	Possibly	Yes
Pulse	Normal	May be >90/min	>90/min
Abdominal tenderness	Absent	Often present	Present
Haematocrit	Normal	>30%	<30%
ESR	<30 mm		>30 mm

Table 2: Comparative Features of Ulcerative Colitis (UC) and Crohn's Disease (CD)

Features	Ulcerative colitis	Crohn's disease
Fever	Less common	Common
Abdominal pain	Mild	Moderate-to-severe
Diarrhoea	Common	Less common
Rectal bleeding	Very common	Less common
Perianal disease	Rare	Common
Abdominal mass	No	Common
Extent	Continuous, starts from rectum	Discontinuous, segmental
Rectal involvement	>90%	<50%
Ileal involvement	<10% (backwash ileitis)	Up to 50%
Anal lesions	Up to 25%	Up to 75%
	Acute fistula formation	Chronic fissures and fistulas
Bowel wall-thickness	Normal to slightly increased	Slight to significant thickening, fibrosed
Mucosa/submucosa	Haemorrhagic, oedematous,	Cobble stones, skip lesions
	Ulcerated	Aphthotic ulcerations
		Fissures
Pseudopolyps	Frequent	Rare
Hyperaemia	Significant	Slight, only in acute flare
Strictures	Rare	Frequent
Fistulae	None	Frequent
Bowel shortening	Yes (fibrous, segmental)	Yes Muscular
Toxic megacolon	Rare (<5%) More common in pancolitis	Rare (<5%)

EXTRAINTESTINAL MANIFESTATIONS

Both CD and UC may be accompanied by extraintestinal manifestations. In CD, nearly 40% of patients experience extraintestinal disease manifestations while this rate is significantly lower in UC. The symptoms can occur as initial symptoms, during the course of the disease or may even follow surgical removal of the diseased bowel. The various extraintestinal manifestations and complications are shown in **Tables 3 and 4**.

Table 3: Extraintestinal Manifestations

Skin	Erythema nodosum Pyoderma gangrenosum
Joints	Arthritis, ankylosing spondylitis, sacroilitis
Eyes	Iridocyclitis, uveitis
Lung	Alveolitis, lung fibrosis
Heart	Myocarditis
Liver	Primary sclerosing cholangitis, fatty liver
Blood	Thromboembolic complications Autoimmune haemolytic anaemia
Tissue	Amyloidosis

Table 4 : Extraintestinal Complications

Deficiencies

- Vitamin deficiency (A, B12, C, D, E, K): Osteomalacia, muscular atrophy, night blindness, hyperkeratoses and anaemia
- Mineral deficiency (iron, calcium, magnesium, zinc): Anaemia, osteomalacia, growth retardation, oligospermia, immune-deficiency
- Protein deficiency: Oedema

Absorption changes

- Hyperoxaluria, water loss: Kidney stones
- Bile acid deficiency: Gallstones

DIAGNOSIS

Chronic pattern of symptoms (persisting for more than 4 weeks), abdominal pain, diarrhoea, with or without blood, weight loss or growth disturbance raises a suspicion of IBD. The diagnosis is made on the basis of careful medical history, close observation of the clinical picture, the evaluation of endoscopic, histological and radiological findings and, finally, the results of laboratory investigations. Laboratory abnormalities include elevated ESR and C-reactive protein, thrombocytosis, anaemia, leucocytosis and hypoalbuminaemia. Stool examination is required to look for pus cells, RBC's, infective organism and markers of inflammatory exudation in the bowel like faecal calprotectin, α_1-antitrypsin and lactoferrin. Differentiation of CD and UC on the basis of laboratory parameters alone, however, is difficult. Antibodies such as p-ANCA (increased in UC) and anti- *Saccharomyces cerevisiae* antibody (ASCA, primarily in CD) shows too much overlap in the distribution to permit exact differentiation.

A plain X-ray film of the abdomen is indicated in patients with severe disease when there is suspicion of complications like toxic megacolon, ileus or perforation. Double contrast (**Figure 2**) barium examination of the colon used for long has been replaced by endoscopy. Small bowel series or enteroclysis is primarily used for evaluation of the small bowel. Although aphthoid and small erosions usually escape detection with these methods, enteroclysis effectively visualises ulcerations, cobblestoning, strictures and fistulae.

Computer tomography (CT) is sensitive in detecting both luminal and extra-luminal disease in patient with CD. It can recognise extra-intestinal complications with high sensitivity. However, subtle mucosal changes may escape detection with CT. MRI (magnetic resonance imaging) has, in comparison to CT, significantly better tissue contrast and because of the lack of radiation exposure has gained wide acceptance. In addition, MRI is more sensitive for detecting anorectal lesions. The main disadvantages of MRI in comparison with CT are poorer resolution and longer duration of examination. Both CT and MRI can be utilised for enteroclysis examination and mucosal details are delineated better.

The diagnosis of IBD is facilitated by direct inspection of mucosal membrane and stepped biopsies, which permit exact determination of the extent of disease. In early stages, the diagnosis is only possible using endoscopy, since small discrete mucosal lesions may not be visualised using radiology. Endoscopic findings in ulcerative colitis include pale mucosa, erythema, granularity, loss of mucosal visible vessels, ulcerations and contact and spontaneous bleeding. Pseudopolyps may be noticed in patients with chronic disease. The typical endoscopic characteristic of CD is the discontinuous spread of the disease: healthy mucosa alternates with affected segments and lesions are distributed asymmetrically. Endoscopic findings include aphthoid lesions in normal mucosa (early sign), bizarre 'map-like' ulcers and fissures, cobblestoning of mucosa which is caused by deep fissures, ulcerations and intact mucosa. Pseudopolyps are less common but an inflammatory mass may at times simulate growth. Wireless capsule endoscopy (CE), allows direct visualisation of the small bowel mucosa. Tight stricture or visceral fistulous communications should be excluded before planning CE. Enteroscopy (double balloon or

Figure 2: Double contrast barium enema showing multiple pseudopolyps in a patient of ulcerative colitis.
Courtesy: Dr B Nagi

single balloon) can be planned after localising the disease with more basic radiological investigations.

COMPLICATIONS

Ulcerative colitis can be associated with complications like massive haemorrhage, toxic megacolon, perforation, stricture and colo-rectal carcinoma. Toxic megacolon occurs when inflammation extends beyond the mucosa and the colon dilates excessively (transverse colon diameter >6 cm on plain X-ray). Clinical features suggestive of toxic megacolon include fever, tachycardia, leucocytosis and abdominal tenderness and distension. Perforation of the colon may complicate toxic megacolon but can also occur in cases of severe UC without toxic megacolon. Benign strictures are rare. The risk of development of colo-rectal carcinoma is high in patients with long standing disease, young age of onset of disease, pancolitis and presence of sclerosing cholangitis. Free perforation is less common with CD as serosal adhesions provide pathways for fistulae formation. Intestinal obstruction due to strictures occur more often in patients with CD. Malabsorption and nutritional deficiencies develop in patients with extensive small bowel involvement.

DIFFERENTIAL DIAGNOSIS

The diagnosis of UC or CD can be made when, after careful work-up, other causes of colitis or ileocolitis have been ruled-out. Many disorders can mimic the clinical, endoscopic or radiological picture of UC or CD (**Table 5**).

Table 5: Differential Diagnosis of UC and CD

- Bacterial infections
  - Tuberculosis
  - Campylobacter
  - *Salmonella* and *Shigella*
  - *Yersinia enterocolitica*
- Viral infections
- Parasitic infections
- Pseudomembranous colitis
- Ischaemic colitis
- Radiation enterocolitis
- Diverticulitis
- Primary intestinal lymphoma
- Behcet's disease
- Eosinophilic gastroenteritis
- Scleroderma
- Drug-induced colitis

MANAGEMENT

As the aetiology of IBD has not yet been established, curative therapy is yet not available. Treatment is aimed to eliminate symptoms during an acute flare or exacerbation as well as to maintain remission. The principal classes of drugs used in IBD are: 5-aminosalicylic acid (5-ASA) derivatives, corticosteroids and immunosuppressants. In recent years, anti TNF-α antibodies have been introduced in the therapy of IBD. They can be successful in corticosteroid-refractory disease. Therapeutic response leading onto remission occurs in nearly 75% of the patients with these drugs.

General Measures

No major dietary modification is required. Patients with strictures should avoid high-residue foods. Iron, calcium and vitamins supplements may be required if there is evidence of deficiency. Extensive terminal ileal resection may lead to vitamin B_{12}, fat and bile salt malabsorption, and hence vitamin replacement and low fat diet is recommended. Parenteral nutrition may be required in patients with fulminant disease.

Medical Therapy (Tables 6 and 7)

Sulphasalazine (SLZ)/5-aminosalicylic acid (5-ASA)

These agents are the mainstay of therapy for mild-to-moderate disease. Sulphasalazine (SLZ) consists of sulphapyridine and 5-ASA joined by a diazo bond, which is cleaved by colonic bacteria, releasing the active 5-ASA molecule and the inert antibiotic moiety. Sulphasalzine is started at low doses and is gradually increased to 4 to 6 gm per day and can be tapered by 1 to 2 gm per day during remission. Maximum dose of mesalamine is upto 4.8 gm for active disease while for maintenance, 800 to 1200 mg may be sufficient. Their role in maintenance of remission in Crohn's disease is less convincing. Main side-effects of SLZ are nausea, vomiting, headache, abdominal discomfort and haemolysis. Other side-effects include reduced sperm count, which is reversible after stopping the therapy. Side-effects are less with non-sulpha based 5-ASA agents, but nephrotoxicity is known to occur.

Table 6: Ulcerative Colitis—Therapeutic Options

Active disease	Maintenance therapy
Mild flare	
Mesalazine or sulphasalazine, olsalazine	Mesalazine or sulphasalazine Probiotics Azathioprine/6-MP
Moderate flare	
Mesalazine or sulphasalazine Corticosteroids Oral Topically acting, e.g. hydrocortisone, budesonide	
Severe flare	
Corticosteroids—intravenous Mesalazine or sulphasalazine Parenteral or enteral nutrition Intravenous cyclosporine A Anti-TNF-α antibodies Surgery	

Table 7: Crohn's Disease—Therapeutic Options

Active disease	Maintenance therapy
Mild-to-moderate flare	
Mesalazine or sulphasalazine Corticosteroids Topically acting: For example, budesonide Systemically acting: For example, prednisolone	Mesalazine (after surgery) Azathioprine/6-MP
Severe flare	**Chronic active course, steroid dependence and fistulae**
Corticosteroids Systemically acting: e.g. prednisolone Immunosuppressants Elemental diet Biologicals	Azathioprine Methotrexate If no response to immunosuppressants: Anti-TNF-α antibodies

Corticosteroids

Corticosteroids are effective in inducing remission but should not be used for maintenance of remission. Oral steroids are used for moderately active disease while severe disease generally requires intravenous administration. Steroid enema can be effective in treating left-sided UC. As systemic absorption of the steroid enaema is significant, long-term use should be avoided. Corticosteroids also produce remission in cases of CD; however, the presence of abscess should be excluded to minimise the risk of septicaemia. Oral prednisolone is usually started at the dose of 40 to 60 mg/day and gradually tapered off over the next 8 to 12 weeks.

The potential side-effects of corticosteroids are multiple and quite severe. They suppress intrinsic adrenal function and immune function. They may also induce hyperglycaemia, truncal obesity, cataracts, abdominal striae, myopathy, psychiatric disturbances, and avascular necrosis. Budesonide is a steroid having increased first-pass metabolism in the liver, and this results in less systemic toxic effects. Budesonide is preferred to conventional corticosteroids in patients with ileal and right colonic disease.

Immunomodulators

The role of immunologic mechanisms in the pathogenesis of IBD forms the basis for using immunomodulators. Azathioprine (AZA) and 6-mercaptopurine (6-MP) are useful for patients with UC who are steroid-dependent and suffer frequent relapses or are steroid-refractory. These agents also are beneficial in healing fistulae in CD. One major limitation of these agents is their delayed onset of action of 3 to 6 months. For this reason the primary role of these agents is in maintenance of remission and not to induce remission. Major side-effects of these drugs include nausea, vomiting, bone marrow toxicity, hepatitis, pancreatitis, alopecia and infections. Regular blood count and liver biochemical tests are recommended to detect toxic effects. The doses for 6-MP and AZA are 1.5 mg/kg/day and 2.5 mg/kg/day, respectively.

Cyclosporine (CSA), which is a potent inhibitor of T cells, has been found to be useful for patients with severe UC who do not respond to glucocorticoids. Cyclosporine may be able to avert colectomy in these patients. Patients require concomitant therapy with AZA/6-MP. Cyclosporine has not shown convincing efficacy in CD. Methotrexate (MTX) is a folic-acid antagonist and has both immunomodulatory and anti-inflammatory properties. Patients who do not tolerate AZA/6-MP may benefit from MTX. Mycophenolate mofetil and tacrolimus are other agents which have been tried with limited success. Infliximab is a mouse-human chimeric monoclonal antibody directed against tumour necrosis factor (TNF-α). This is effective in inducing remission in patients with refractory CD, in healing fistulae, and as maintenance therapy for CD. It has been used in UC also, but the results are less convincing. Reactivation of tuberculosis is known to occur with these biological drugs. These drugs may increase the risk of lymphoma.

Antibiotics/probiotics

Broad-spectrum antibiotics are required for treating complications of CD like abscess and perianal disease and small intestinal bacterial overgrowth which occur from stasis proximal to strictures. Metronidazole and ciprofloxacin have been shown to be beneficial. Antibiotics are not very useful in the treatment of UC. Probiotics are live bacteria that are non-pathogenic and confer health benefits beyond their nutritional value. *Escherichia coli*, Nissle, 1917 and VSL#3 are the probiotic preparations that have shown promise in the treatment of UC.

Miscellaneous agents

Nicotine patch has been shown to induce remission in patients with UC. Anti-diarrhoeal agents (loperamide, diphenoxylate), which may reduce stool frequency, and anti-cholinergic drugs, which can reduce pain and cramps, should be avoided in severe disease because of the risk of developing toxic megacolon.

Surgery

Patients with severe UC not responding to medical therapy or those who develop complications like toxic megacolon, perforation, massive haemorrhage, high-grade dysplasia or colon cancer need surgery. Ileal pouch-anal canal anastamosis is the procedure of choice for most patients. Surgery can be curative for patients with UC. Indications for surgery in CD include disease intractability, failure of medical therapy, intestinal obstruction, persistent fistulae, and abscess formation.

PREGNANCY AND IBD

Most pregnant women with IBD can carry their pregnancy normally, although the incidence of spontaneous abortion is slightly higher than that in the general population. Medical therapy which has achieved remission in such cases should not be stopped. However, drugs like CSA and infliximab should be avoided, if possible. Methotrexate is contraindicated during pregnancy.

13.13 Ischaemic Bowel Disorders

Deepak Kumar Bhasin

Gastrointestinal ischaemia is a rare disorder that is seen infrequently in routine clinical practice and, therefore, a high index of suspicion is required to diagnose it correctly that too in the early phase of intestinal ischaemia so that appropriate therapeutic measures can be instituted in time. The ischaemic bowel disease can be caused by occlusion of the supplying arteries or draining veins and the onset can be acute or chronic. The ischaemia can also be caused by physiological vasoconstriction during low perfusion states. Each subtype of intestinal ischaemia requires its own diagnostic and therapeutic plan. Earlier digital subtraction angiography (DSA) was the mainstay for diagnosis of intestinal ischaemia but recently computed tomography (CT) and magnetic resonance (MR) angiography have emerged as effective alternatives for imaging splanchnic vessels. Because of rarity of intestinal ischaemia there are no randomised controlled trials. The treatment protocols are usually based on case series and clinical experience. The treatment of intestinal ischaemia is individualised and is mainly based on precise vascular anatomy, co-morbidity and severity of ischaemia. The advancement in therapeutic angiography has revolutionised the management of these disorders.

CLINICAL ANATOMY

Stomach, small intestine and colon are supplied by three major arteries. Celiac artery supplies stomach, proximal duodenum, liver and spleen. Superior mesenteric artery (SMA) supplies distal duodenum, rest of the small intestine, right colon and upto proximal two-thirds of the transverse colon. Inferior mesenteric artery (IMA) supplies from the distal third of the trasnverse colon to the proximal rectum. Distal rectum is supplied by the inferior rectal branch of the internal iliac artery. Splenic flexure and sigmoid colon have limited anastomosis; thus, ischaemic injury is more common in these areas. There are three pathways of communication between SMA and IMA: (i) marginal artery of Drummond which runs parallel to the intestinal wall, (ii) arch of Riolan, and (iii) central anastomotic artery.

PATHOPHYSIOLOGY

Splanchnic circulation receives one-fifth of the cardiac ouput, and this blood flow can increase up to 2 L/min post-prandially. The bowel can tolerate three-fourths reduction in its blood supply for up to 10 to 12 hours after which vasoconstriction and ischaemic injury develop. This is secondary to hypoxia and re-perfusion injury that sets in due to the reactive oxygen species following establishment of the blood flow.

CLINICAL FEATURES

Gastrointestinal ischaemia can be acute or chronic and both of these can be due to occlusive and non-occlusive lesions of the blood vessels known as non-occlusive mesenteric ischaemia (NOMI). Early diagnosis of mesenteric ischaemia is the key for successful management of these potentially catastrophic disorders.

Acute Mesenteric Ischaemia (AMI) or Acute Splanchnic Syndrome

It is by far more common than chronic mesenteric ischaemia. It is most commonly due to an embolism into the SMA that arises from the heart in about a half of the cases. Many of them also have a history of previous peripheral arterial emboli. These emboli lodge at the normal anatomical narrowing. Emboli are labeled major when they are lodged proximal to the origin of ileocolic artery. The most important symptom of acute mesenteric arterial occlusion is severe abdominal pain, which is out of character to the physical findings early in the course of the illness. This difference between the patient's presenting complaints and the lack of physical findings, which usually is responsible for delay in establishing the correct diagnosis is the most important feature of AMI. When physical findings arise that usually denotes that bowel infarction has set in.

Non-Occlusive Mesenteric Ischaemia (NOMI)

It occurs because of compromise of intestinal blood flow in the absence of an anatomic arterial occlusion or venous thrombosis as a result of severe mesenteric vasoconstriction. This usually occurs in the setting of low cardiac output or diseases associated with dehydration or hypo-perfusion like septicaemia, haemorrhage, shock, severe diarrhoea and those diseases where third-space fluid sequestration occurs, such as pancreatitis and burns. Because of more focus on underlying condition, the correct diagnosis of NOMI is ignored and delayed.

Mesenteric Venous Thrombosis (MVT)

It is predisposed by underlying hypercoagulable states, inflammatory conditions like diverticulitis, portal hypertension, etc. Selective mesenteric angiography can differentiate venous from arterial thrombosis. CT and MR can also demonstrate thrombus in the mesenteric veins.

Acute Superior Mesenteric Artery Thrombosis (SMAT)

It occurs in the areas of severe atherosclerotic narrowing. On angiography absence of collateral vessels denote acute occlusion.

Ischaemic Colitis and Colonic Ischaemia

These can have a spectrum of presentation in the form of: (i) transient colitis, (ii) chronic colitis, (iii) reversible colopathy, (iv) stricture, (v) gangrene, and (vi) fulminant universal colitis. Changes of ischaemia can vary from mild form of mucosal oedema to transmural infarction. In most cases of colonic ischaemia a specific cause cannot be identified. Patients most commonly present with sudden onset of crampy pain in the left lower abdomen followed by diarrhoea with bright red or maroon blood. Watershed areas of splenic flexure and rectosigmoid are involved in non-occlusive ischaemic injury.

Chronic Mesenteric Ischaemia [Chronic Splanchnic Syndrome (CSS), Intestinal Angina]

Patients typically have post-prandial pain which can last for 1 to 3 hours. There is fear of eating because of pain, resulting in weight loss. They can also have pain in the abdomen after exercise, history of nicotine abuse, classical abdominal angina and bruit on auscultation of the abdomen. Uncommonly they may have unexplained gastric ulcers or gastroparesis. It can be a single-vessel disease or multi-vessel disease former can be due to atherosclerosis or compression by the crus of the diaphram. Since there are a large number of collaterals, it is considered that single-vessel stenosis is usually asymptomatic. A classical example is coeliac artery compression syndrome. In multi-vessel disease, symptoms are as mentioned above and it is a big challenge even for the most experienced clinician to make a diagnosis as presentation can mimic simple dyspepsia and unexplained diarrhoea.

DIAGNOSIS

Routine blood investigations early in the course of intestinal ischaemia are usually normal. The findings of leucocytosis, acidosis, and elevated amylase level usually suggest advanced intestinal ischaemia and likely infarcted bowel.

Plain radiograph of the abdomen may show evidence like formless loops of intestine and thumb printing. In AMI it may show gas in the portal venous system. The main role of abdominal radiography lies in ruling-out other causes of acute abdomen. Duplex ultrasound is most frequently used modality for diagnosis. Air filled stomach, at times interferes in the visualisation of coeliac artery and SMA. Blood flow pattern and velocity can be measured to diagnose stenosis of arteries. It is recommended that duplex ultrasound should be done in fasting as well as post-prandial status.

CT angiography performed on multi-slice CT scanner can detect abnormalities in splanchnic arteries, veins and collaterals. Beside this, it can rule out alternate possibilities, such as perforation, pancreatitis, etc. MR angiography with contrast enhancement has been used to assess narrowing of splanchnic arteries. It has a sensitivity and specificity of more than 90%, but there is marked inter-observer variation in interpretation of stenosis. Digital subtraction angiography can detect lesions which can be treated in the same session and it provides a road, map for operative revascularisation. Thus it is the investigation of choice.

Endoscopy is preferred to barium studies. In colonic ischaemia it may show areas of haemorrhagic nodules, ulceration, friability which are segmental thus differentiating it from ulcerative colitis. Care should be taken not to overdistend the colon with air. Upper gastrointestinal endoscopy may reveal gastric ulcers.

In ischaemia there is increased carbon dioxide tension in the tissue. Tonometry measures the difference in luminal and arterial pCO_2. In chronic ischaemia gastric tonometry has been used following exercise to increase the yield of diagnosis.

Other investigations include serum D-lactate and I-FABP (intestinal fatty acid binding protein) have been used as markers for intestinal ischaemia.

MANAGEMENT

It is important to diagnose these patients before infarction of intestine sets in. It is necessary to use angiography judiciously and to relieve vasoconstriction by intra-arterial infusion of papaverine. We have to decide whether we are dealing with acute or chronic ischaemia, if chronic, which and how many vessels are involved, are there any co-morbid conditions, has infarction of intestine got established.

Acute Mesenteric Ischaemia (AMI)

Resucitate the patient, correct underlying hypovolaemia, treat underlying conditions like congestive heart failure, start broad-spectrum antibiotics. Confirm the diagnosis by CT angiogrpahy, contrast enhanced MRI, or selective angiography. Based on findings of angiography, plan further treatment and also infuse papaverine at the rate of 30 to 60 mg per hour to keep the blood vessels patent. In case infarction of intestine has set in proceed for surgical treatment.

For patient with SMA emboli, if peritoneal inflammation has set in, embolectomy and bowel resection is performed. Continue intra-arterial papaverine before, during and up to 24 hours in the post-operative period. If there are no features of peritoneal inflammation cases with minor emboli can be treated by intra-arterial infusion of papaverine, vasodilators and thrombolytic agents like streptokinase, urokinase, recombinant tissue plasminogen activator. Patients with major emboli may need surgical exploration.

Non-Occlusive Mesenteric Ischaemia (NOMI)

Intra-arterial infusion of papaverine should be given and if peritoneal signs are present, resect the necrotic bowel. When peritoneal signs are absent, patients can be managed with intra-arterial infusion of papaverine. Apart from treating underlying conditions, nitrates, ketanserin and sympathetic alpha receptor blockers have been tried with some benefit.

Acute SMAT

An attempt is made to place angiography catheter in proximal SMA and papaverine infusion is started. Thrombolytic agents and percutaneous angioplasty have also been employed.

Acute MVT

In case peritoneal signs are present, laparotomy and resection of the infarcted bowel is performed. In the absence of peritoneal signs immediate heparinisation followed by oral anti-coagulation for 3 to 6 months is used.

Chronic MVT

The main aim is to control the bleeding from varices by endoscopic banding and sclerotherapy.

Colonic Ischaemia

If there are signs of gangrene and infarction of bowel, patient should be operated upon. In the absence of these signs parenteral fluids and broad-spectrum antibiotics should be administered. Rectal tube should be inserted if colonic distension is present. Underlying cardiac failure and arrhythmia should be treated. In half of the cases of colonic ischaemia disease is reversible.

In patients with ischaemic stricture of colon, surgery is required in case of symptomatic obstruction. Endoscopic balloon dilatation can be used to relieve the obstruction.

Chronic Magnetic Ischaemia (Chronic Splanchnic Syndrome)

Single-vessel disease

In coeliac artery compression syndrome, relief of compression from diaphragmatic crus tends to relieve the symptoms.

Multi-vessel disease

Patients can proceed to acute splanchnic syndrome. Aim of treatment is to relieve obstruction and prevent acute splanchnic syndrome. Patients are strongly advised to stop smoking. Revascularisation can be done by surgery or percutaneous transluminal mesenteric angioplasty with or without stent placement.

Angioplasty is a recent advancement and high-risk patients not fit for surgery can undergo this form of therapy. However, recurrence of symptoms are more when compared to surgical revascularisation.

Follow-up

A severe reperfusion injury can set in, manifesting with nausea, abdominal pain, diarrhoea. Massive ascites may develop. To distinguish reperfusion injury from vessel re-occlusion, CT or MR angiography should be used to assess the patency of the vessel.

CONCLUSION

The wide spectrum of ischaemic bowel disease includes a number of disorders and each type of requires its own plan of management. The hallmark of diagnosis is high index of suspicion.

Aim should be to diagnose and manage the patient before intestinal infarction sets in. Mesenteric angiography (conventional or CT or MR angiography) should be done if no cause for the pain is found on plain radiographic film of the abdomen or CT in a patient suspected to have mesenteric ischaemia. Treatment options, including non-invasive, minimal invasive and classical open vascular reconstructive techniques, are available and require a multi-disciplinary team-approach for selection of appropriate case for appropriate treatment. The role of anti-coagulants and thrombolytics in mesenteric ischaemia is evolving.

13.14 Gastrointestinal Symptoms in Systemic Diseases

Rakesh Tandon, Sudeep Khanna

Gastrointestinal (GI) symptoms may be a manifestation of an extra-abdominal or a systemic disease, the prime examples being chronic diarrhoea in diabetes or hyperthyroidism and constipation in hypothyroidism. It is important to keep this fact in mind while doing the clinical examination of a patient who presents with abdominal pain, nausea, vomiting, diarrhoea, constipation or jaundince.

Given below are some diseases that should be considered while investigating the patients presenting with the common gastrointestinal symptoms.

ABDOMINAL PAIN

Abdominal but Extra-Gastrointestinal Causes of Pain

1. ***Diseases of kidney, ureters and urinary bladder***

   Pyelonephritis: The patient may be a diabetic who presents with flank pain or a diffuse abdominal pain. The pain may radiate downwards. Fever may or may not be present. Urine examination will show pus cells. CECT should be diagnostic.

   Cystitis: Depending upon the clinical scenario, this may be bacterial, viral or fungal infection of the bladder. The patient may have an underlying immunocompromised state. The pain is generally localised to the lower abdomen.

   Ureteric stone: Sudden onset, shooting pain with difficulty in passing urine, haematuria and radiation to the testis is highly suggestive of ureteric colic.

2. ***Gynaecological conditions***

   Endometritis: The pain is generally associated with onset of menstruation and would disappear during pregnancy. MRI pelvis may pick-up the diagnosis. Laparoscopy may however, be needed to confirm.

   Acute salpingitis with or without tubo-ovarian abscess: Acute lower abdominal pain may be the first presentation. History of multiple sexual partners or sexually transmitted diseases may be forth coming. CT scan and/or MRI are good radiological modalities to pick-up the pathology.

   Ovarian cysts or torsion: Sudden onset tearing pain in pelvis is the hallmark. CECT is the investigation of choice. Surgery is curative.

   Ectopic pregnancy: The patient will present with acute lower abdominal pain and vaginal bleeding. There is a history of amenorrhoea. Ultrasonography (USG) may pick-up the ectopic pregnancy. If not, CECT/MRI may be done. Urine pregnancy test will be positive.

3. ***Abdominal aortic aneurysm***

   The pain is sudden acute, severe, constant, localised to the mid-abdomen or paravertebral or flank areas. The pain is tearing in nature and associated with prostration, light-headedness, and diaphoresis. If the patient does not sccumb to it on the way to the hospital, shock is the most common presentation. Physical examination reveals a pulsatile, tender abdominal mass in about 90% of cases. The classic triad of hypotension, a pulsatile mass, and abdominal pain is present in 75% of cases and mandates immediate surgical intervention.

Extra-Abdominal Causes of Acute Abdominal Pain

Cardiac

1. Myocardial ischaemia and infarction
2. Congestive heart failure (CHF)
3. Endocarditis
4. Myocarditis

Epigastric pain is classical of inferior wall ischaemia. It is important to think of it in the elderly, diabetic, hypertensive patient or the patient with a known history of coronary artery disease. The excruciating nature of the pain and associated symptoms like rapid or irregular heart beat, nausea/vomiting or pain radiation to chin or left arm may further alert the clinician to this possibility.

CHF may present with right upper quadrant pain and a tender hepatomegaly. Presence of pedal oedema and fullness of neck veins suggest the diagnosis of CHF. Pulse may be irregular in any of the above conditions. Past-history may be contributory. ECG, Echocardiogram, Trop-T tests will clinch the diagnosis.

Thoracic

1. Oesophageal rupture and spasm
2. Empyema, pneumonia and pneumothorax
3. Pulmonary embolism and infarction
4. Abdominal aortic aneurysm

All the above-mentioned conditions would be generally associated with chest pain. History of fever with cough may suggest empyema and lower lobe pneumonitis. Sudden onset pain and breathlessness would favour the diagnosis of pneumothorax and pulmonary embolism in the appropriate clinical setting.

Haematological causes

1. Haemolytic anaemia, e.g. sickle cell anaemia
2. Henoch-Schönlein purpura (HSP)
3. Haemolytic uraemic syndrome

Patients with HSP may present with the classical triad of palpable purpura (**Figure 1**), abdominal pain and arthritis. Renal involvement and GI bleeding may occur (**Figure 2**). Haemolytic uraemic syndrome is characterised by haemolytic anaemia, thrombocytopaenia and renal failure. It is a disease of children and abdominal manifestations include bloody diarrhoea, abdominal pain and vomiting.

Figure 1: Palpable purpura on lower extremities in a patient with HSP.

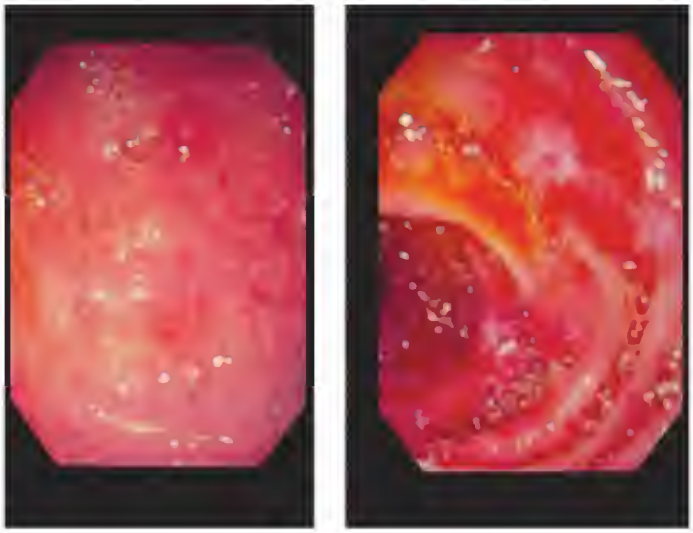

Figure 2: Erosions and erythema in duodenum and stomach in HSP.

Haemolytic anaemias may present as cholecystitis due to pigment gall stones, pain due to splenic infarct and abscess specifically with underlying sickle cell disorder.

Metabolic disorders

1. Acute adrenal insufficiency (Addison's disease)
2. Diabetes mellitus (especially with ketoacidosis)
3. Hyperlipidaemia
4. Hyperparathyroidism
5. Porphyria
6. Uraemia

Acute adrenal insufficiency may present as non-specific abdominal pain with vomiting and/or diarrhoea. There may be significant hyponatraemia. History of autoimmune disorders, tuberculosis, sarcoidosis may be present. Diabetes may present as abdominal pain due to neuropathy or more importantly due to uncontrolled sugar levels with sepsis and ketoacidosis. Acidotic breathing will give a clue. Blood sugar levels, arterial blood gases and urine ketones will clinch the diagnosis. Hypertrighlyceridaemia level (>1,000 mg/dL) can cause acute pancreatitis and, thus, present with severe epigastric pain with radiation to the back and vomiting. Hyperparathyroidism (primary) is seen most frequently in post-menopausal women. Most of the patients are asymptomatic. Among the symptomatic patients the presentation may be with acute epigastric pain of pancreatitis or dull to severe epigastric or right upper quadrant pain of gastric or duodenal ulcers. Involvement of kidneys, nervous system and musculoskeletal system will provide further clues to the diagnosis. Elevated serum ionised calcium levels, low serum phosphorus and normal or elevated serum alkaline phosphatase are also present.

Abdominal pain is present in more than 90% of patients during an acute attack of porphyria, followed in frequency by tachycardia and dark urine in about 80% of patients. Neuropsychiatric features include hysteria, depression, psychosis, confusion, hallucinations, seizures, and coma. Other features are constipation, pain in extremities, paraesthesias, nausea, vomiting, urinary retention, hypertension, peripheral sensory deficits (often in a 'bathing trunk' distribution), and weakness leading to ascending paralysis or quadriplegia. These neurologic attacks appear to be related to the over-production of ALA and porphobilinogen (PBG), which leads to higher serum and tissue levels of these neurotoxic products.

Patients with underlying chronic kidney disease (CKD) can present with acute abdominal pain secondary to ulcer disease or pancreatitis which are more common in this setting. Past-history of CKD and a serum creatinine level will give the clue towards the diagnosis.

Neurological conditions

1. Herpes zoster
2. Abdominal epilepsy
3. Transverse myelitis
4. Radiculopathy

Abdominal epilepsy is an exceptionally rare syndrome of epilepsy that is more likely to occur in children than adults. Very little is known about abdominal epilepsy. There have only been 36 cases reported in medical journals in the last 40 years. With abdominal epilepsy, seizure activity causes abdominal symptoms. For example, it may cause pain and nausea. Anti-convulsant medications can improve the symptoms.

With abdominal epilepsy, the seizures are thought to affect primarily the digestive system, resulting into the following GI symptoms:

(a) Abdominal pain, usually sharp or cramping and lasting seconds to minutes
(b) Nausea and/or vomiting
(c) Fatigue, lethargy, or sleep following seizures
(d) Altered level of consciousness, such as confusion or unresponsiveness, and
(e) Convulsive seizures known as generalised tonic-clonic seizures

People with reported abdominal epilepsy have different patterns of symptoms. Symptoms may also vary in the same person from one time to the other. For example, a person might have convulsive seizures and abdominal pain during one episode. Then the person may only have abdominal pain during another seizure.

Herpes zoster presents with severe pain/paraesthesia along a dermatomal distribution. One needs to think about it in the

differential diagnosis so that unnecessary tests are not conducted.

Miscellaneous causes

1. Narcotic withdrawal
2. Familial mediterranean fever
3. Muscle contusion, subcutaneous/parietal haematoma
4. Heat stroke
5. Psychiatric disorders

Narcotic drugs produce their effect by stimulating opioid receptors in the central nervous system (CNS) and surrounding tissues. The abuse of narcotics occurs as a result of the euphoria and sedation that narcotics produce within the central nervous system. Narcotics used for short-term medical conditions rarely require weaning since stopping the medication after a brief period rarely produces adverse effects.

The withdrawal syndrome from narcotics generally includes signs and symptoms opposite of the drug's intended medical effects. The severity of the withdrawal syndrome increases as the drug dose increases. The longer the duration of the physical dependence, the more severe is the withdrawal syndrome. Although uncomfortable, acute narcotic withdrawal for adults is not considered life-threatening unless the person has a medical condition that compromises his/her health (for example, if someone has severe heart disease). Some of the signs and symptoms of narcotic withdrawal include: anxiety, irritability, increased respiratory rate, yawning, rhinorrhoea, goose bumps, hypersalivation, nausea, vomiting, abdominal cramps, muscle cramps, diarrhoea, confusion, etc.

Familial mediterranean fever (FMF) is an inherited disorder featuring short recurring crises of severe abdominal pain and bouts of fever. Other symptoms include arthritis, chest pain from inflammation of the lung cavity and skin rashes. In between the attacks, the patient looks and feels healthy. Amyloidosis (the abnormal deposition of a particular protein, called amyloid, in various tissues of the body) is a potentially serious complication and can develop without overt attacks of FMF. The kidney is a prime target for the amyloid.

Daily use of the drug colchicine prevents attacks of fever in 60% of patients and significantly reduces the number of attacks in another 20% to 30% of patients.

Heat exhaustion results from prolonged heavy activity in a hot environment with subsequent dehydration, electrolyte loss and rectal temperature more than 37.8°C but less than/equal to 40°C. Heat stroke is a continuum of heat exhaustion with core temperature more than 40°C and neurological manifestations. Nausea, vomiting and abdominal cramps can be seen in both the conditions.

NAUSEA AND VOMITING

Nausea, retching, and vomiting may occur separately or together. Vomiting is a complex act that requires central neurologic coordination, whereas nausea and retching do not imply activation of the vomiting reflex. Nausea is an unpleasant subjective sensation that most people have experienced at some point in their lives and usually recognise as a feeling of impending vomiting in the epigastrium or throat. Retching consists of spasmodic and abortive respiratory movements with the glottis closed. When part of the emetic sequence, retching is associated with intense nausea and usually ends in vomiting.

Principal Extra-Gastrointestinal Causes of Nausea and Vomiting

Drugs

1. Aspirin and other NSAIDs
2. Anti-tuberculosis drugs
3. Steroids
4. Antibiotics, e.g. nitrofurantoin, clarithromycin, doxycycline, etc.
5. Anti-diabetic drugs, specifically metformin
6. Oral contraceptives
7. Theophyllines
8. Chemotherapeutic agents
9. Anti-retrovirals
10. Anti-arrhythmics, e.g. quinidine, digoxin
11. Antiprotozoals
12. Azathioprine
13. Sulphasalazine

Non-gastrointestinal systemic infections

1. Pneumonias
2. Meningitis
3. Urinary tract infections
4. Myocarditis

Patients with pneumonia may complain of associated pleuritic pain, cough with expectoration and breathlessness. Those with meningitis would present with fever, headache, neck rigidity and neurological signs. Urinary tract infections may be associated with burning micturition and flank pain along with fever.

Metabolic and endocrine causes

1. Addison's disease
2. Porphyrias
3. Diabetic ketoacidosis
4. Hypercalcaemia
5. Hyponatraemia

Labyrinthine disorders

1. Labyrinthitis
2. Meniere's disease
3. Motion sickness
4. Otitis media

History of related specific ear complaints will give a clue, e.g. presence of tinnitus, vertigo, ear discharge, etc.

Neurological disorders

1. Hydrocephalus due to any cause including tuberculous meningitis, normal pressure hydrocephalus
2. Brain abscess
3. Large infarct
4. Intracerebral bleed
5. Subdural haematomas

The onset of neurological signs will give a clue. Presence of projectile vomiting without nausea is characteristic of a

neurological illness. There will be presence of focal neurological signs.

Other causes include cyclical vomiting syndrome (there are days of vomiting followed by months of no episodes of vomiting during which the patients gain weight lost during the acute episode), eating disorders [bulimia (binge eating followed by induced vomiting)], alcohol binge, radiation therapy.

DIARRHOEA

Metabolic and Endocrine Disorders

1. Addison's disease
2. Diabetic autonomic neuropathy
3. Amyloidosis
4. Hyperthyroidism
5. Medullary carcinoma of thyroid
6. Phaeochromocytoma

Diarrhoea in diabetic autonomic neuropathy is either due to intestinal hurry or bacterial growth. Secondary amyloidosis may present as chronic diarrhoea with features of malabsorption. Renal involvement in the form of proteinuria is a prominent feature. Patients with hyperthyroidism will have associated tachycardia, tremor, hyper-reflexia, anxiety, heat intolerance, sweating, weight loss, etc. Patients with phaeochromocytoma presenting with diarrhoea will have associated hypertension (which may be sustained or paroxysmal), headache, palpitation and hyperhidrosis during the attack.

Drugs (need to be considered while taking the clinical history)

1. Antacids containing magnesium
2. Anti-arrhythmics (quinidine)
3. Antibiotics
4. Anti-neoplastic agents
5. H2-receptor antagonists, protein pump inhibitors
6. Theophylline
7. Various herbal preparations, etc.

CONSTIPATION

The various non-GI causes of constipation that need to be considered in differential diagnosis include:

Metabolic and Endocrinologic Disorders

Diabetes mellitus, hypothyroidism, hyperthyroidism, hypokalaemia, hypercalcaemia, pregnancy, phaeochromocytoma, panhypopituitarism, porphyria, heavy metal poisoning.

Medications

Calcium channel blockers, mu-opioid agonists (e.g. loperamide, fentanyl, morphine), anticholinergic agents (e.g. antispasmodics, anti-psychotics, tricyclic anti-depressants, etc.), anti-convulsants (e.g. phenytoin, carbamazepine, etc.), antacids, diuretics, NSAIDs.

Neurologic and Myopathic Disorders

Progressive systemic sclerosis, amyloidosis, dermatomyositis, multiple sclerosis, Parkinsonism, intestinal pseudo-obstruction, etc.

FAECAL INCONTINENCE

Among the systemic diseases which may cause faecal incontinence, the predominant ones are various neurological disorders including: dementia, mental retardation, stroke, brain tumour, spinal cord lesions (e.g. multiple sclerosis, *tabes dorsalis*), peripheral nervous system disorders including *cauda equina* lesions, diabetes mellitus, various polyneuropathies, sedation and hypothyroidism.

1. *Endocrinopathies:* Hyperthyroidism, Addison's disease, various neuroendocrine tumours (discussed earlier), medullary carcinoma thyroid, mastocytosis and phaeochromocytoma.
2. *Disordered motility:* Post-vagotomy diarrhoea, post-sympathectomy diarrhoea, diabetic autonomic neuropathy.
3. *Infiltrative diseases like lymphoma.*

The disease-symptom associations given above are only a few examples of the wide variety of manifestations of the diseases. Metabolic and endocrine disorders are the commonest in this category and some of them have been cited above. Neoplasia and connective tissue disorders are other groups of diseases that often manifest with GI symptoms. Intestinal metastases occur in up to 20% of all non-gut cancers. Breast, lung, ovarian cancer and melanoma are the commonest source. Serosal metastases may cause pain, *ascites*, obstruction or recurrent GI bleeding. Paraneoplastic pseudo-obstruction is a rare feature of small cell lung cancer. Chemotherapy can cause diarrhoea due to *Clostridium difficile* infection (especially, with neutropaenia), mucositis or autonomic neuropathy.

Connective tissue disorders such as rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus may present with dysphagia or other GI manifestations like diarrhoea or malabsorption or abnormal liver function tests, particularly raised serum alkaline phosphatase. Behcet's syndrome is a rare cause of ileocolic disease.

The clinician should, thus, always keep in mind that the gastrointestinal or abdominal symptoms may reflect diseases pertaining to organs away from the gastrointestinal tract.

14.1 Basic Considerations of Hepatobiliary Disorders

Vivek Anand Saraswat

INTRODUCTION

The normal liver occupies the right upper quadrant, extending from the 5th intercostal space in the midclavicular line to the right costal margin. With a median weight of 1800 g in men and 1400 g in women, the liver is the largest organ in the body and accounts for 4% to 5% of total body weight at birth and 2% to 3% after the first year of life. It is strategically situated, being the first organ to receive nutrient-enriched blood supply from the portal system, and its unique vascular structure provides hepatocytes with unparalleled access to nutrients and xenobiotics absorbed from the intestinal lumen, enabling it to serve key functions in critical metabolic and synthetic pathways.

FUNCTIONS OF THE LIVER

The liver is a factory, a storehouse, a filter, a policeman and above all, orchestrator and regulator of the complex ballet of metabolic functions that keeps the body running. It is an excretory organ, an endocrine organ, an immune organ, at times a haemopoeitic organ. Its various functions include processing and redistribution of metabolic fuels such as glucose and fatty acids, and modification and detoxification of compounds absorbed from the small intestine for which the liver contains a host of biochemical pathways. The functions are summarised in **Table 1**.

Table 1: Functions of the Liver

Regulation of *intermediary metabolism* ensures a constant supply of fuel (glucose, ketone bodies) to the entire body during periods of fasting and stress
Lipid and cholesterol metabolism and reverse cholesterol transfer
Interorgan *trafficking of aminoacids* and *synthesis of essential aminoacids*
Excretion of endogenous and exogenous toxins, directly through bile or indirectly by converting to polar compounds excreted through the kidneys
Storage of excess energy fuels (e.g. glycogen, fats) and vitamins (e.g. vitamin A)
Synthesis of plasma proteins, e.g. albumin, coagulation factors, complements C3, C4, α1-antitrypsin, caeruloplasmin, transferrin, ferritin, orosomucoid, haptoglobin, serum amyloid A protein, etc.

Intermediary Metabolism

A major responsibility of the liver is to provide a continual source of energy for the entire body. The liver's ability to store and modulate the availability of systemic nutrients is regulated by numerous local factors and the requirements of peripheral organs for energy sources. Hepatic metabolic function is subject to hormonal modulation by endocrine organs, such as the pancreas, adrenal gland, and thyroid, as well as to neuronal regulation. The liver regulates nutrient flux during periods of nutrient absorption (meals), when absorbed nutrients are metabolised, modified for storage in the liver and fatty tissue, or made available to the remaining organs as sources of energy metabolism, and during non-absorptive periods (fasting), when metabolic requirements need to be maintained from stored fuel sources or by synthesis. The regulation of these metabolic pathways involves complex interactions among the nutrient content of the blood, end-products of nutrient metabolism that are present in the blood and represent precursors for hepatic synthesis, and hormonal regulation.

Ammonia Handling by the Liver

Liver is the principal site of conversion of ammonia to urea. Nearly one-fourth of the nitrogen incorporated into urea comes from ammonia generated in the splanchnic viscera by bacterial degradation of luminal urea in the colon and from breakdown of glutamine extracted from the arterial blood by small intestinal enterocytes. The rest of the urea nitrogen comes from the breakdown products of aminoacids (alanine and glutamine) transported to the liver. In the liver, there are two methods of ammonia disposal: a low-affinity, high-capacity urea synthesis localised to the periportal hepatocytes and a high-affinity, low-capacity glutamine synthesis by the perivenous hepatocytes. Since the synthesis of each mole of urea utilises 2 moles of bicarbonate, the liver also plays an important role in pH regulation. The urea cycle and synthesis of glutamine illustrate how compartmentalisation of hepatic metabolic pathways in different zones leads to efficient utilisation of metabolic by-products. Ammonia is converted to urea by the concerted activity of urea cycle enzymes in the liver. This high-capacity, low-affinity system is located predominantly in the periportal and central zones of the liver acinus. These same populations of cells also are the principal sites of ammonium generation as a by-product of amino acid metabolism. Glutamine synthesis utilises ammonium and is catalysed by glutamine synthetase, which is expressed exclusively in hepatocytes lining the pericentral vein. Pericentral hepatocytes thus scavenge ammonium and convert it to glutamine, thereby eliminating toxic ammonium from the systemic circulation.

Bilirubin Handling by the Liver

Jaundice or icterus is the hallmark of hepatobiliary disease and reflects a breakdown in the orderly sequence of bilirubin production, transport and biliary excretion that keeps serum bilirubin levels within a narrow range of 0.2 to 0.8 mg/dL.

Bilirubin Metabolism

Briefly, bilirubin is mainly produced in the spleen from the break down of the haem moiety of haemoglobin derived from senescent red cells. It is transported to the liver bound to albumin and is taken up by the hepatocytes where it undergoes microsomal conjugation to bilirubin mono- and diglucuronides. These conjugates are then actively transported to the biliary canaliculus, then through the intra- and extra-hepatic biliary

channels to the intestine, from where they are largely excreted in faeces (**Figure 1**). A small amount undergoes bacterial deconjugation and conversion to urobilinogen that undergoes enterohepatic circulation and renal excretion. Perturbations at each of these steps, which are elaborated below, may result in the clinical outcome of jaundice.

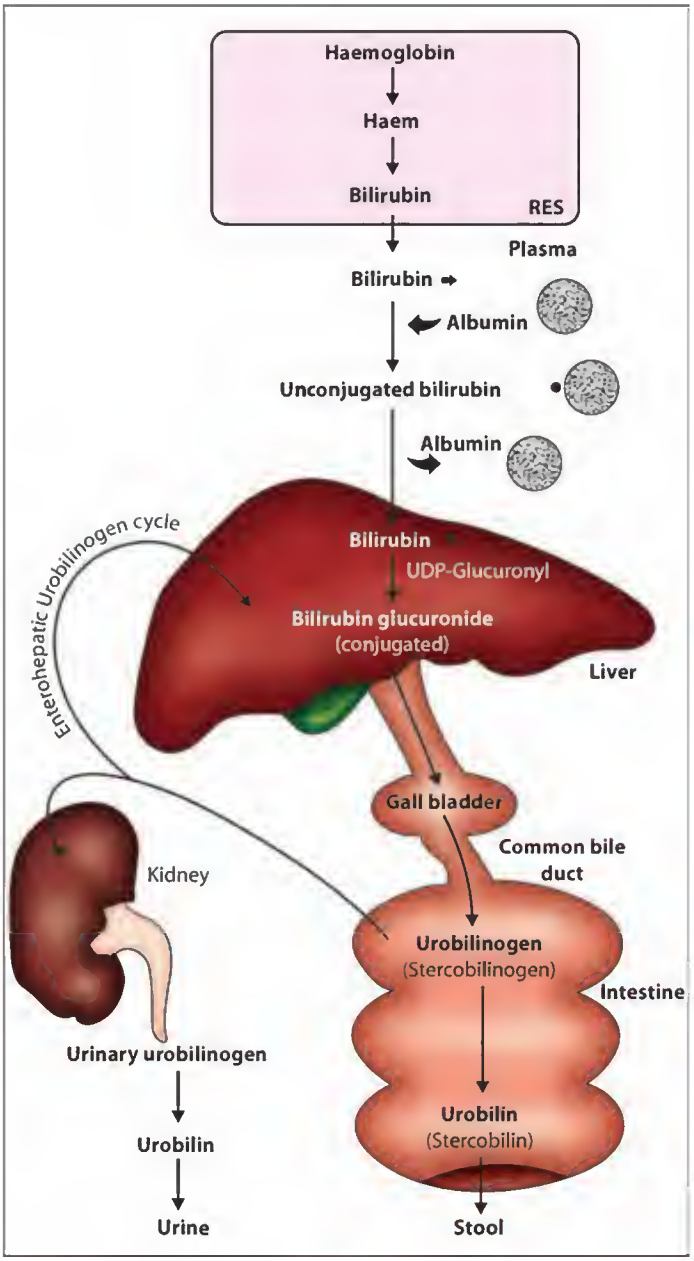

Figure 1: Bilirubin metabolism.

Bilirubin production

Under steady state normal metabolic conditions, about 3.9 mg/kg or 250 to 350 mg of bilirubin is produced each day, nearly 80% of which is derived from haemoglobin. The closed tetra pyrole ring of haem is opened up by microsomal enzymes haem oxygenase, with nicotinamide adenine dinucleotide phosphate hydrogenase (NADPH) and molecular oxygen used as co-factors. This reaction is the rate limiting step in haem catabolism. Each gram of haemoglobin produces 36.3 mg of bilirubin.

Biliverdin, a green pigment which is the predominant bile pigment in avian and fish bile, is converted to bilirubin in mammals by biliverdin reductase, a cytosolic enzyme that uses NADPH as co-factor. Using radio-labelled precursors of haem, two-phase elimination of bilirubin has been identified. Approximately 20% is excreted within 24 to 72 hours as an early peak or early labelled bilirubin (ELB) while 80% is excreted during late-phase elimination at about 110 days. The ELB consists of an initial 'fast' fraction, derived from hepatic haem containing proteins, and a slower fraction derived from *ineffective erythropoiesis* or destruction of maturing erythroid precursors in the bone marrow. Ineffective erythropoiesis markedly increases in conditions like porphyria, sideroblastic anaemia, megaloblastic anaemia and lead poisoning. Bilirubin derived from senescent red blood cells at the end of their life span appears over a broad range of 90 to 150 days.

Bilirubin transport

Lipophilic unconjugated bilirubin circulates in the blood and body fluids bound tightly and reversibly to albumin, which solubilises it in aqueous solutions. Albumin binding also protects against kernicterus by preventing entry of unconjugated bilirubin into the brain when its levels are elevated or when the blood-brain barrier is immature. The likelihood of developing kernicterus in Crigler-Najjar syndrome therefore is influenced by serum albumin levels. Drugs such as sulphonamides and long chain fatty acids used in parenteral nutrition may displace bilirubin from albumin binding sites, resulting in an increase in free unbound bilirubin in plasma.

Hepatic uptake

On reaching the liver, albumin-bound unconjugated bilirubin dissociates and is taken up by the hepatocyte across the sinusoidal membrane (**Figure 2**). While some uptake of unconjugated bilirubin across the cell membrane occurs by passive diffusion, active uptake against a concentration gradient is most important, particularly at low plasma bilirubin concentrations, and is mediated by *organic anions transporting protein 2* (OATP2). Conjugated bilirubin shares the same transporter for hepatic uptake. Thus, in predominantly conjugated hyperbilirubinaemic conditions, elevation of unconjugated bilirubin also occurs because of a competitive uptake defect.

Intrahepatocytic transorganelle trafficking

Within the hepatocyte, unconjugated bilirubin is bound to intracellular transport proteins called *ligandins* that play an important role in preventing reflux back to plasma. Intrahepatocytic movement of bilirubin from the plasma membrane to the endoplasmic reticulum for conjugation and to the canalicular membrane for export is predominantly carried out by organelle-dependent tubulovesicular transport. The most important event occurring within the hepatocyte is conjugation of bilirubin with activated sugar (predominantly glucuronic acid, also glucose, xylose) to make it water soluble for efficient biliary excretion.

Conjugation and the diphosphoglucuronyl transferase gene

In conjugation, propionic acid side chains of bilirubin are esterified by activated uridine diphosphoglucuronic acid (UDPG) to produce first bilirubin mono- and then diglucuronide, in a reaction catalysed by the microsomal enzyme uridine diphosphoglucuronyl transferase (UGT). Bilirubin diglucuronide is the predominant form of conjugated bilirubin in human bile, though increase in monoglucuronides is seen in Crigler-Najjar

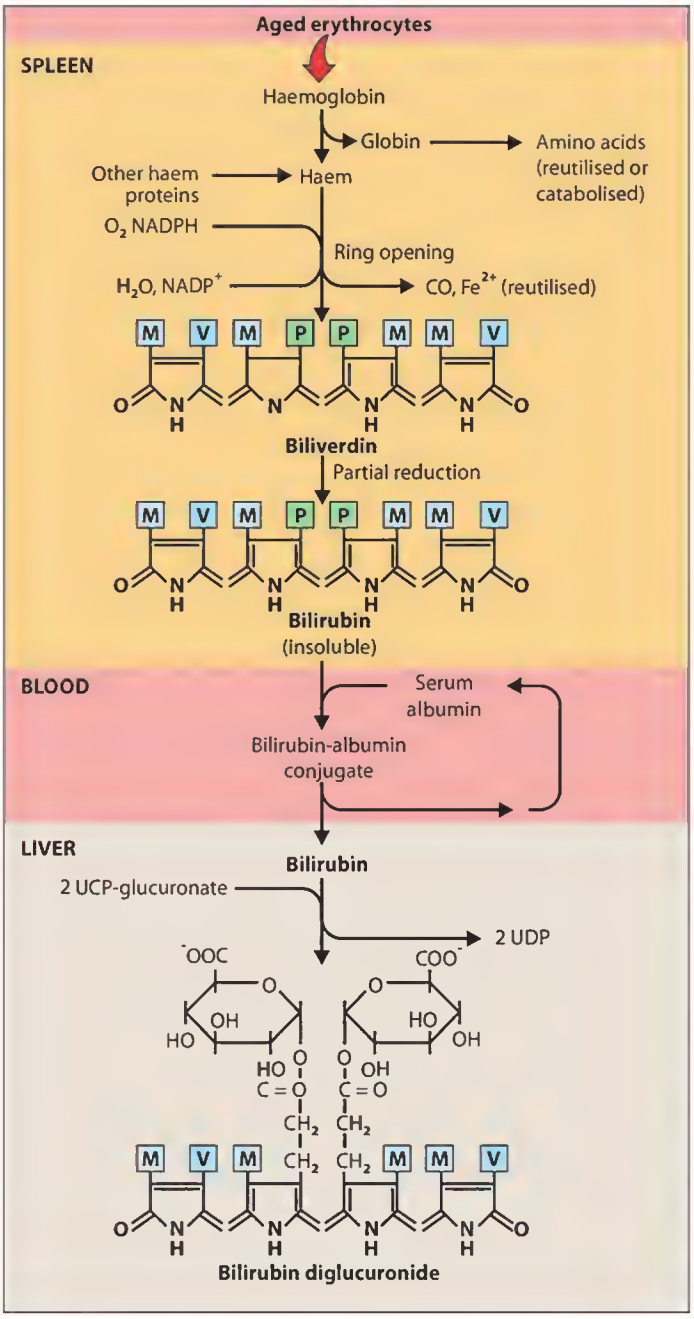

Figure 2: Bilirubin transport.

syndrome when glucuronidation is impaired. Though several independently regulated UGT isoforms are expressed from the human UGT1A locus, only bilirubin UGT1 (BUGT1, also termed UGT1A1) contributes significantly to bilirubin glucuronidation. The UGT1 gene has been mapped to chromosome 2q 37. It belongs to a superfamily of genes that are important in detoxification, encoding more than 10 isoforms with varying substrate specificity. Apart from bilirubin, bile acids, phenol, steroids and various drugs and toxins are substrates for UGT1.

Canalicular export

Transport across the canalicular membrane to the biliary canaliculus is an active carrier mediated process, utilising ATP in the presence of Mg^{++} ions, that transports substances against a steep concentration gradient. The transport protein multiple drug resistant protein 2 (MDR2/MRP2) functions as the canalicular transporter of bilirubin, bromsulphthalein, glutathione and glucuronide conjugated drugs and xenobiotics. MDR2/MRP2 is also called canalicular multispecific organic anion transporter (cMOAT) and belongs to a class of membrane transporters that forms a superfamily called ATP binding cassette (ABC) proteins.

Intestinal phase

Though conjugated bilirubin is not absorbed to any significant extent from the intestinal tract, it is deconjugated by bacterial glucuronidases, yielding urobilinogens that can be absorbed from the intestine and undergo enterohepatic circulation and renal excretion. Urobilinogen is colourless but is converted to urobilins that are yellow coloured. Absence of urobilinogen from stool may be indicative of complete biliary obstruction.

Molecular Mechanism of Inherited Disorders of Bilirubin Metabolism

With rapid advances in the understanding of genetic regulation of bilirubin homeostasis, molecular mechanisms of inherited disorders characterised by unconjugated and conjugated hyperbilirubinaemia have been elucidated. Inherited unconjugated hyperbilirubinaemic conditions are the result of impaired or absent conjugation due to abnormalities of UGTI AI. Gilbert's syndrome (GS), Crigler-Najjar syndrome type II (CN II), and Crigler-Najjar syndrome type I (CN I) form a spectrum in terms of increasing degree of enzyme deficiency. Dubin Johnson and Rotor syndrome are inherited, conjugated hyperbilirubinaemias.

Gilbert's syndrome

Gilbert's syndrome is the most common among these and is characterised by mild persistent unconjugated hyperbilirubinaemia (usually less than 5 mg/dl), normal liver structure and function, no evidence of haemolysis and an excellent prognosis. The genetic defect in GS lies in the promoter region upstream of exon I. Normal TA/TAA repeats are of the sequence (TA)6TAA. GS patients are homozygous for a longer sequence, (TA)7TAA. This dinucleotide polymorphism reduces the expression of a structurally normal UGTI gene to less than 30% of the normal and results in higher levels of bilirubin monoglucuronides (14% to 34%) in bile in GS patients, normal range being 0% to 7%. It is interesting to note that mere presence of the GS genotype may not be sufficient to produce clinically evident hyperbilirubinaemia. Variations in the amount of bilirubin production may also be important for phenotypic expression, accounting for clinical observations such as GS being uncommon in females who produce less bilirubin than males and commoner after fasting, exercise and following intercurrent infections.

Crigler-Najjar syndrome

In the Crigler-Najjar syndromes, hyperbilirubinaemia is more severe due to more pronounced deficiency of UGT. In CN II, some residual enzyme activity remains (partial deficiency) and serum bilirubin fluctuates between 7 and 20 mg/dl. Bile contains high concentration of bilirubin monoglucuronides. Prognosis in CN II is generally good, but intercurrent infection and debility might precipitate bilirubin encephalopathy even in this relatively benign phenotype. On the other hand in CN I, absence of UGT1 results in high levels of unconjugated hyperbilirubinaemia and kernicterus, unless phototherapy is instituted soon after birth. In both the CN syndromes, there are mutations involving the

coding region (exons 2 to 5) of the UGT1A1 gene. These may take the form of nonsense or missense mutations, insertions, deletions as well as a premature stop codon. In CN I, genetic lesions are widespread, involving more than one exon at critically important sites for enzyme less in number, leading on to diminished but not absent UGT activity. Interestingly, in India, presence of Gilbert's type promoter abnormality in one gene together with coding region mutation in the other (compound heterozygosity) might be an important genetic mechanism producing the CN II phenotype. Apart from its significance in inherited hyberbilirubinaemias, it has been shown that the Gilbert's type promoter abnormality might be responsible for the high serum bilirubin levels seen in some patients with chronic hepatitis.

Dubin Johnson and Rotor syndromes

A number of inherited disorders are characterised by conjugated hyperbilirubinaemia including Dubin Johnson syndrome, Rotor syndrome and progressive familial intrahepatic cholestasis (PFIC). The molecular defect in Dubin Johnson has been found to be associated with abnormal structure of MRP2, due to mutations that alters protein assembly. As a result canalicular export of bilirubin glucuronides and other organic anion is hampered. In PFIC–1, there is a defect in canalicular bile salt transporter.

14.2 Hepatobiliary Disorders—A Clinical Approach

Nagaraja Rao Padaki

INTRODUCTION

Liver is considered as a major metabolic organ in the body performing diversified functions, namely metabolisms of carbohydrate, protein and fat, regulation of coagulation and detoxification of toxic substances. In addition, being an organ enriched with reticuloendothelial functions, it is the site of immunological activity. It is no surprise that liver is involved whenever any of these functions are deranged. The symptoms and signs may be very minimal or even absent despite advanced, compensated state of liver disease. In addition patients with a liver disease can present signs or symptoms relating to other systems for example pruritus as initial or the only manifestations of many cholestatic diseases. Liver disease, quite frequently is detected incidentally on routine master health check-up or while investigating other symptoms. Hence, the clinician should be aware of various manifestations of acute and chronic liver disease. The presence of liver disease may be indicated by an abnormal laboratory test, incidental finding at endoscopy or ultrasonogram or even surgery done for some other purpose.

In patients with liver disease particularly in jaundiced patient, it is possible to arrive at accurate diagnosis in nearly 85% of patients with a careful history, physical examination and standard laboratory tests.

HISTORY IN LIVER DISEASE

Like in any other system, the importance of history taking can not be underestimated in liver disease. Presence of dark urine, jaundice, haematemesis, and melaena will obviously point towards liver disease. One should be aware of certain non-specific symptoms which may escape from the notice of the physician. These include fatigue, pruritus, anorexia, weight loss or gain and abdominal pain.

Fatigue

This apparently non-specific symptom of fatigue may be present for many years in patients with undiagnosed liver disease. The severity of fatigue in these conditions is thought to be out of proportions to severity of the liver disease. The fatigue associated with liver disease is central fatigue and is thought to be due to abnormal functioning of hypothalamic-pituitary-adrenal axis and or altered opiate mediated neurotransmission. Two important disease states particularly important to remember in this aspect are hepatitis C and cholestatic disorders. The other reasons for fatigue in any liver disease are loss of muscle mass and poor nutrition.

Pruritus

The symptom of pruritus associated with jaundice are easy to point towards extra-hepatic or intra-hepatic cholestasis. One should remember that in primary biliary cirrhosis and benign recurrent intra-hepatic cholestasis, pruritus can be the initial manifestation without jaundice or overt signs or symptoms of liver disease for a long time. Pruritus, or itching, is a common symptom in patients with cholestatic liver disease. The pathophysiology of pruritus is poorly understood. It may be mediated centrally through opioid receptors. The itching typically affects the extremities more than the trunk and face and is usually worse at night. The scratching associated with pruritus may cause fleeting skin excoriations. Non-hepatic systemic causes of pruritus include chronic renal failure, thyroid dysfunction, malignancy, human immunodeficiency virus (HIV) infections, pregnancy and ovarian hormones abnormalities.

Anorexia

Anorexia is common in patients with acute viral hepatitis and in those with neoplasms of the liver, biliary tree, pancreas. Onset of nausea and vomiting during second or third trimester of pregnancy should alert one to the possibility of acute fatty liver of pregnancy. Anorexia in liver disease contributes to muscle wasting further by interfering with nutrition.

Weight Loss or Gain

Weight loss occurs in cirrhosis due to loss of muscle mass which may be secondary to poor nutrition. Characteristically these patients loose fat from face, extremities and chest and do so progressively and rather insidiously. Weight gain in patients with advanced liver disease is typically caused by *ascites* and oedema and may precede other symptoms of the liver disease. At times pedal oedema on prolonged dependency may be the only manifestation of the liver disease.

Abdominal Pain

Abdominal pain is a common complaint in patients with liver disease and is typically located in the right upper quadrant of the abdomen below the right rib cage. The pain tends to be constant and worse with movement as a result of the stretching of the liver capsule in inflammatory conditions like acute viral hepatitis, amoebic liver abscess. Biliary colic in patients with symptomatic gallstones is typically acute in onset and steady in nature, in right upper quadrant or epigastric regions. The pain attacks often occur after a meal or in the early hours of the morning lasting for 30 to 90 minutes. In contrast, the pain due to acute cholecystitis is steady right upper quadrant pain that may radiate to the right shoulder and is often exacerbated by respiration because of diaphragmatic irritation. This may be associated with fever or rigors.

A rapidly enlarging liver resulting from tumour growth, inflammation, or congestion. Slow onset of right upper quadrant pain over several weeks should suggest tumour growth or hepatic congestion. Sometimes pain over left upper quadrant may be due to splenomegaly as a result of portal hypertension. Generalised abdominal discomfort may be due to *ascites* in initial onset when abdominal muscles are not stretched enough to accommodate even smaller amount of fluid accumulation. Pain all over abdomen particularly tenderness may be the manifestation of ensuing

spontaneous bacterial peritonitis. A tense *ascites* merely due to large volume causes generalised pain all over the abdomen. Focal pain over the liver, with associated point tenderness on examination, can occur with liver abscesses and tumours.

OTHER IMPORTANT POINTS IN THE HISTORY

Icterus and Jaundice

Jaundice is a characteristic presentation of liver disease and refers to the yellow colouration of the patient's skin caused by the deposition of bilirubin glucuronides in the tissues. Icterus is the term used to denote yellow sclerae resulting from hyperbilirubinaemia. The jaundice noticed by friends or relatives is usually due to malignancy of extrahepatic biliary tree like slow growing sclerosing cholangiocarcinoma or ampulla of Vater.

Abnormal Stool

A mild increase in the frequency or decrease in the consistency of bowel movements is often seen in patients with liver disease; constipation is infrequent. Diarrhoea may result from a decrease in the concentration of intestinal bile salts, leading to an increase in faecal fat.

In patients with cholestasis or acute hepatitis, the stool is typically pale or "clay-coloured" as a result of decreased bilirubin excretion into the intestinal lumen. It is important to question patients with chronic liver disease about malaena (dark, tarry stool) which indicates upper gastrointestinal bleeding. Sometimes slow bleed from gastric fundal varices can have only slow onset anaemia due to malaenic stool without any other features of the liver disease.

Sleep Disturbance

In patients with known or suspected end-stage liver disease, a disruption of the normal sleep pattern may be the earliest symptom of hepatic encephalopathy. Patients may have trouble falling asleep, interrupted sleep at night, or day-time somnolence. The sleep disturbance is thought to result in part from changes in melatonin secretion in cirrhotic patients.

Change in Mental Status

Patients with worsening hepatic encephalopathy may experience mental impairment, ranging from lethargy and confusion to stupor and coma. Encephalopathy can be associated with personality changes, depression, irritability, and inappropriate and disinherited behaviour. These symptoms are typically not noted by the patient but reported by friends and family. The diagnosis of minimal hepatic encephalopathy (MHE) rests on the confirmation of a disease that can cause MHE, such as, cirrhosis or presence of portosystemic shunt, exclusion of normal mental status, on clinical examination, demonstration of abnormalities of cognition and/or neurophysiological variables and exclusion of concomitant neurological disorders.

Leg Cramps

Patients with end-stage liver disease have a high frequency of muscle cramps, typically in the legs and mostly at night.

ROLE OF PHYSICAL EXAMINATION IN LIVER DISEASE

General inspection of the patient gives several clues. Icterus which is evident if bilirubin is more than 3.0 mg/dL should be seen in day-light so as not to miss. Wasting is indicative of advanced liver disease or malignancy. Presence of skin excoriations confirms pruritus. Interscapular area which the patient cannot access will be devoid of excoriations. **Table 1** lists common clinical features present in liver diseases.

Table 1: General Physical Examination in Liver Disease

Manifestations	Key Points-Significance
Ocular manifestations	
Jaundice, be aware of	Non-hepatic causes of jaundice Haemolytic jaundice Heredofamilial causes Gilberts syndrome/Crigler-Najjar type 2 syndrome Dubin-Johnson syndrome Systemic causes of febrile jaundice Primary biliary cirrhosis Long-standing obstructive jaundice
Cutaneous manifestations	
Spider angioma	Cirrhosis-hormonal changes
Palmar erythema	Cirrhosis-vasodilatation
Spontaneous bruising	Cirrhosis-impaired coagulation
Petichae	Thrombocytopaenia
Palpable purpura	Polyarteritis nodosa (Hepatitis B virus related) Cryoglobulinaemia (Hepatitis C virus related)
Excoriations	Cholestatic liver disease
Endocrine and other manifestations	
Gynaecomastia	Indicative of advanced liver disease Spironolactone induced (tender and painful) Non-hepatic systemic causes include: Physiological at neonatal and puberty Hormone producing neoplasms Renal disease, hyperthyroidism
Testicular atrophy	Advanced liver disease
Dupuytren's contracture	Thickening of flexor tendons of hand-disease advanced liver
Parotid enlargement	Indicative of alcoholic liver disease
Asterixis (liver flaps, flapping tremors)	Indicative of early hepatic encephalopathy, seen also in advanced cardiac, renal, pulmonary failures
Lymphadenopathy	Not a usual finding in liver disease, suggests Epstein-Barr virus infection, lymphoma

LIVER FUNCTION TESTS: SOME PRACTICAL POINTS

Liver performs various complex synthetic, metabolic or excretory functions. All these functions can not be assessed by any single or group of tests. Biochemical liver function tests popularly known as "LFT" are frequently used as screening tests in asymptomatic or symptomatic subjects. The pattern of abnormalities noted usually give a clue towards predominantly, haemolytic or obstructive nature of jaundice.

Causes of isolated unconjugated hyperbilirubinaemia include Gilbert's syndrome (<6 mg/dL), Crigler-Najjar I (25 to 48 mg/dL), Crigler-Najjar II (6 to 25 mg/dL), haemolysis (<5 mg/dL), ineffective erythropoiesis, neonatal jaundice and sepsis, congestive heart failure, and some drugs like pregnanediol, chloramphenicol, novobiocin, rifampicin, probenecid.

Some practical points to remember about liver functions are presented in **Tables 2 to4**.

Table 2: Abdominal Examination of Liver Disease

Manifestation	Key Points-Significance
Engorged abdominal veins	Typical caput medusae is rare More prominent in *ascites* Seen only in intra-hepatic and supra-hepatic causes of portal hypertension Absent in extra-hepatic portal vein thrombosis due to collapsed umbilical vein which joins L portal vein Veins over the back suggests Budd-Chiari syndrome Longitudinal veins along side of abdomen suggest IVC obstruction
Hepatomegaly	
Left lobe alone palpable	Indicates cirrhosis or mass lesion in the left lobe
Generalised tender enlargement	Acute hepatitis, hepatic congestion
Localised tenderness	Liver abscess
Splenomegaly	Large spleen suggests EHPVO/NCPF
Palpable gall bladder	Courvoiseur's law/hypothesis Indicates obstruction below the level of cystic duct
Ausculatatory findings	
Hepatic bruit	Alcoholic hepatitis, hepato-cellular carcinoma Hepatic artery aneurysm, Traumatic A-V fistula
Venous Hum	Cruveihier-Baumgarten syndrome/ disease Portal hypertension
Hepatic rub	Liver abscess, hepato-cellular carcinoma

ICV = Inferior vena cava; EHPVO = Extra-hepatic portal vein obstruction; NCPF = Non-cirrhotic portal fibrosis.

Table 3: Clinical Significance of AST/ALT Ratio

Clinical Status	AST/ALT	Remarks
No underlying liver disease	0.8	
Alcoholics without liver disease	<1.0	
Alcoholic liver disease	>2	ALT <300 U/L
Non-alcoholic liver disease	>1	Indicates underlying cirrhosis (specifically 94% to 100%) and sensitivity 44% to 75%
NAFLD	<1	

AST = Aspartate aminotransferase; ALT = Alanine aminotransferase; NAFLD = Non-alcoholic fatty liver disease.

Table 4: Non-Hepatic Causes of Elevation of Transaminases

Clinical Status	Remarks
Hyperthyroidism	Both AST and ALT
Strenous exercise	AST elevation can cap up to 3-fold
Muscle injury Rhabdomyolysis Polymyositis Muscular dystrophy	
Diurnal variation	ALT lowest at night and highest in the afternoon
Coeliac disease	
Haemolysis	

ROLE OF IMAGING PROCEDURES IN DIAGNOSIS OF LIVER DISEASE

If clinical and laboratory features are suggestive of acute liver disease, ultrasound may not help further. Some characteristic but not pathognomonic findings in ultrasonogram in acute hepatitis include oedematous gall bladder wall and portal lymph-adenopathy. However, an ultrasonogram of the abdomen will be helpful in acute presentations of underlying chronic disease, like flares in chronic hepatitis B and acute on chronic liver disease.

In a patient with jaundice, if the biochemistry is suggestive of obstructive type (grossly elevated alkaline phosphatase with ALT/AST less than 300 U/L ultrasonogram is helpful. It has been observed that if the bilirubin is more than 10 mg/dL for atleast 2 weeks, the sensitivity and specificity of ultrasonogram in differentiating intra-hepatic from extra-hepatic cholestasis is 95%.

If an ultrasonogram reveals dilated intra-hepatic bile ducts then an additional imaging procedures like computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasonography (EUS) with or without biopsies are often necessary to establish the cause of the obstruction.

On the other hand, if bile ducts are not dilated, i.e. medical jaundice is considered, then liver biopsy is helpful if not contraindicated otherwise.

If cholelithiais is suspected, ultrasonography is sufficient along with liver function tests. If choldocholithiasis is suspected then ERCP is indicated especially if cholangitis is suspected since a therapeutic intervention like NBD, papillotomy and retrieval of stone can be done. In doubtful cases a prior EUS is likely to give some guidance.

In new onset ascites a color Doppler ultrasound will be helpful in evaluating the portal and hepatic venous systems. Ascitic fluid analysis to differentiate high and low SAAG is of immense immediate value in diagnosing portal hypertension.

In patients with obstructive jaundice due to suspected pancreatic carcinoma, EUS is superior to CT with regard to detecting a pancreatic mass, tumour staging. While predicting operability, both are comparable.

DIFFERENTIAL DIAGNOSIS OF LIVER DISEASE

If the patient is jaundiced, a reliable history, physical examination, and standard biochemical tests are sufficient to make near accurate diagnosis in about 85% of the cases. Splenomegaly, ascites and prominent veins over the anterior abdominal wall are good indicators of presence of portal hypertension.

If you have two physical findings like *ascites* and asterexis and two laboratory values like hypoalbuminaemia and prolonged prothrombin time are sufficient to make, one have sufficient evidence to make a diagnosis of cirrhosis. Parotid swelling, gynaecomastia and Dupuytren's contracture are more or less certain pointers towards alcoholic aetiology.

But nowadays with increasing awareness and excellent imaging modalities, the challenge is diagnosing and differentiate between various liver diseases early enough to prevent disease progression.

When confronted with a clinical scenario of a liver disease, be it incidental detection of abnormal liver tests, acute hepatitis or chronic hepatitis, one should differentiate between a predominantly hepatocellular disease or cholestatic disease or a mixed pattern on the basis of liver functions.

Hepatocellular

When hepatocytes are mainly affected, it results in hepatocellular jaundice and is characteristically but not always associated with predominant elevation of aminotransferases.

The next step is to decide if it is acute hepatitis, chronic hepatitis or acute or chronic liver disease. Some common causes of acute and chronic hepatitis are listed in **Table 5**.

Table 5: Common Causes of Hepatitis

Causes	Clinical Clues	Diagnostic Clues
Acute hepatitis		
Hepatitis A	Exposure to travel, etc	IgM, anti HAV
Hepatitis B	Injection sexual risk factors	HBsAg, IgM anti HBV
Hepatitis C	Injection sexual risk factors	Anti HCV, HCV, RNA
Ischaemic hepatitis	Vascular occlusion/low BP	Very high AST, ALT elevation with rapid decline, elevated LDH
Alcoholic hepatitis	History of alcohal abuse - associated large tender liver	AST: ALT > 2, AST < 400
Drug induced	History of drug intake/other corroborative evidence	None, improvement on withdrawal
Chronic hepatitis including cirrhosis		
Hepatitis B	Features of cirrhosis, non-specific	HBsAG, HBeAg, HBV DNA
Hepatitis C	Features of cirrhosis, non-specific	Anti HCV, HCV RNA
Alcoholic liver disease	Features of cirrhosis, non-specific	AST: ALT >2, AST <400
NAFLD/NASH	Obesity abdominal girth	Metabolic syndrome
Autoimmune hepatitis	Female gender, other auto-immune diseases	ANA, ASMA, LKM
Wilson's disease	KF ring in eyes, young age	Caeruloplasmin, urinary copper
Haemochromatosis	Diabetes, arthritis, family history	Iron studies, HFE genetic studies
Alpha-1 anti-trypsin	Young age	AAT levels and phenotype

Note: Liver biopsy desirable but not feasible at times, may not be required
Metabolic syndrome: Increased abdominal girth, elevated triglyceride, blood sugar, hypertension, low HDL (International Diabetic Federation 2007)
IgM = Immunoglobulin M; HAV = Hepatitis A virus; HBV = Hepatitis B virus; NAFLD = Non-alcoholic fatty liver disease; NASH = Non-alcoholic steatohepatitis; KF = Kayser-Fleischer; HCV = Hepatitis C virus; RNA = Ribonucleic acid; AST = Aspartate aminotransferase; ALT = Alanine aminotransferase; DNA = Deoxyribonucleic acid; ANA = Anti-nuclear antibodies; ASMA = Anti-smooth muscle antibody; LKM = Liver kidney microsome; HFE = Haemochromatosis gene; AAT = Alpha-1 Anti trypsin.

Cholestatic Liver Disease

When biliary tract is affected predominantly it results in cholestatic liver disease (pruritus, high coloured urine, markedly elevated alkaline phosphatase). The first step is to rule out extra-hepatic biliaty obstruction by stone or tumour by appropriate imaging modalities. The common causes of intra-hepatic cholestasis include primary biliary cirrhosis, primary sclerosing cholangitis and drug induced (**Table 6**).

Table 6: Common Causes of Cholestatic Liver Disorders

Causes	Clinical Clues	Diagnostic Clues
Primary biliary cirrhosis	Middle aged female, other autoimmune diseases	Antimitochondrial antibodies
Primary sclerosing cholangitis	Association with ulcerative colitis	Cholangiography
Drug induced	History of drug toxicity/abuse	None, improvement on withdrawal
Systemic infectious association	Symptoms of organ sepsis	Appropriate bacterial cultures

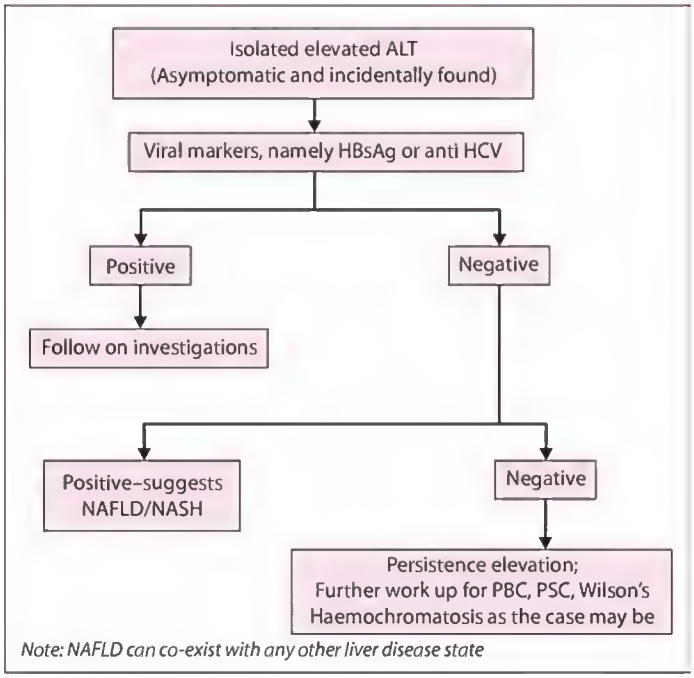

Figure 1: An approach to isolated elevation of ALP.

It is not always possible to differentiate haemolytic, extra-hepatic and intra-hepatic causes of jaundice despite making use of all biochemical and imaging investigations and liver biopsy may become mandatory. There could be a mixed situation like choledocholithiasis in a patient with cirrhosis, haemolysis due to G6PD deficiency with acute viral hepatitis, etc.

INCIDENTALLY FOUND ABNORMAL LIVER FUNCTIONS

Sometimes one could come across clinical situations like pre-anaesthetic, pre-employment, master health check etc with abnormal liver functions (isolated or mixed).

It has been found that atleast 6% to 25% of asymptomatic individuals have abnormal liver tests. Atleast one-third of such patients will have normal enzymes on subsequent testing.

On the other hand, prevalence of significant liver disease in general population is significantly low. The commonest abnormal biochemical liver functions are hyperbilirubinaemia, elevated ALT/AST and elevated alkaline phosphatase. The following algorithmic approaches are general guidelines that can be followed (**Figures 1, 2 & 3**).

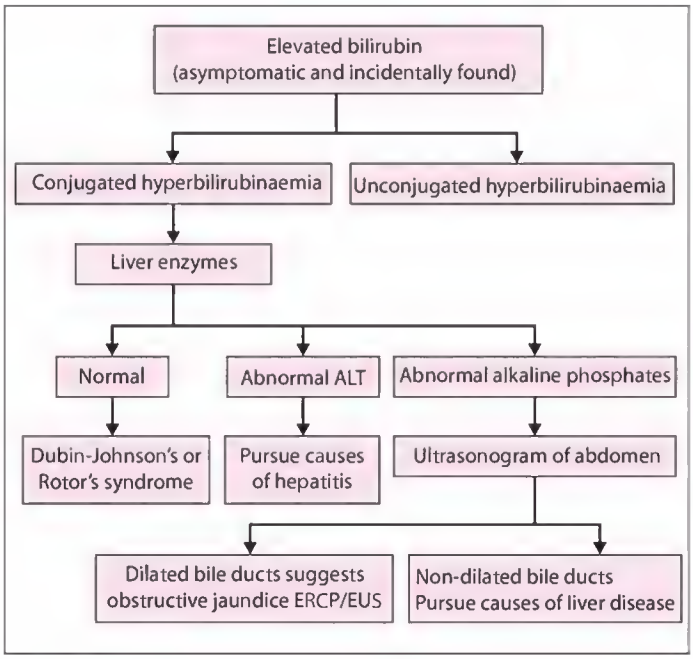

Figure 2: Approach to conjugated hyperbilirubinaemia.

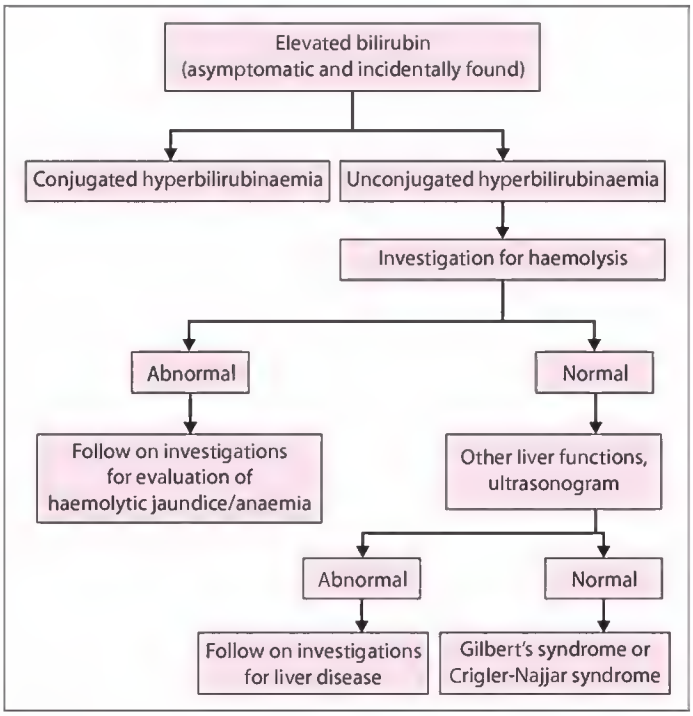

Figure 3: Approach to unconjugated hyperbilirubinaemia.

14.3 Hepatobiliary Disorders—Investigations

Radha K Dhiman

INTRODUCTION

A number of investigations can be performed in patients with liver disorders. In this chapter, we will discuss liver function tests indicative of hepatocellular necrosis, cholestasis and biosynthetic functions and utility of liver biopsy.

BIOCHEMICAL MARKERS

Several biochemical tests are useful in the evaluation and management of patients with hepatic disorders. Accurate interpretation of these biochemical tests in the context of a carefully obtained history and thorough physical examination is crucial because non-specific aberrations in these tests can occur. Biochemical test abnormalities can have patterns that suggest predominantly hepatocellular or cholestatic liver injury or a mixed pattern. Therefore, it is best to use these tests as a battery, rather than rely on a single test.

Markers of Hepatocellular Necrosis

Aminotransferases

Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are sensitive indicators of hepatocellular injury of diverse causes, such as viral hepatitis, liver ischaemia, or toxin or drug-induced injury. ALT is primarily found in liver and is confined to the cytoplasm, whereas AST is found in liver, myocardium, skeletal muscles, pancreas, kidney, brain and blood cells and is present in both cytoplasm and mitochondria.

Hepatocyte injury results in leakage of these enzymes into circulation. However, there is a poor correlation between the degree of liver cell injury and the serum levels of amino-transferases. Serum levels of aminotransferases can be in the normal range in patients with advanced fibrosis or cirrhosis. Various liver disorders are associated with typical ranges of AST and ALT. The highest ALT levels, usually more than 10,000 U/L, are found in patients with acute toxic injury as a result of acetaminophen overdose or acute ischaemic insult. ALT levels often rise to 1000 to 5000 U/L in patients with acute viral hepatitis. AST and ALT levels fall rapidl1y after an acute insult. Among patients with alcoholic hepatitis or biliary obstruction serum transferase levels are usually less than 300 U/L. However, during the acute phase of biliary obstruction, the AST or ALT levels may go up transiently to 1000 to 2000 U/L.

Clinical history should focus on prodromal illness for acute viral hepatitis, alcohol intake, intravenous drug abuse, hepatotoxic drug intake, family history of liver disease, etc. Further investigations should be based on suspected hepatic disorder (**Figure 1**).

Aspartate aminotransferase/alanine aminotransferase ratio

The relative levels of AST and ALT also provide some useful information. AST/ALT ratio of ≤1 indicates acute hepatocellular injury with an exception of alcoholic hepatitis. An AST/ALT ratio of ≥2:1 is suggestive and a ratio of ≥3:1 is highly suggestive of alcoholic liver disease (**Table 1**). A lower level of ALT than AST in patients with alcoholic liver disease is due to associated pyridoxine deficiency and poor nutritional status of these patients. Supplementation with pyridoxine in patients with alcoholic liver disease results in increased serum ALT levels and a reduction in AST/ALT ratio. An AST/ALT ratio of >1:0 is also seen in patients with cirrhosis due to any cause and in Wilson's disease.

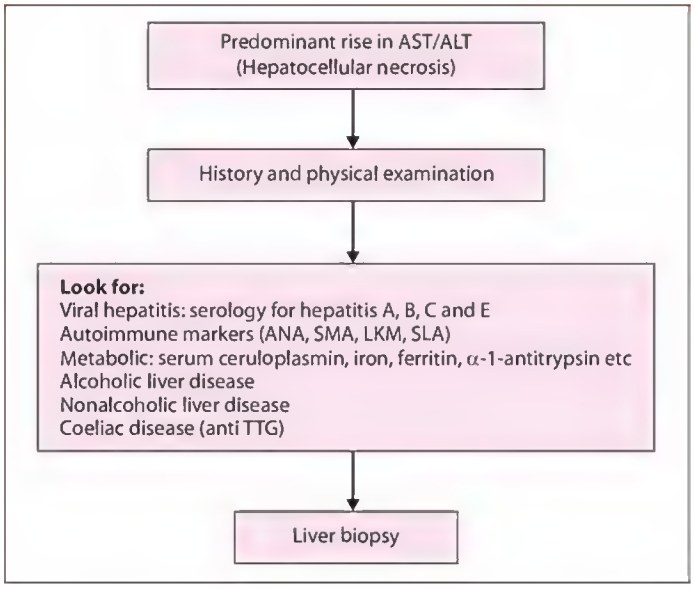

Figure 1: Algorithm for the management of hepatic disorder with raised transaminases.

AST = Aspartate aminotransferase; ALT = Alanine aminatransferase; ANA = Anti-nuclear antibody; SMA = Smooth muscle antibody; LKM = Liver kidney micrasamal antibody; SLA = Soluble liver antigen antibody, anti-TTG.

Table 1: Clinical Significance of AST/ALT Ratio

Clinical Status	AST/ALT	Remarks
No underlying liver disease	0.8	
Alcoholics without liver disease	<1.0	
Alcoholic liver disease	>2	ALT < 300 U/L
Non-alcoholic liver disease	>1	Indicates underlying cirrhosis (specificity 94% to 100%) and sensitivity 44% to 75%
NAFLD	<1	

AST = Aspartate aminatransferase; ALT = Alanine aminatransferase; NAFLD = Nan-alcahalic fatty liver disease.

Markers of Cholestasis

Alkaline phosphatase (ALP), 5'-nucleotidase and gamma glutamyl transpeptidase (GGT) are markers of cholestasis. ALP and 5'-nucleotidase are present near the canalicular membrane of the hepatocytes, whereas GGT is located in the endoplasmic reticulum and in the bile duct epithelium.

Alkaline phosphatase

ALP consists of several isoenzymes present in liver, bone, leucocytes, placenta, intestine, etc. ALP levels are physiologically elevated in children and adolescents during periods of rapid bone growth and in pregnant women, due to ALP of bone and placental origin, respectively. The ALP levels may rise after a fatty meal; hence, its determination should be done in the fasting state. If the origin of an elevated ALP level is in doubt, then serum 5′-nucleotidase and GGT should be measured; elevation of these enzymes suggests liver origin of ALP. **Figure 2** has shown an algorithmic approach for patients with isolated or predominantly elevation of ALP.

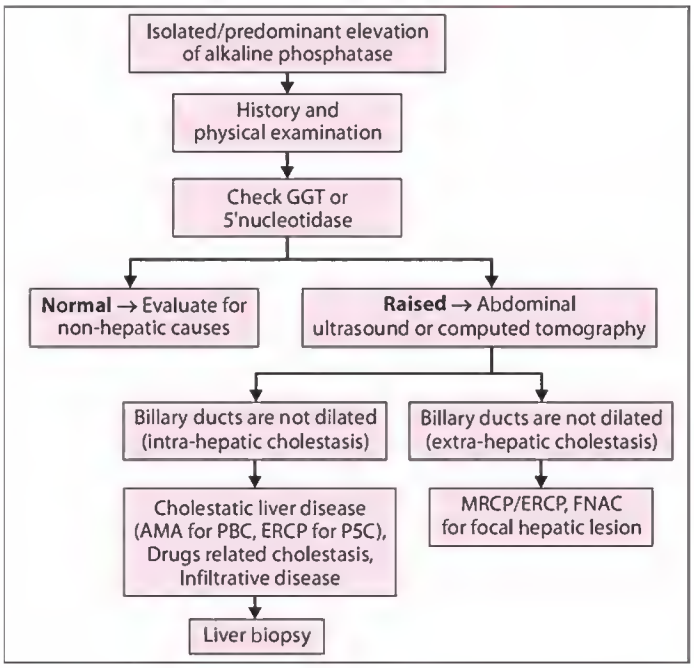

Figure 2: Algorithm for the management of isolated or predominant elevation of alkaline phosphatase.

GGT = Gommo-glutamyl tronspeptidose; AMA = Anti-mitochondrial antibody; PBC = Primory biliory cirrhosis; PSC = Primory sclerosing cholongitis; MRCP = Mognetic resononce cholongiopancreatogrophy; ERCP = Endoscopic retrogrode cholongioponcreotogrophy; FNAC = Fine needle aspirotion cytology.

Gamma glutamyl transpeptidase

GGT is a microsomal enzyme, which can be induced by stimulants, such as alcohol, phenytoin, phenobarbital, warfarin, etc. In addition to liver, GGT is also present in kidney, pancreas, spleen, heart, lung and brain. However, it is not present in the bone; this helps in distinguishing whether elevated ALP in a person is from a liver source or from a bone source.

Elevated GGT level has also been used as a marker of occult alcohol use. However, lack of specificity makes its use for this purpose unreliable.

5′-Nucleotidase

5′-nucleotidase is found in several tissues, which include liver, myocardium, brain, pancreas, etc. An elevated 5′-nucleotidase is commonly associated with liver disease. In biliary obstruction, the rise in serum 5′-nucleotidase may lag behind elevations in ALP and GGT.

Serum bilirubin

Bilirubin, a breakdown product of heme, is found in the blood in two forms: conjugated (direct) and unconjugated (indirect).

Unconjugated bilirubin is conjugated with glucuronic acid in hepatocytes by uridine diphosphate glucuronosyl (UDPG) transferase enzyme to increase its water solubility and is then rapidly transported into the bile. The rate-limiting step in bilirubin metabolism is not conjugation of bilirubin but its excretion from the hepatocytes (excretory capacity). Thus, liver disease is associated with elevated serum levels of conjugated bilirubin. However, this elevation does not appear until the liver has lost at least 50% of its excretory capacity. In healthy persons conjugated bilirubin is not detectable.

Serum bilirubin level is an indicator of prognosis in parenchymal liver diseases; the higher the level, the worse is the prognosis. However, familial defects in hepatic excretory function, such as Dubin-Johnson's and Rotor's syndromes, can result in isolated conjugated hyperbilirubinaemia without any abnormality in other routine laboratory tests.

Isolated unconjugated hyperbilirubinaemia results from either increased bilirubin production due to haemolysis, ineffective erythropoiesis or muscle injury, or from defects in hepatic uptake or conjugation (**Figure 3**). Careful history and physical examination may provide diagnostic clues to the presence of haemolysis, which can be confirmed further by specific diagnostic tests.

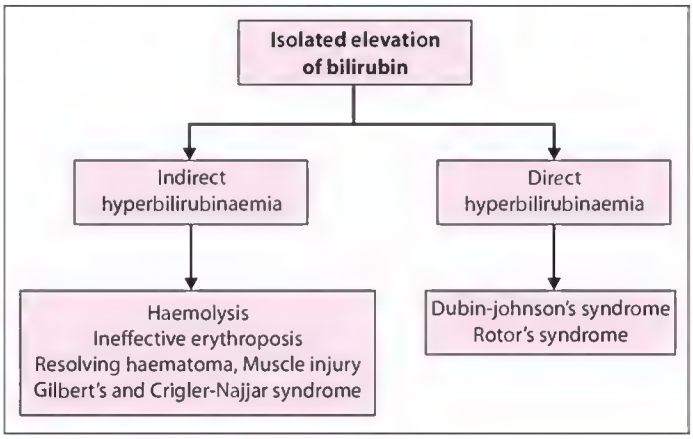

Figure 3: Algorithm for the management of isolated elevation of serum bilirubin.

Urinary bilirubin

Only conjugated bilirubin is filtered by the kidneys. Therefore, any bilirubin found in the urine is conjugated bilirubin and its presence implies presence of conjugated hyperbilirubinaemia and liver disease.

Markers of Biosynthetic Functions

Prothrombin time

All clotting factors, except factor VIII, are synthesized exclusively in the liver by hepatocytes. Prothrombin time collectively measures the activity of factors II, V, VI, IX and X. Prothrombin time does not become abnormal until more than 80% of liver synthetic capacity is lost. Therefore, prothrombin time prolongation may be considered as a sign of advanced liver dysfunction. Factor VII is sensitive to rapid changes in liver synthetic function because it has a short half-life of 6 hours. Hence, it is a useful marker of recovery from acute liver failure.

Biosynthesis of factors II, V, IX and X depends on vitamin K. Consequently, vitamin K deficiency can result in prolongation

of prothrombin time; however, this abnormality is corrected by vitamin K injections. Marked prolongation of prothrombin time, not corrected by vitamin K, indicates hepatocellular disease.

Albumin

Serum albumin is synthesised exclusively in the liver. It has a long half-life of about 3 weeks, making it a poor indicator of acute/mild liver dysfunction. Low serum level of albumin is more common in chronic liver disease, such as cirrhosis, and usually indicates advanced disease.

QUANTITATIVE ASSESSMENT OF HEPATIC FUNCTION

Quantitative liver function tests are helpful for determining the severity of liver disease, long-term prognosis, disease progression, surgical risk and in monitoring treatment. The most frequently used tools are: galactose elimination capacity to assess hepatocyte cytosol activity; indocyanine green clearance (ICG) to assess excretory function; monoethylglycinexylidide (MEGX) test and; aminopyrine breath-test to estimate microsomal activity. The role of these tests for routine use in clinical practice, however, remains undefined.

USE OF LIVER FUNCTION TESTS FOR THE ASSESSMENT OF PROGNOSIS

Serum bilirubin level and markers of hepatic biosynthetic functions, such as albumin and prothrombin time, are useful for predicting prognosis in liver disorders. Child-Turcotte-Pugh (CTP) scoring system includes all these three parameters along with two clinical parameters (presence or absence of ascites and hepatic encephalopathy) and conveys information about overall liver function and prognosis (**Table 2**).

Table 2: Clinical Staging of Cirrhosis by Child-Turcotte-Pugh Classification

Factor	Points		
	1	2	3
Bilirubin	<2.0 mg/dL	2.0 to 3.0 mg/dL	>3.0 mg/dL
Albumin	>3.5 g/dL	3.0 to 3.5 g/dL	<3.0 g/dL
Prolongation of prothrombin time	0 to 4 sec	4 to 6 sec	>6 sec
International Normalised Ratio	<1.71	1.71 to 2.20	>2.20
Ascites	Absent	Easily controlled	Poorly controlled
Encephalopathy	Absent	Minimal	Advanced coma

CTP score can range from 5 to 15. Based on this score, patients can be classified into CTP A (score 5 to 6), B (score 7 to 9), or C (score 10 to 15). A score of more than 7 indicates decompensation, and is used as a criterion for listing the patient for liver transplantation.

The model for end-stage liver disease (MELD) is a survival model based on a composite of three laboratory variables: serum creatinine, serum bilirubin, and International Normalised Ratio (INR) for prothrombin time. MELD is better than the CTP score in stratifying patients according to mortality, and has replaced the latter to prioritise allocation of cadaveric livers for transplantation in many countries. It can be calculated using an online calculator http://www.mayoclinic.org/meld/mayomodel7.html. Severity of alcoholic hepatitis is calculated using "Maddrey discriminant function". It is calculated with the following formula.

Maddrey discriminant function = 4.6(prothrombin time prolongation) + (serum bilirubin in mg/dL)*

A value above 32 signifies severe alcoholic hepatitis.

LIVER BIOPSY

Liver biopsy is the ultimate and most specific investigation for assessing the nature and severity of the liver disease. It is a safe procedure and can be done through percutaneous, laparoscopic and transjugular approaches.

Liver biopsy is indicated in the following situations: grading and staging of liver diseases, unexplained hepatomegaly, hepatocellular disease of unknown aetiology including infiltrative hepatic disorders, unexplained splenomegaly, pyrexia of unknown origin, hepatic malignancies, autoimmune and cholestatic liver disease, and to assess the effectiveness of treatment for liver disease.

Grading refers to an assessment of the severity or activity of liver disease (inflammation, liver cell necrosis) such as mild, moderate or severe. Staging refers to an assessment of the disease as early or advanced in terms of fibrosis score (e.g. Ishak scoring system).

Percutaneous liver biopsy should not be performed in an uncooperative patient, patients with prothrombin time more than 3 seconds over control or International Normalised Ratio (INR) $\geq$1.5, patients with platelet counts less than 80,000/mm^3 and inability to tackle complication as a result of the procedure.

Liver biopsy carries a small but definite risk of mortality and complications, with rates of approximately 0.01% and 0.1 to 0.3%, respectively. The common complications include pain arising from pleura, peritoneum or diaphragm, intra-peritoneal haemorrhage, intra-hepatic haematoma, haemobilia, bile peritonitis, infection, etc. These complications can be managed using intravenous analgesics, blood transfusions, and radiological or endoscopic interventions. Surgical intervention is rarely required.

Transjugular liver biopsy is used in patients with abnormal coagulation, massive ascites or small liver, or those who need measurement of hepatic venous pressures. It does not carry the risk of bleeding complications, but is costly and needs a trained operator.

IMAGING STUDIES

These are discussed in chapter on "Hepatobiliary Disorders—Imaging".

HAEMODYNAMIC STUDIES

A balloon catheter is introduced into the hepatic vein via the femoral or internal jugular veins. Pressure measurements are taken in the hepatic veins by inflating [wedged hepatic venous pressure (WHVP)] and deflating [free hepatic venous pressure (FHVP)] the balloon catheter. The hepatic venous pressure gradient (HVPG) represents the difference between the WHVP and the FHVP, and is a measure of portal hypertension.

The normal value for HVPG is less than 5 mm Hg. The HVPG value more than 5 mm Hg signifies "portal hypertension" and more than 10 mm Hg signifies "clinically significant portal hypertension". Increase in value above 10 mm Hg is required for the development of oesophageal varices and above 12 mm Hg for the appearance of other complications, such as variceal bleeding. Decline of HVPG below 12 mm Hg or through more than 20% of the baseline level is associated with prevention of variceal bleeding, and at times with a reduction in size and possibly disappearance of varices. The achievement of these haemodynamic targets also lowers the risk of developing ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, hepatorenal syndrome and death.

14.4 Hepatobiliary Disorders—Imaging

Shrinivas B Desai

Imaging plays a crucial role in the management of hepatobiliary diseases. This topic can be divided into imaging in liver diseases and imaging of the biliary system.

IMAGING IN LIVER DISEASES

Techniques for studying the liver include plain radiograph, ultrasonography (USG), computed tomography (CT), magnetic resonance imaging (MRI), angiography and radionuclide scanning.

Abdominal Radiograph

The liver casts an appreciable soft tissue density shadow, with its borders outlined against fat and gas in adjacent organs. Hepatomegaly can be made out on plain radiographs of the abdomen by noting the displacement of gas in the adjacent gas-filled organs. Riedel's lobe, a normal variant seen commonly in women, is an inferior tongue-like projection of the right lobe. Focal hepatic lesions may distort one or more hepatic margins or may be seen as diffuse hepatomegaly on the plain radiograph.

Calcification within the liver may be localised or diffuse. Hydatid disease is the commonest cause. Other causes include old abscess or granuloma (single or multiple foci), hepatocellular carcinoma (stippled or sunburst type) and metastasis from mucous secreting adenocarcinoma and medullary carcinoma of the thyroid gland (faint fluffy calcification).

Gas is normally not seen in the liver. It may be seen confined to the parenchyma (e.g. abscess), within the biliary tree (e.g. after bilioenteric anastomosis or endoscopic papillotomy) or within the portal vein radicals (e.g. necrotising enterocolitis). Distribution of air helps in differentiation between air in the biliary tree (centrally located) and that in the portal veins (more peripherally distributed).

FOCAL HEPATIC LESIONS

Simple Liver Cyst

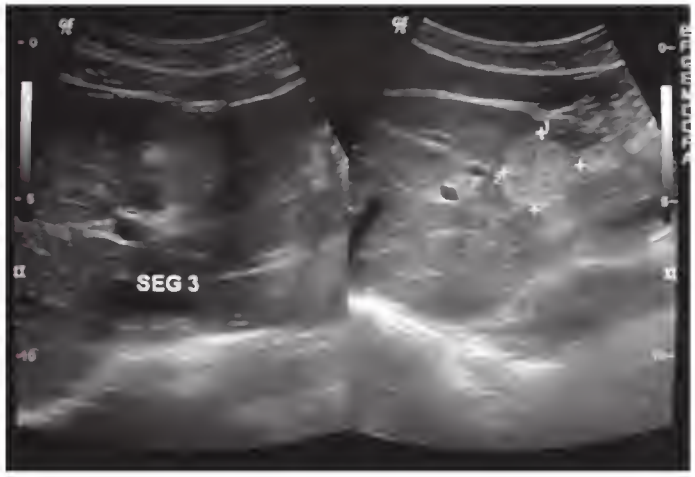
A liver cyst is a fluid-filled space with an epithelial lining. On sonography, liver cysts appear as anechoic, thin-walled lesions with posterior acoustic enhancement. On CT, they appear as well-defined, non-enhancing and thin walled cystic lesions. On MRI, they are hypointense on T1 WI images and hyperintense on T2 WI images.

Haemangioma

It is the most common benign tumour of the liver. On sonography, these appear as well-defined homogenously hyperechoic lesions (**Figure 1**). On non-enhanced CT (NECT) (**Figure 2**), they are seen as hypodense well defined mass lesions. Following contrast administration, there is filling in of the contrast from the periphery. On MRI, haemangiomas show a characteristic very long T2 relaxation time and therefore appear hyperintense on T2 WI images. On labelled RC SPECT scans, they appear as filling defects on early scans with prolonged and persistent radiotracer uptake on delayed scans.

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is a developmental hyperplastic lesion comprising of hepatocytes, Kupffer cells, biliary ducts and components of portal triads. It appears as a well-defined mass



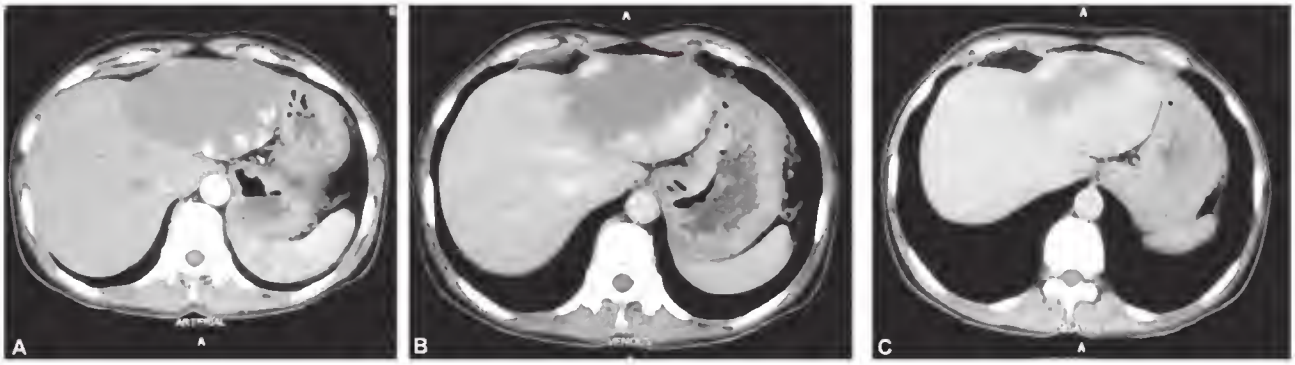


Figure 1: Ultrasound showing a hyperechoic lesion in segment 3 of left lobe of liver. Diagnosis: Haemangioma.
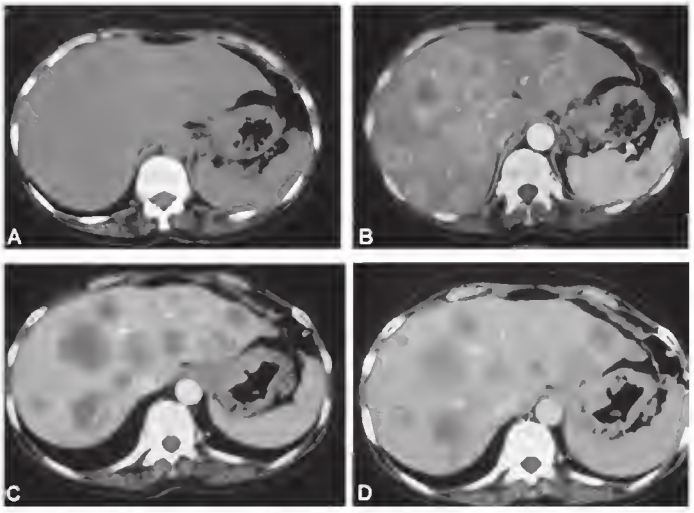
Courtesy: Dr Raju Sharma, AIIMS.

Figures 2A to C: Triple phase CT of the abdomen. Arterial phase (A) shows peripheral nodular discontinous enhancement with progressive centripetal extension on venous (B) and delayed (C) phase. Retention of contrast in the lesion is seen on the delayed image (C). Diagnosis: Liver haemangioma.
Courtesy: Dr Raju Sharma, AIIMS.

lesion with a central stellate scar that is isoechoic with the liver parenchyma on USG. The central scar appears hyperechoic with significant vascularity on Doppler imaging. On NECT, these lesions are iso- to hypodense to the liver parenchyma with a hypoattenuating central scar. Being highly vascular, these lesions show marked enhancement on arterial phase of contrast-enhanced CT (CECT) with rapid washout of the contrast, whereas the scar shows persistent enhancement. On T1 WI images, FNH appears iso- to slightly hypointense and turns iso- to slightly hyperintense on T2 WI images. The central scar is typically hypointense on T1 and hyperintense on T2 WI images. On administration of gadolinium contrast agents, the enhancement pattern is similar to that seen on CECT. On sulphur colloid scan, 50% of these lesions take up sulphur similar to adjacent normal liver and 10% appear as hot spots.

Hepatocellular Adenoma



It is a benign neoplasm that contains hepatocytes with dilated sinusoids but lacks bile duct components. The lesions are very heterogeneous on imaging due to the presence of fat, old or fresh blood and necrosis. Majority of adenomas are hyperintense to surrounding liver parenchyma on T1 WI images, and iso- to hyperintense on T2 WI images. They show marked contrast enhancement and are seen as cold spots on sulphur colloid scans.

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is a common malignant tumour. It can be solitary, multifocal or a diffusely infiltrating tumour. The sonographic features of HCC are very variable. It can be hypoechoic, echogenic or complex. In smaller tumours, there is seen a hypoechoic halo corresponding to fibrous capsule. Portal vein thrombosis is a frequent feature. The CT appearance is also variable. Most HCC are hypodense to the liver parenchyma on NECT, show enhancement on arterial phase and become iso- to hypodense on portal venous phase. As they are vascular tumours supplied by the hepatic artery, hypertrophy of the hepatic artery may be noted. Calcification is seen in 5% to 10% of HCC. Portal and hepatic vein thrombosis and arterioportal shunting may also be seen. On MRI, they are seen to be iso-, hypo- or hyperintense to the liver parenchyma on T1 WI images, and usually hyperintense on T2 WI images. They are heterogeneous with intratumoural septations. Fibrolamellar HCC is a histological subtype that shows no gender predilection and occurs in a younger age group. It arises commonly in non-cirrhotic livers. It is a vascular mass with a central scar, which is often calcified. On MRI, it is hypointense on T1 and hyperintense on T2 WI images, whereas the central scar remains hypointense on both sequences and shows no contrast enhancement.

Metastatic Tumours

They are usually multiple and hypoechoic on USG. Hyperechoic lesions are seen with GIT and urogenital tumours. Occasionally, metastatic disease may be seen as target lesions. They are typically hypodense to the liver parenchyma on NECT and show peripheral rim enhancement on arterial phase in CECT (**Figure 3**). Hypervascular metastases may become isodense to liver on portal venous phase and may be visualised on arterial phase as hyperdense lesions. Therefore, it is necessary to do dual phase imaging of the liver when looking for metastatic disease. On MRI, they are usually hypointense on T1 and hyperintense on T2 WI images and show an enhancement pattern similar to CT.

Figures 3A to D: Triple phase CT of the abdomen. Non-contrast CT (A) shows no lesion. Arterial phase (B) shows multiple hypodense lesions with thick rim enhancement. Portal venous phase (C) and delayed phase (D) shows washout from these lesions. Diagnosis: Liver metastases.
Courtesy: Dr Raju Sharma, AIIMS.

Liver Abscess

Liver abscesses may be pyogenic, amoebic (**Figure 4**) or fungal in nature. They are seen as hypoechoic lesions. As liquefaction sets in, the abscesses become more echo poor. Fungal abscesses show a hyperechoic central punctum, which represents an artery plugged by the fungus. On CT and MRI, they are seen as necrotic lesions with thick enhancing capsule.

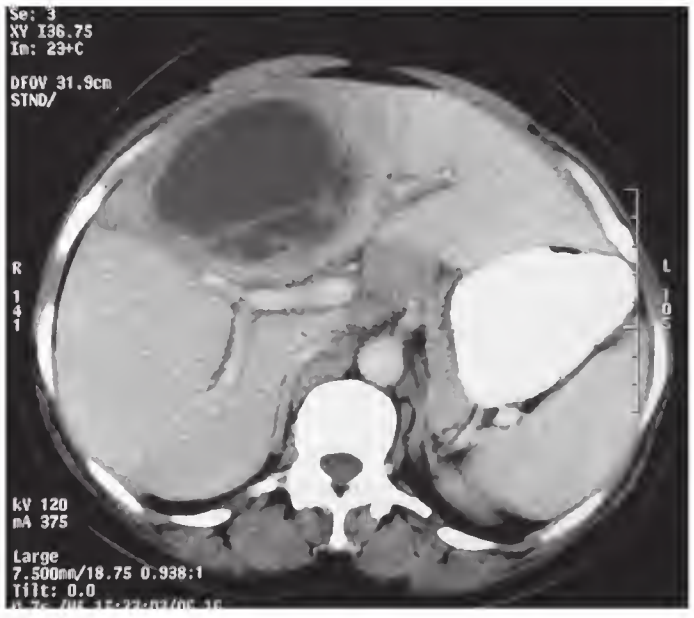


Figure 4: CT scan shows a hypodense lesion in segment IV of liver with thick peripheral enhancement and oedema in adjacent liver. Diagnosis: Amoebic liver abscess.
Courtesy: Dr Raju Sharma, AIIMS.

Hydatid Disease

Liver presents as a hypodense mass with multiple daughter cysts (water lily sign) (**Figures 5 to 7**). Hydatid cysts can rupture into the peritoneal cavity, biliary tree or pleural cavity with resultant pleural effusion. Calcification can be noted in longstanding hydatid cysts.

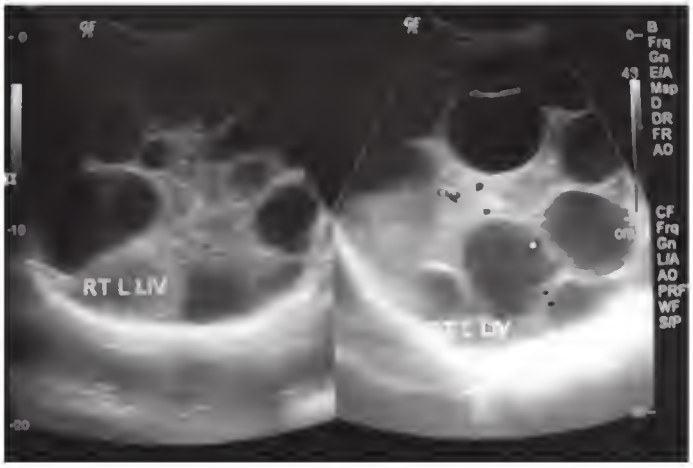

Figure 5: Ultrasound shows a multiloculated mass with daughter cysts in the periphery. Diagnosis: Hydatid cyst.
Courtesy: Dr Raju Sharma, AIIMS.

Figure 6: Hydatid cyst: CT scan shows a multilocular lesion in the left lobe of the liver. Density of daughter cysts is less than the centre of the lesion.
Courtesy: Dr Raju Sharma, AIIMS.

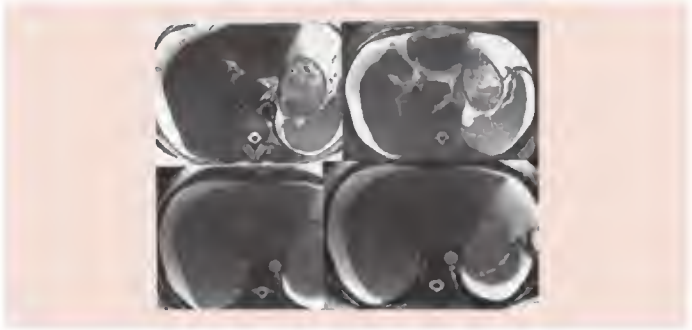

Figure 7: Hydatid cyst: Ultrasound reveals a right lobe cyst with multiple daughter cysts, pre and post aspiration.

DIFFUSE DISEASE OF THE LIVER

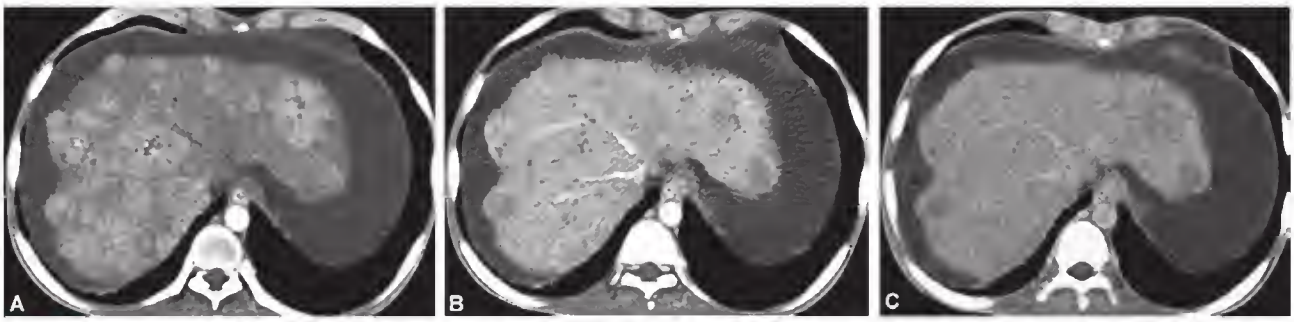
Fatty Liver

On USG, this is seen as diffuse increase in the echogenicity of the liver with poor visualisation of intrahepatic vessels and diaphragm. On CT (**Figure 8**), it is seen as a generalised low attenuation of the liver. MRI can confirm the diagnosis by utilising chemical shift imaging. On opposed phase images, areas of fat deposition show signal drop-out. In focal fatty deposition, focal deposits of fat stand out against the background of normal liver parenchyma; the reverse occurs in focal fatty sparing. None of above the imaging methods can differentiate simple fatty liver from those with steatohepatitis and fibrosis.

Ultrasound elastography (Fibroscan) is a new non-invasive method for assessment for hepatic fibrosis. It uses a modified

Figure 8: CECT scan shows liver is markedly hypodense as compared to the spleen suggestive of diffuse fatty change.
Courtesy: Dr Raju Sharma, AIIMS.

ultrasound probe to measure the velocity of a shear wave created by a vibratory source. Estimates of stiffness (fibrosis) of the liver by ultrasound correlate with fibrosis stage, and values above 12.5 kPa are indicative of cirrhosis. This technique is used in fatty liver/chronic hepatitis for separating patients with minimal or no fibrosis from those with significant fibrosis or cirrhosis. A linear correlation with increasing fibrosis has not been demonstrated, and 15% discordance between elastography scores and histologic fibrosis has been observed.



Cirrhosis

Sonographic features of cirrhosis include coarse echogenic echotexture, nodular surface and regenerating nodules surrounded by fibrous septae. The nodules are seen as iso- to hypoechoic lesions with echogenic borders corresponding to fibrous septae. There may be features of complication of cirrhosis in the form of portal hypertension or HCC. The caudate lobe to right lobe liver ratio of >0.65 is highly specific for cirrhosis.

CT and MRI show similar features (**Figure 9**). Regenerating nodules appear iso- to hyperdense to liver on NECT. Better appreciated on MRI, they are seen as hyperintense lesions on T1 and hypointense lesions on T2 WI sequences, and show an enhancement pattern similar to the rest of the liver. These features help in differentiating metastases and hepatomas from regenerating nodules. Of the various imaging techniques, MRI is the most sensitive and specific for this differentiation.

Viral Hepatitis

Imaging has little role in the diagnosis of viral hepatitis, and may reveal hepatomegaly, diffuse fatty change, periportal oedema and gall bladder (GB) wall thickening in the acute phase.

Figures 9A to C: Triple phase CT abdomen. Arterial phase (A) shows multiple lesions showing homogeneous arterial enhancement with washout in venous phase; (B) with suggestion of a peripheral capsule around some lesions.; (C) Background changes of cirrhosis in the form of nodular liver and ascites are noted. Diagnosis: Multifocal HCC in cirrhotic liver.

Courtesy: Dr Raju Sharma, AIIMS.

VASCULAR DISORDERS

Portal Hypertension

Ultrasonography may show features of underlying liver disease, collaterals, splenomegaly and ascites. Colour Doppler imaging is a non-invasive modality for studying portal haemodynamics (**Figure 10**). A portal vein diameter of >13 mm is characteristic of portal hypertension. Portal venous velocity is reduced in portal hypertension. Colour Doppler imaging can demonstrate the direction of flow in the portal vein. When paraumbilical vein is the major decompressive collateral, the flow in portal vein is hepatopetal. When other collateral channels open up, if the resistance to portal venous flow exceeds that in the collateral bed, the flow in portal vein becomes hepatofugal.

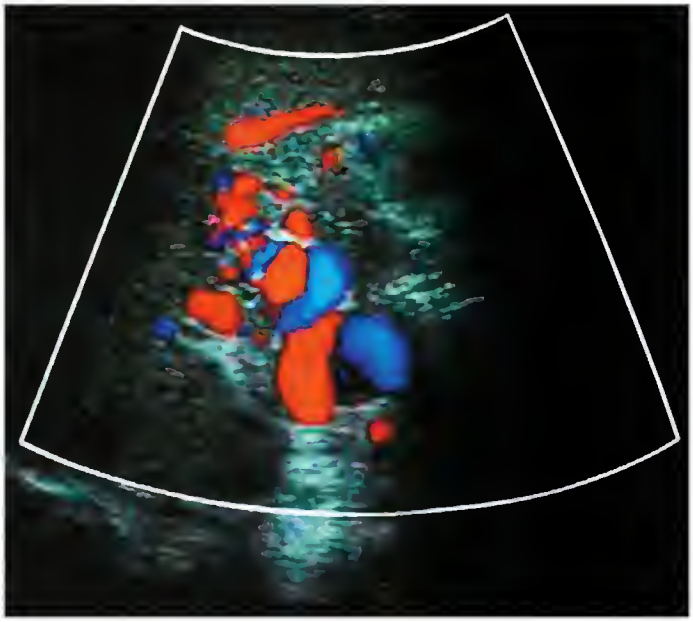


Figure 10: Colour Doppler in portal hypertension: Multiple tortuous serpiginous periportal collateral channels.

Portal vein thrombosis can be well evaluated by sonography. A portal cavernoma comprises multiple tubular structures in the porta hepatis. A pulsed Doppler spectral waveform of portal flow from multiple tubular channels at the porta is highly diagnostic of a portal cavernoma. In portal hypertension, variability of calibre of the splenic and superior mesenteric veins with respiration is lost.

Colour Doppler imaging can also be used to assess surgical porto-system shunts for patency. CT with angiography and portovenography can show the collateral circulation, and the presence of underlying cirrhosis, splenomegaly and ascites. It can also effectively monitor for development of hepatoma in the cirrhotic liver. The currently available 3D CT techniques can provide excellent three-dimensional images of the portal venous system with the entire collateral circulation, and have replaced splenoportograms (**Figure 11**).

Figure 11: Contrast-enhanced computed tomography in a patient with portal hypertension: Multiple tortuous serpiginous splenic hilar, lienorenal gastric bed and paraoesophageal collateral channels.

Budd-Chiari Syndrome

Obstruction to the hepatic venous outflow either due to hepatic veno-occlusive disease or due to IVC obstruction can be well evaluated by colour Doppler, CT, MRI and inferior venacavogram. The flow on Doppler imaging in IVC and hepatic veins changes from the normal phasic flow to absent, reversed, turbulent or continuous flow. In long standing disease, changes of cirrhosis and porta hypertension may set in. In the acute stage, NECT shows a large liver with generalised hypoattenuation, due to congestion and ascites. CECT shows patchy parenchymal enhancement and thrombosis of the IVC or the hepatic veins. In chronic stages, caudate lobe hypertrophy and dilated azygous and hemiazygous veins can be seen. MRI is very sensitive in Budd-Chiari syndrome and shows hepatomegaly, reduction in calibre or non-visualisation of hepatic veins, IVC thrombosis and generalised increase in signal intensity on T2 WI images due to congestion in the acute stage. Once the disease becomes chronic, the hepatic signal is low on both T1 and T2 WI images. Caudate lobe hypertrophy, dilated azygous and hemiazygous venous systems, and comma-shaped foci of signal void representing intrahepatic collaterals are seen.

IMAGING OF THE BILIARY SYSTEM

The various imaging modalities available today for studying the biliary system include plain radiographs, USG (trans-abdominal and endoscopic), endoscopic retrograde cholangiopancreaticography (ERCP), CT, MRI, MR cholangiopancreaticography (MRCP) (**Figure 12**), percutaneous transhepatic cholangiography (PTC), T-tube cholangiograms and radionuclide imaging.

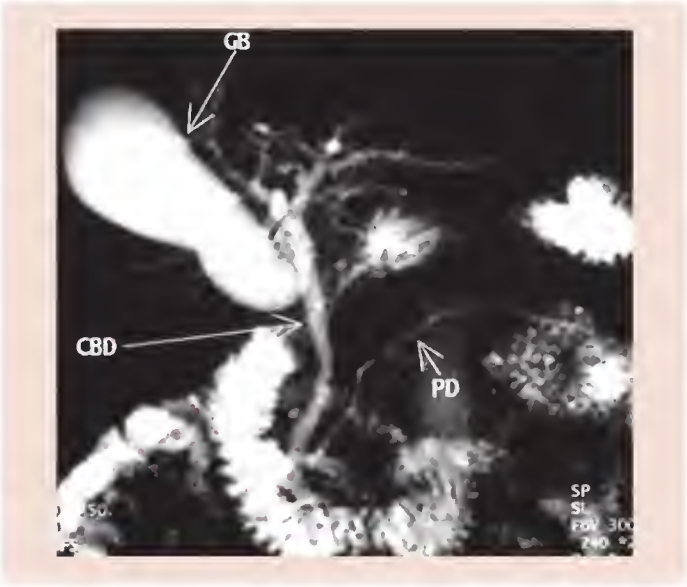

Figure 12: MRCP: Rare sequence delineating normal pancreatico-biliary tree.

Oral and IV cholangiography are of historical interest today, and CT cholangiography is hardly used in India.

Plain Radiographs

Gall stones

Approximately 20% to 30% of gallstones are radio-opaque and are seen on plain radiographs. A characteristic feature is the presence of central stellate fissure that contains gas (Mercedes Benz sign).

Limey bile

On horizontal ray projections, a horizontal level representing layered high-density bile, that contains a mixture of calcium carbonate and calcium phosphate, is seen.

Porcelain gall bladder

The GB wall shows calcification, as a result of chronic inflammation.

Emphysematous cholecystitis

Seen particularly in diabetics and following hepatic artery embolisation, this condition is a severe form of cholecystitis with gas-forming organisms. On plain radiographs, air is identified within the GB wall.

Air within the biliary tree

This will be seen as a centrally-located branching pattern of air confined to the biliary tree. The causes include bilio-enteric fistulae caused by gallstones, perforated peptic ulcer, and malignant diseases. It may also occur following biliary surgery or ERCP, and in elderly persons with physiological laxity of the biliary sphincter (old age).

Ultrasonography (USG)

The free availability, low cost, lack of ionising radiation and high sensitivity and specificity in detecting biliary diseases make USG a favoured imaging modality. The biliary system can be visualised by subcostal scanning. The normal GB is well distended after a fast of 8 to 12 hours and its wall should not be >3 mm in thickness. The GB should be scanned in two planes and in two patient positions so as not to miss any disease. The intrahepatic biliary ducts are seen as tubular structures accompanying the portal vein. Normally, they are 2 mm or less in diameter. The entire extrahepatic biliary tree can be well visualised on sonography. The normal mean duct diameter of common bile duct (CBD) is 4 mm at age 40, 5 mm at age 50, 6 mm at age 60 years, and so on.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

It involves cannulation of the major minor duodenal papilla under endoscopic visualisation and injection of iodinated contrast medium into the bile duct and pancreatic duct under fluoroscopic monitoring. Spot films in multiple projections are obtained. ERCP has the advantage of allowing collection of brushings and biopsy for cytological and histopathological examination, respectively, as also therapeutic procedures such as biliary stenting, balloon dilatation of strictures and extraction of stones.

CT and MRI

These are non-invasive and highly sensitive methods of determining the level and nature of biliary obstruction, and the extent of the disease process. They also play a useful role in postoperative evaluation. The normal GB is seen on CT as an oval structure located along the inferior surface of the liver, with a density (0 to 20 HU) similar to that of water. On MRI, it is seen as a bile-filled structure, bile in a non-fasting patient is hypointense on T1WI and hyperintense on T2WI images as compared to liver parenchyma. In fasting patents, bile gets concentrated and appears hyperintense to liver on both T1WI and T2WI sequences.

Magnetic Resonance Cholangiopancreatography

This is a non-invasive technique for visualisation of the biliary tree and pancreatic ducts which is based on heavily T2WI sequences. It does not require the use of any contrast medium. Magnetic resonance cholangiopancreatography (MRCP) has 95% accuracy in differentiating normal from dilated ducts, 100% accuracy in determining the level of biliary obstruction and 96.4% accuracy in determining the cause of obstruction.

Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography (PTC) is an interventional technique in which the biliary tree is punctured percutaneously using a Chiba needle under fluoroscopic guidance. After ensuring a secure access to the biliary system, iodinated contrast medium is injected and spot films of the opacified biliary stem are taken. It also permits therapeutic procedures like drainage of the obstructed biliary system and stenting of strictures.

Biliary Scintigraphy

99mTc-labelled N-substituted iminoacetic acid compounds (99mTc-HIDA) are used for imaging the hepatobiliary tree. After a

2 hour fast, 3 to 10 mCi of 99mTc-HIDA is administered intravenously and sequential images obtained with a gamma camera at 1-minute intervals over the first 1 hour and then at longer intervals over 24 hours. Functional and morphological information about the hepatic parenchyma is obtained over the first 10 minutes and about of the extrahepatic biliary tree over the next 10 minutes; normally, the dye reaches the bowel by 1 hour.

Biliary Disorders

Biliary atresia

Features on sonography include non-visualisation of the GB or a hypoplastic thick GB, non-visualisation of the common hepatic duct and presence of intra- or extra-hepatic cysts.

Choledochal cyst

Choledochal cyst, or cystic dilatation of extrahepatic bile ducts, is seen on CT as a hypodense (0-20 HU i.e. water density) lesion, which does not enhance on contrast administration. The lesion runs along the course of the CBD, and a separate CBD is not seen. On MRI, it appears as a fluid intensity lesion, which is hypointense on T1 WI images and markedly hyperintense on T2 WI images.

In patients without cholangitis, calculi or history of previous surgery, presence of contrast enhancement, or focal or diffuse thickening of the cyst wall should arouse a suspicion of carcinoma. In a large majority of cases, a long common channel with the pancreatic duct is seen which supports the hypothesis of reflux of pancreatic juice into the CBD as a causative factor in the development of choledochal cyst.

Based on the cholangiographic features, choledochal cysts are divided into five types (Todani classification; **Table 1**). Knowledge of the type of choledochal cyst (**Figure 13**) aids in planning surgery.

Figure 13: MRI of choledochal cyst: fusiform dilatation of the common hepatic duct and the common bile duct.

Table 1: Todani's Classification of Choledochal Cysts, based on Cholangiographic Features

Type 1a	–	Cystic dilatation of the CBD
Type 1b	–	Focal segmental dilatation of distal CBD
Type 1c	–	Fusiform dilatation of both CHD and CBD
Type 2	–	True diverticulum arising from the CBD
Type 3	–	Choledochocoele of the intraduodenal portion of CBD
Type 4a	–	Intra- and extrahepatic cysts
Type 4b	–	Extrahepatic cysts
Type 5	–	Intrahepatic bile duct cysts

Gall stones

USG is very sensitive in detecting gallstone disease. On sonography, the typical feature is that of a mobile highly reflective echo with posterior acoustic shadowing. CT is less sensitive than USG for this purpose, but is better for detecting calcified gallstones. On MRCP, gallstones produce no signal, and therefore, appear as inclusion defects against the background of bright bile; it is very sensitive in detecting gallstones in the lower CBD (**Figure 14**). Endoscopic USG also permits good evaluation of the lower CBD, which may be obscured by bowel gas or obesity on a transabdominal USG.

Figure 14: MRCP showing gall bladder calculi.

Cholecystitis

USG features of acute cholecystitis include presence of gallstones, oedema of the GB wall (wall thickness > 3 mm with a hypoechoic rim around it), calcific inclusion defect in the GB, probe tenderness over the GB, pericholecystic fluid collection, GB enlargement and gas in the GB wall (emphysematous cholecystitis). In chronic cholecystitis, the GB is contracted and has a thickened wall which may get calcified (porcelain GB). HIDA scan may show obstruction of the cystic duct. CT is more sensitive in picking up features of acute cholecystitis, which include pericholecystic fluid, GB wall thickening, GB enlargement, GB or CBD calculi, pericholecystic abscess, and gas within GB wall. It also helps to exclude other diseases that mimic cholecystitis.

GB carcinoma

CT and MRI usually show a soft tissue mass within the GB or in the GB fossa with direct extension into the adjacent liver. Lymphadenopathy may be present. Occasionally, there may only be focal or diffuse thickening of the GB wall (**Figure 15**). These tumours are usually hypodense and show heterogeneous enhancement. On T1 WI images they appear hypointense and hyperintense on T2 WI sequences. Fat-suppressed gadolinium-enhanced images are the best for detecting local invasion.

Bile duct tumour

They are usually adenocarcinomas of the scirrhous or papillary type. On imaging, there is proximal biliary dilatation with an abrupt cut-off due to a soft tissue mass that may occasionally be entirely intraluminal or may be apparent only as thickening of the bile duct wall. On non-enhanced CT, these tumours are frequently isodense to the liver and show minimal enhancement. On MRI, they are usually low signal on T1 WI and bright on T2 WI sequences. Fat-suppressed, gadolinium-enhanced images are the best for detection of periductal extent of the tumour.

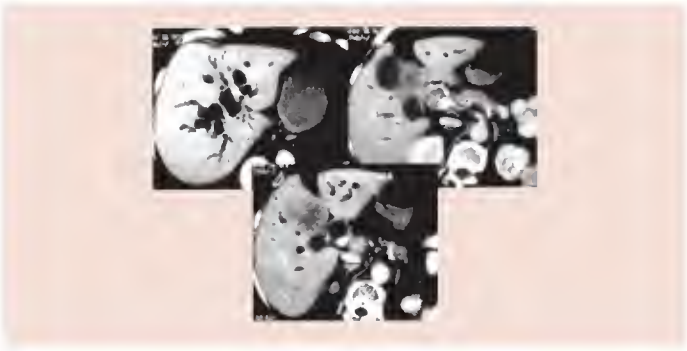

Figure 15: Carcinoma of gall bladder: Enhancing mass arising from GB wall with infiltration of porta hepatis and segment 4B of liver with resultant marked intrahepatic biliary radical dilatation.

Primary sclerosing cholangitis

In this condition, bile ducts have multiple strictures with focal areas of ductal dilatation leading to a beaded appearance on cholangiography (**Figure 16**). There may also be evidence of cirrhosis or portal hypertension. It predisposes to malignancy and there is an association with ulcerative colitis, retroperitoneal and mediastinal fibrosis, Riedel's thyroiditis and orbital pseudotumour.

Biliary parasitic infestations

Parasites that commonly infest the biliary tree include *Clonorchis sinensis*, *Ascaris lumbricoides* and *Echinococcus granulosus*. The infestation may be asymptomatic or may present with cholangitis. On MRCP, ascariasis is seen as linear filling defects within the bile duct or GB. Presence of fluid (bile) within the intestine of the round worm appears as a hyperintense line within the linear filing-defect. *Clonorchis sinensis* infestation may be associated with intrahepatic biliary structures and intraductal calculi (**Figure 17**).

Figure 16: Colour Doppler in porta hypertension: Mutiple tortuous serpiginous periporta collateral channels.

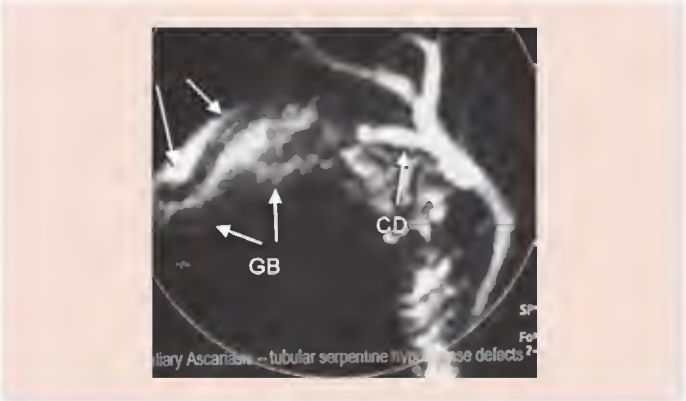

Figure 17: Contrast-enhanced computed tomography in a patient with portal hypertension: Multiple tortuous serpiginous splenic hiar, lienorenal, gastric bed and paraoesophageal collateral channels.

14.5 Acute Viral Hepatitis

Deepak Amarapurkar

INTRODUCTION

Acute viral hepatitis (AVH) was known to mankind since the middle ages. During the second world war, AVH was described to be of two types: (1) infectious hepatitis transmitted through contaminated water, (2) serum hepatitis transmitted by percutaneous exposure. The landmarks in the history of AVH are discoveries of Australia antigen by Barry Bloomberg in 1965, hepatitis A virus (HAV) by Feinstone in 1973, hepatitis C virus (HCV) by Hougton and colleagues in 1989, and hepatitis E virus (HEV) in 1990 by Reys *et al.*

Acute hepatitis is characterised by the parenchymal liver damage by any agent on an underlying normal liver which produces similar clinical and biochemical features. It can be caused by viral infections, non-viral infections, drugs,toxins, alcohol, metabolic diseases and ischaemia. A proper history and serological tests for infectious agents and assays for identifying drugs/poisons are required to diagnose the cause. When viral hepatitis is suspected, special emphasis should be given in history taking on blood transfusion, intravenous drug use, sexual practices, contact with jaundice person, needle stick exposure, working in hospitals in the areas like dialysis, trauma units, shared razors or tooth brushes, body piercing, tattooing, type of domestic water supply, and history of travel to the endemic areas for Hepatitis A and E. Sometimes, acute hepatitis may be first manifestation of underlying occult chronic liver disease e.g. acute exacerbation of chronic liver disease, or acute hepatitis may bring to light underlying chronic liver disease e.g. AVH occurring on underlying undiagnosed Wilsons' disease.

AETIOPATHOGENESIS

AVH is a systemic infection mainly affecting liver caused by hepatotropic viruses (hepatitis A to E). Other viruses like cytomegalovirus (CMV), herpes simplex, Coxsackie and adenovirus can also cause hepatitis in certain situations. AVH caused by hepatitis A to E is most common cause of liver disease worldwide and is a major public health problem in India. AVH leads to 1 to 2 million deaths annually worldwide.

The agents causing AVH are classified into two groups: (1) enterically transmitted (HAV and HEV) and (2) parenterally transmitted (HBV, HCV and HDV). Enterically transmitted viruses are not enveloped viruses, they are shed in faeces, survive intact when exposed to bile, do not cause chronicity and do not have prolonged viremia or carrier state. HAV and HEV are highly endemic in India. HEV is the main cause of most of the epidemics in India and accounts for 30% to 70% cases of acute sporadic hepatitis and a major cause of acute liver failure especially in pregnant women in India. In paediatric population, HAV is predominant cause of AVH. Dual infections with HAV and HEV have been reported in children and adolescents especially in acute liver failure in India.

Parenterally transmitted hepatitis viruses are HBV, HDV and HCV which are enveloped viruses which can cause chronicity and be associated with persistent viraemia and carrier state. About 15% to 30% of acute cases in India are due to HBV infection. HDV infection is found in less than 10% patients with HBV infection. HCV is rarely a cause of icteric AVH.

Majority of the AVH episodes are anicteric or subclinical; but when symptoms appear they are all similar in different types of AVH. The symptoms are characterised by prodrome of fever, anorexia, nausea, vomiting, mild abdominal pain, dark coloured urine followed by development of scleral icterus. AVH is characterised by 5 to 10 times elevation in serum alanine transaminases (ALT) with or without rise in serum bilirubin. However, the levels of ALT do not reflect the severity of AVH. To determine the severity of AVH estimation of prothrombin time (PT) (expressed as INR) is essential. PT expressed as INR more than 1.5 is considered severe acute hepatitis. Majority of the AVH are self limiting. Chance of fulminant liver failure varies from 0.01% to 1%.

HEPATITIS A VIRUS (HAV)

Virology and Modes of Transmission

HAV is a RNA virus belonging to Picorna virus family which is non enveloped, 27 nano micron size, has 7.5 kb genome. HAV is transmitted faeco orally. In rare instances, parenteral transmission via blood transfusion has been documented. Incubation period for HAV is 15 to 50 days with an average of 30 days.

Epidemiology

HAV has worldwide distribution and highly endemic in developing countries. India is hyperendemic region for HAV. There are estimated 1.5 million cases of HAV annually worldwide. Most of these cases occur in areas of poor hygiene and poor sanitation. Risk factors for HAV are children living in unhygienic condition, poor sanitation, consumers of high risk food, e.g. raw shell fish, people travelling to endemic areas and those participating in anal sex, intravenous drug abuses.

Natural History and Clinical Course

Main symptoms of HAV are fatigue, abdominal pain, anorexia, nausea, fever, dark coloured urine, jaundice, and diarrhoea. Rarely, HAV is associated with prolonged cholestasis leading to prolonged icetric illness. HAV never causes chronic infection and produces life long immunity. The risk of fulminant hepatic failure (FHF) is 0.01% to 0.1% which increases with age and patients having pre-existing liver disease (**Figure 1**).

Diagnosis

HAV is diagnosed by serological tests. IgM anti-HAV suggests acute infection; IgG anti-HAV suggests previous infection or vaccine acquired immunity. HAV RNA can be detected in blood, stool and liver during early part of the illness, but this test is not used in clinical practice.

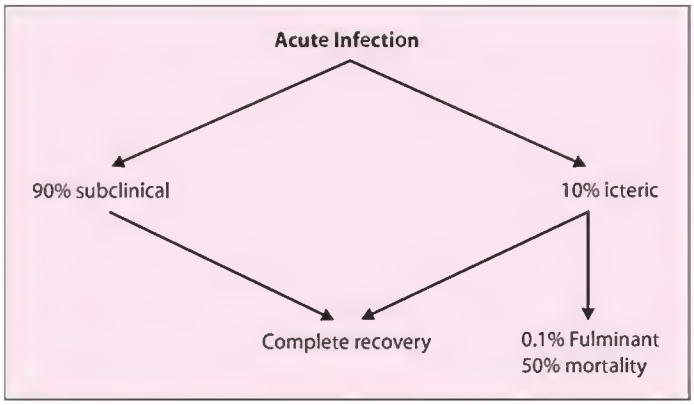

Figure 1: Natural history of hepatitis A virus infection.

Treatment

Management of HAV includes symptomatic and supportive measures; no specific antiviral treatment is required. Majority of the patients do not require hospital admission. Patients should be advised rest and given normal hygienic diet. Antiemetics may be given for nausea and vomiting. Patients with severe AVH and patients with HAV super imposed on underlying chronic liver disease require hospitalisation. Patients with HAV should be advised to avoid hepatotoxic agents such as alcohol, oral contraceptive medicines, paracetamol and non-steroidal anti-inflammatory drugs.

Prevention

Provision of clean drinking water, proper sewage disposal, public education about the hygiene are the mainstay for prevention of HAV infection. Infection with HAV provides long term immunity. Highly effective active and passive immunisation are available. Pre-exposure prophylaxis with inactivated vaccines can give protection up to 20 years. Passive immunisation is used for post-exposure prophylaxis within two weeks and should be accompanied with active vaccination (**Table 1**).

Table 1: Immunisation for Hepatitis A

Indication for active vaccination
Travellers to high risk area
Homosexual men
Injection drug users
Children and young adults when there is community outbreak
Susceptible patients with chronic liver disease
Food handlers
Children in the area of high endemicity
Schedule for hepatitis A vaccination
Children over two years of age, 3 dose regime
Inactivated HAV vaccine (360 ELISA units) 0, 1 and 6 to 12 months
Two dose regime : Inactivated HAV vaccine (720 ELISA units) 0, 6 to 12 months
Adults above 19 years of age
Inactivated HAV vaccine (1440 ELISA units) 0–6 to 12 months
Combined hepatitis A and B vaccine also can be used containing 20 mu/g HBsAg protein and more than 720 ELISA units of inactivated hepatitis A vaccine scheduled at 0, 1 and 6 months.
Post-exposure immunoprophylaxis—0.02 mL/kg body weight immunoglobulin specific to HAV on deltoid as early as possible after the exposure.

HEPATITIS B VIRUS (HBV)

Virology and Pathogenesis

HBV is a single-stranded DNA virus, with particle size 22 to 42 nano micron with 3.2 kb circular DNA genome. HBV replicates through an RNA intermediate using a virus-encoded reverse transcriptase enzyme. HBV genome has four genes, namely: surface, core, DNA polymerase and X. Four antigens HBsAg, HBcAg, HBeAg and HBxAg that have been identified in relation to HBV. Antibodies against this can be detected in the blood and are useful in diagnosis of various phases of HBV infection. There are at least 7 HBV genotypes (from A to G). Genotype D and A are more common in India. In immunocompetent persons, HBV is not cytopathic, and liver damage in this infection is caused through an immune-mediated mechanism directed against HBV-infected hepatocytes. However, in post-transplant patients, the virus appears to produce liver damage via a cytopathic effect.

Modes of Transmission

HBV is transmitted by blood-borne route, such as transfusion of infected blood and blood products, intravenous drug use, haemodialysis, sexual contact, percutaneous exposure (like needle-stick injuries, shared razor blades and tooth brushes, tattooing, acupuncture, etc.), and mother-to-newborn (i.e. perinatal) transmission. In India, a majority of chronic HBV infections are acquired horizontally, and less than 20% of chronic HBV infections results from vertical mother-to-child transmission.

Epidemiology

Acute hepatitis B is generally seen in patients with high risk behaviour for parenteral transmission in the western countries while in endemic region it can be seen in family contacts of patients infected with hepatitis B. More than one million people are infected with hepatitis B annually. In India 15% to 30% of the acute hepatitis cases are due to HBV infection.

Natural History and Clinical Presentations

Incubation period of HBV varies from 15 to 180 (average 60 to 90) days. In adults, almost 70% of acute infections are silent and subclinical; 30% develop icteric hepatitis. The proportion with clinical illness is smaller when infection occurs in early life. Thus, perinatal or childhood HBV infections are usually asymptomatic. About 1% of patients with acute hepatitis B develop fulminant hepatic failure (**Figure 2**).

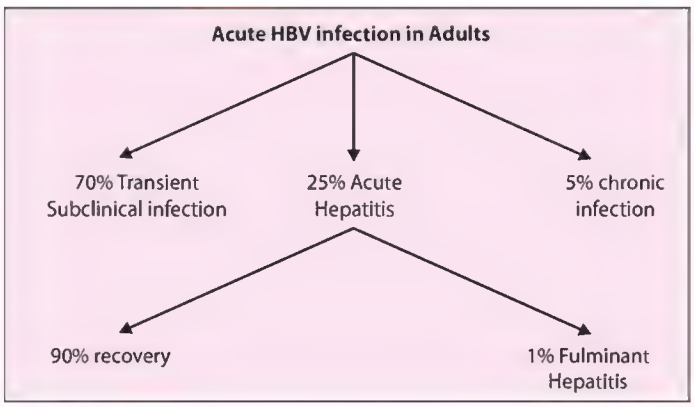

Figure 2: Natural history of hepatitis B virus infection.

HBV viraemia lasts for weeks to months after infection. Infection persisting beyond 6 months is labelled as chronic HBV. Risk of developing chronic HBV infection after acute exposure is dependent on age at the time of acquisition of infection; thus, nearly 90% of neonates, around 50% of young children aged 1 to 5 years, and 1% to 5% of adults with acute HBV infection develop chronic infection and persistent viraemia. The risk of chronic HBV infection is higher among immunocompromised individuals like HIV-infected, patients under immunosuppressive therapy and haemodialysis patients.

Diagnosis

Diagnosis of HBV infection is based on detection of various antigens and antibodies in the serum, or of HBV-DNA in serum or liver tissue. Presence of HBsAg in the blood suggests the presence of HBV infection. Presence of HBeAg in blood suggests active viral replication. IgM anti-HBc antibodies indicate recent (acute) infection. Anti-HBc IgG antibodies persist in the blood life-long after exposure to HBV. Anti-HBs antibodies appear with the clearance of HBV infection, and their presence suggests complete recovery. Detecting the presence and quantity of HBV-DNA in blood by polymerase chain reaction is useful in assessing whether virus is actively replicating, judging the need for and response to treatment. More specialised tests are used to detect mutant virus strains. Diagnosis of acute HBV is based on detecting IgM anti HBc in the blood.

Treatment

Acute HBV infection in adults is mostly a self-limiting disease and hence does not require any specific anti-viral treatment. The patients should be followed up to detect those in whom the infection becomes chronic; this is particularly important for children. Treatment with oral antivirals like Lamivudine, Telbivudine or Entecavir is indicated in patients with fulminant HBV, protracted severe HBV infection in immunosuppressed patients.

Prevention

HBV infection can be prevented by screening the transfused blood and blood products for HBsAg, using disposable needles and syringes, using safety precautions and practicing safe sex. Both active and passive immunisation are available. HBV vaccines, recombinant as well as plasma-derived, have more than 95% efficacy and are very safe. Hepatitis B immunoglobulin is useful for post-exposure prophylaxis (i.e. within 48 hours) and prevents mother-to-child transmission. HBV vaccination has been shown to reduce chronic HBV infection rate, and the incidence of hepatocellular carcinoma. HBV vaccination should be integrated into routine infant immunisation programme (**Table 2**).

HEPATITIS C VIRUS (HCV)

Virology and Pathogenesis

HCV is a single-stranded, enveloped RNA virus with a single open reading frame and 9.5 kb linear RNA genome. The anti HCV antibody has been used for the diagnostic purposes and does not have a protective value. The viral strains have significant genetic variability and have been grouped into six genotypes. In India, genotype 3 is the commonest; it is characterised by a good response to interferon treatment.

The exact mechanism of hepatocellular injury in HCV infection is unknown. Initially, HCV-induced liver injury was considered to be cytopathic in nature but current data suggest that host immune responses to HCV-infected hepatocytes play a major role in the pathogenesis of chronic hepatitis C.

Table 2: Immunisation for Hepatitis B

Indication for active vaccination	
	Universal infant immunisation shortly after the birth
	Catch up vaccination for adolescents if not previously vaccinated
	High risk groups
	Household contacts of HBV carriers
	Health care professionals
	Injection drug abusers
	Homosexual men
	Individual with multiple sex partners
	Haemodialysis patients
	Patients with chronic liver disease
HBV vaccine schedule	
	Below the age of 19 years 10 mu intramuscularly on deltoid at 0, 1, 6 months
	Above the age of 19 years 20 mu intramuscularly on deltoid at 0, 1, 6 months
	Accelerated schedule of 0, 1, 2, 12 also can be used
	Post exposure prophylaxis
	0.04 – 0.07 mL/kg HBIG intramuscularly within 48 hours alongwith the first dose of active vaccine. Further doses of active vaccine at 1 and 6 months should be continued.
	In neonates born to HBsAg positive mothers should be vaccinated at a dose of 0.5 ml of HBIG within 12 hours of birth along with the first dose of active vaccination. Futher doses of active vaccine at 1 and 6 months should be continued.

Mode of Transmission

Similar to HBV infection, HCV is also transmitted by blood-borne routes. Transmissibility of HCV is much lower than that of HBV. Recipients of infected blood and blood products, intravenous drug abusers, and haemodialysis patients form the major HCV risk groups. Sexual and perinatal transmission of HCV is uncommon. More than 80% of Indian patients with chronic HCV infection are either transfusion recipients or undergoing haemodialysis.

Epidemiology

Worldwide prevalence of HCV infection is around 1% with marked geographical variation. HCV carrier rate in India is around 1% to 2%, thereby meaning that 15 million people in India are infected with this virus. HCV is responsible for 20% to 30% of patients with chronic liver disease in India.

Natural History and Clinical Presentation

Incubation period of HCV ranges from 15 to 160 days. Prolonged viremia and persistent infection are common. More than 75% of acute HCV infections are silent. Only 25% acute HCV infections manifest as clinical hepatitis. In the stage of acute hepatitis, patients should be monitored for spontaneous viral clearance. Patients with symptomatic acute hepatitis and female gender are more likely to clear the virus. Fulminant hepatic failure due to HCV infection alone is extremely uncommon. Nearly 50% to 85% of patients with HCV infection develop chronic infection;

of these, 60% to 70% develop chronic hepatitis, 30% develop cirrhosis and 15% develop hepatocellular carcinoma. Average time duration between acquisition of infection and development of chronic hepatitis, cirrhosis and HCC is 10 years, 20 to 30 years and 40 years, respectively.

Diagnosis

Diagnosis of HCV infection depends on detection of anti-HCV antibodies, using third generation enzyme immunoassays (EIAs); the current tests for this purpose are highly sensitive and specific. In acute HCV infection serum HCV RNA are detected within 1 to 2 weeks of exposure while elevation in ALT occurs 2 to 8 weeks after exposure. Anti HCV antibody develop 4 to 6 weeks after exposure to hepatitis C.

Treatment

More than 50% patients with acute HCV infection develop chronicity. Treatment of acute HCV infection after 12 weeks is recommended as spontaneous resolution at this stage is unlikely. The objective of antiviral treatment in acute HCV infection is to prevent chronicity. Interferon alpha, peg interferon alpha and peg interferon alpha + ribavirin have been shown to be highly effective in treatment of acute HCV infection.

Prevention

Use of blood from voluntary blood donors (as opposed to professional donors) and screening of blood and blood products using an anti-HCV antibody test prior to blood transfusion can bring down HCV transmission dramatically. Use of disposable syringe and needles is also helpful. Currently, no active or passive immunisation is available for preventing HCV infection.

HEPATITIS D INFECTION (HDV)

HDV is an incomplete enveloped virus with particle size of 35-37 nano microns, 1.7 kb circular RNA genome. It uses HBsAg of HBV as its envelope protein, and hence can cause infection only in the presence of HBV infection. Infection with both HDV and HBV may be acquired simultaneously (known as delta-coinfection); alternatively, HDV infection may occur in a person previously having chronic HBV infection (delta-superinfection). HDV is transmitted by parenteral and sexual routes; vertical transmission is extremely rare. HDV infection is prevalent worldwide. However, its frequency has shown a decline globally, as well as in India.

HDV coinfection has a good prognosis with 80% to 90% of patients showing complete recovery. Fulminant hepatic failure is seen in 5% to 10% of patients as compared to only 1% of those with isolated acute HBV infection. HDV superinfection in a chronic HBV infected person is associated with increased rates of progression to cirrhosis, decompensation, development of hepatocellular carcinoma and death as compared to isolated chronic HBV infection. Clinical presentation of HDV infection varies from asymptomatic carrier stage, acute hepatitis, fulminant hepatitis, chronic hepatitis, cirrhosis decompensation and HCC. Acute deterioration in chronic stable HBV infection should lead to suspicion of delta superinfection. Diagnosis of HDV infection depends on demonstration of anti-HDV antibodies in the serum and HDV-RNA in serum or liver tissue.

Response of HDV infection to interferon as well as lamivudine is suboptimal. Since HDV depends on HBV for survival and multiplication, it can be prevented using methods to prevent the latter.

HEPATITIS E VIRUS (HEV)

Virology and Modes of Transmission

HEV is a positive stranded 7.6 kb base non enveloped RNA virus and belongs to family of calcivirus. The particle size of HEV virus is 32 to 34 nano microns. HEV antibodies have protective value are also used for the diagnostic and epidemiological purpose. HEV is predominantly transmitted by faeco-oral route with incubation period of 2 to 9 weeks with mean of six weeks. Rarely parenteral transmission, person to person transmission and mother-foetal transmission has been documented.

Epidemiology

HEV infection is most common cause of acute sporadic and epidemic viral hepatitis in India. Contamination of drinking water due to sewage has been the important source of majority of these epidemics. Faecal contamination may be due to backflow during the floods, leaking sewers located close to the corroded drinking water pipes and contamination of well water during raining seasons.

Natural History and Clinical Course

Clinical manifestation of HEV infection ranges from asymptomatic to icteric hepatitis to fulminant hepatic failure (FHF). Prodromal symptoms are similar to other forms of AVH. Cholestatic hepatitis with striking jaundice and itching may last for several months in 20% to 30% patients with acute HEV infection. By and large HEV is a self-limiting acute infection. 1% of the patients with HEV can develop FHF. Pregnant females (especially during 2nd and 3rd trimester) have high attack rates and 10% to 12% chance of FHF (**Figure 3**).

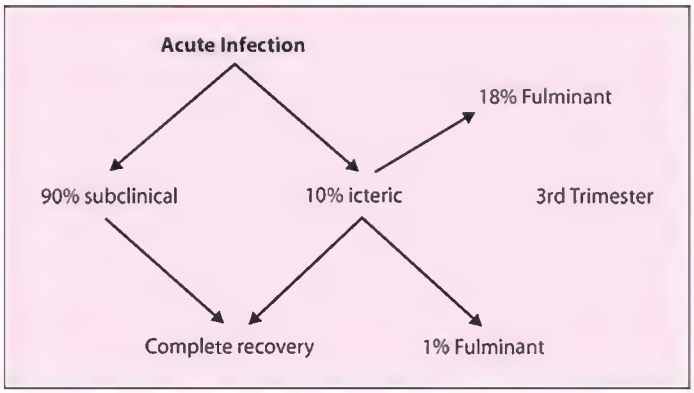

Figure 3: Natural history of HEV infection.

Diagnosis

IgM anti HEV antibodies are available for diagnosing of acute HEV infection. IgG anti HEV antibodies can be used for the sero-epidemiological studies. The virus can be identified in faeces, bile and the liver but this is not used in clinical practice.

Treatment

Treatment is supportive as described initially.

Table 3: Acute Viral Hepatitis in Special Situations

Specilist	HAV	HEV	HBV	HCV
Children	Benign course	Infrequently affected	Chance of chronicity is high	Chance of chronicity is high
Adolescents	Benign course Severe disease above the age of 40 years	Common benign course	Need to exclude underlying chronic hepatitis B	Chance of chronicity
Pregnant females	Course similar to non pregnant	Increase attack rate and increased chance of fulminant failure in 3rd trimester Increased foetal loss, possibility of transmission to foetus	Perinatal transmission to foetus likely Active and passive vaccination to child immediately at birth should be given	Chance of transmission to foetus if mother is coinfected with HIV
Immunosuppressed patients	Course can be severe	Course can be severe, can become chronic in post transplant period	High risk of chronicity may need antiviral treatment. Risk of chronicity in post treatment situation	High risk of chronicity, may need antiviral treatment. Risk of chronicity in post treatment situation

Acute Viral Hepatitis in Special Situation

The general clinical features of acute viral hepatitis have to kept in mind while dealing with such group. The clinical features and investigations are delineated in **Tables 3 and 4**.

Prevention

The best way of avoiding HEV infection is using safe drinking water, uncooked shell fish and foods which are contaminated. HEV vaccine has been recently shown to be effective and is awaiting commercial availability.

In conclusion, all forms of AVH in immune competent persons are self limiting. They do not require any specific therapy other than stopping hepatotoxic medications, including oral contraceptives and paracetamol. There is no role of vitamin supplementations, hepato-protective medications and dietary restrictions like avoiding proteins, fats and tamarind. Patients can start their routine work as soon as they feel fit to do so. Dietary restrictions and alternative medications may have deleterious course in AVH.

Table 4: Diagnostic Tests for Acute Viral Hepatitis

Hepatitis	Diagnostic Test For Acute Stage
HAV	IgM Anti HAV
HBV	IgM Anti HBc, HBsAg
HDV	Anti HDV in presence of IgM Anti HBc +ve
HCV	No antibody test to determine acute stage HCVRNA +ve in the absence of Anti HCV +ve in immune competent phase suggestive of acute infection
HEV	IgM anti HEV

14.6 Chronic Viral Hepatitis

Rajesh Upadhyay, Nitin Gupta

Chronic hepatitis is defined as hepatic necro-inflammation (detectable by biochemical or histological methods) continuing for more than 6 months. The condition may be self-limiting but usually progresses to fibrosis and subsequent architectural distortion with regenerating nodules leading to cirrhosis. There are many diverse causes of chronic hepatitis which can be broadly categorized into viral and non-viral causes (**Table 1**). This chapter presents an overview on chronic viral hepatitis.

Table 1: Causes of Chronic Hepatitis

Viral	Non-Viral
Chronic hepatitis B	Alcoholic hepatitis
Chronic hepatitis C	Non-alcoholic steatohepatitis
Chronic hepatitis D	Wilson's disease
	Drugs
	Auto-immune hepatitis
	Others

AETIOLOGY

Chronic viral hepatitis may be caused by hepatitis B, hepatitis C and hepatitis D. Of these, hepatitis B and C are the two most common viruses. In India, deaths from chronic hepatitis B (HBV) and chronic hepatitis C (HCV) infections are increasing over the years.

Hepatitis B Virus (HBV)

Epidemiology

HBV is a ds DNA virus belonging to Hepadnaviridae family of viruses. Hepatitis B is endemic throughout the world (350 million infected worldwide) especially in countries like Bangladesh, Thailand and Myanmar which have HBsAg carrier rates as high as 9 to 12%. In India, the carrier rate has been found to be around 4 to 7% with an estimated 45 million infected individuals. HBV is present in the blood, saliva, semen, vaginal secretions, and menstrual blood and, to a lesser extent, perspiration, breast milk, tears and urine of infected individuals. The virus can survive outside the body and is easily transmitted through contact with infected body fluids. The pattern of infection differs in developed and developing nations. Sexual transmission is common in the western world, whereas in developing countries like India, vertical transmission (mother to child at birth) and early childhood infections predominate.

Chronic infection leads to cirrhosis and hepato-cellular carcinoma (HCC) in 15 to 40% patients.

Clinical features and outcome

The clinical presentation of chronic viral hepatitis is similar for both HBV and HCV.

Chronic HBV infection is usually asymptomatic and is commonly detected on routine blood testing or during evaluation of incidental, unexplained elevation in alanine aminotransferase (ALT) levels. The clinical symptoms, when present, are generally mild and non-specific such as fatigue, mild right upper quadrant pain, nausea, weight loss, weakness, pruritus, etc. Patients with more advanced disease may have jaundice, abdominal swelling, gastrointestinal (GI) bleed or hepatic encephalopathy. Sometimes, the condition is diagnosed when the patient presents with an acute hepatitis illness which is due to reactivation of chronic hepatitis B.

Physical examination is usually unremarkable but stigmata of chronic liver disease may be present. Hepatomegaly with or without splenomegaly may be present depending on the stage of disease.

The outcome of chronic HBV infection depends on the age of acquisition of infection. Most patients are infected in early childhood and initial infection leads to inactive HBeAg-positive disease with high-level viraemia and minimal liver damage (immune tolerant phase). With advancing age, many patients develop an immune response (immune clearance phase) that leads to liver inflammation with progressive disease (high AST/ALT levels) and often seroconversion to HBeAg-negative phase of infection with low-level viraemia and normal liver function tests (LFT) (inactive replicative phase). A proportion of patients have reactivation of infection (reactivation phase) and develop HBeAg negative disease with fibrosis progression. The stages of chronic hepatitis B infection are shown in **Figure 1**.

Diagnosis

When chronic viral disease is suspected, the next step involves work-up of viral hepatitis using serological or molecular biological methods.

Patients with chronic hepatitis B (CHB) are diagnosed when hepatitis B surface antigen (HBsAg) persists in serum for more than 6 months. There are two main forms of chronic hepatitis B: (a) HBeAg-positive form associated with wild-type infection; and (b) HBeAg negative form associated with core promoter and/or pre-core mutant viruses.

Hepatitis B core antibody (Total) is present in CHB infection and presence of HBeAg or high HBV-DNA are markers of replicative virus. The transaminases (AST, ALT) are typically elevated usually 1 to 5 times the upper limit of normal with ALT> AST, whereas the alkaline phosphatase level is only mildly elevated. The albumin: globulin ratio remains normal except in advanced stages of disease where reversal of A:G ratio may be seen.

Abdominal ultrasonography (USG) is the most commonly used imaging modality although it is not useful in making the diagnosis. Its importance, however, lies in distinguishing patients with cirrhosis (small, shrunken nodular liver or atrophy of right lobe with hypertrophy of caudate/left lobe) or those with portal hypertension. It is also a useful screening test for

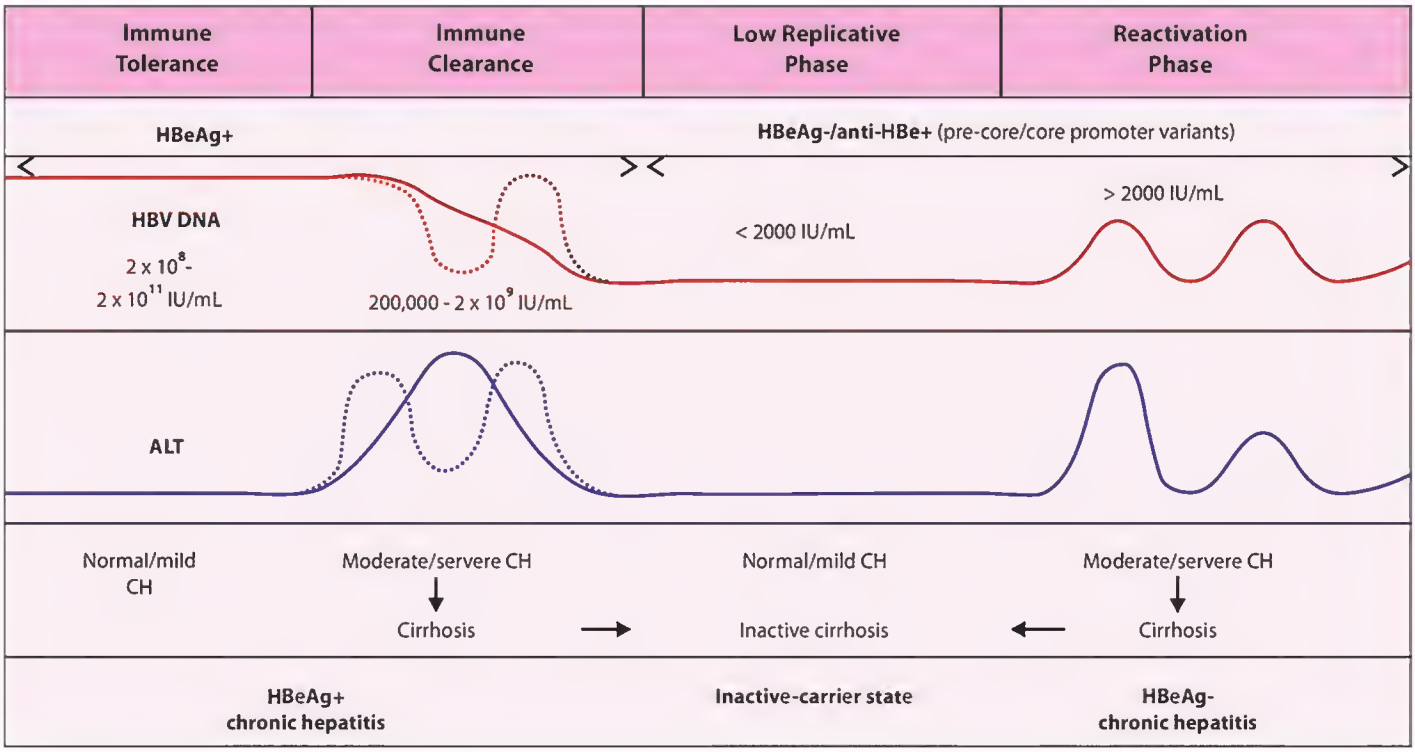

Figure 1: Stages of chronic hepatitis B infection.

hepato-cellular carcinoma. (USG) elastography (fibroscan) is a new non-invasive imaging modality used for assessment of fibrosis (stiffness) in chronic hepatitis. It may be useful in detecting patients with advanced fibrosis.

Chronic hepatitis is a necro-inflammatory process that may be complicated by fibrosis. A hallmark of chronic hepatitis is portal inflammation (portal hepatitis), predominantly lymphocytic. These changes are common to all aetiologies of chronic hepatitis. Certain changes are characteristic, but not pathognomonic, of chronic HBV. "Ground-glass" hepatocytes are a hallmark of hepatitis B infection which is due to proliferation of smooth endoplasmic reticulum containing HBs antigens.

Liver biopsy is not required for diagnosis of chronic viral hepatitis. Its usefulness lies in the histological assessment of liver for severity of necro-inflammation (grading) and degree of fibrosis (staging). Several histological classification systems are used for this purpose, e.g. Knodell-Ishak score, Scheuer score, Metavir score, etc. Such information is often useful for making therapeutic decisions.

Treatment

Treatment for chronic HBV infection should be restricted to patients with active inflammation and high replicative state (HBeAg positive or high level HBV-DNA). Such patients have higher risk of progressive disease leading to cirrhosis and hepato-cellular carcinoma.

Inflammation may be assessed indirectly by elevated ALT or directly by assessing liver biopsy specimen. Biopsy is usually not required for patients with ALT more than two times upper limit of normal. It may be considered in patients with borderline elevated ALT levels. Current guidelines advocate treatment in patients with HBV-DNA >20,000μ/ml in HBeAg-positive patients and HBV-DNA >2000μ/ml in HBeAg-negative patients.

The short-term goal of treatment is to convert patients from the high replication phase (HBeAg-positive or high HBV-DNA) to the low replication phase characterized by the appearance of HBeAb (called as seroconversion) or disappearance of HBV-DNA. This end-point is associated with lower or normal ALT levels and histological improvement. The long-term goals are to delay or prevent histological progression to cirrhosis and hepato-cellular carcinoma leading to improved survival. The ideal aim of treatment is HBsAg/HBsAb seroconversion which is difficult to achieve.

Treatment options include interferon injections (both standard and pegylated) and anti-viral drugs, such as nucleoside or nucleotide inhibitors. Currently used oral anti-viral drugs include lamivudine, adefovir, emtricitabine, entecavir and tenofovir. Interferon therapy is of finite duration, whereas a long-term therapy should be planned when using nucleoside analogues. The usual regimen for Peg-interferon is a weekly dose for 12 months. Nucleoside treatment should be continued for at least 6 months (preferably 12 months) after seroconversion in HBeAg-positive patients, or after HBV DNA levels have become undetectable in HBeAg-negative patients. Interferons should be avoided in HBeAg-negative patients as the results are disappointing and the end-points of treatment are not well defined. The problem with oral anti-viral drugs is the long duration of treatment and the risk of resistance (albeit low with newer anti-virals).

Hepatitis C Virus

Epidemiology

Hepatitis C virus is an RNA virus belonging to the Flaviviridae family of viruses. It was first identified in 1989. About 3% of the world population is infected with HCV and among them 170 million individuals are chronic carriers, and at risk of developing cirrhosis and liver cancers. In India, the prevalence of HCV

antibodies has been found to be 2% in voluntary blood donors, and 42% of patients with hepato-cellular cancer. The prevalence of HCV infection is also age-related with children and adolescents exhibiting very low rates (0.4%). The hepatitis C virus is blood borne and in the developed world transmission is common in IV drug abusers sharing contaminated needles or those who received blood or blood products before screening for HCV was introduced. The routes of transmission are diverse and include contaminated medical equipment (used in treatment or immunization) as well as contaminated non-medical equipment (such as barbers' razors).

Clinical features

Acute infection with hepatitis C leads to chronicity in almost 85% of the patients. Chronic infection leads to a slowly progressive hepatitis that can cause significant liver disease including cirrhosis and sometimes hepato-cellular carcinoma over 15 to 30 years. The disease is usually asymptomatic and detected during routine testing or during evaluation for asymptomatic elevation of transaminases. Sometimes it is present with icteric hepatitis and a few patients may present for the first time with decompensated cirrhosis.

The differentiation of acute from chronic HCV infection depends on the clinical presentation, namely the presence of symptoms and whether or not there was a prior history of ALT elevation and its duration.

The clinical features of chronic hepatitis C are similar to those of CHB infection. However, these patients are less likely to present with a past history of icteric hepatitis compared to patients with chronic hepatitis B.

Diagnosis

The diagnosis is based on the presence of both anti-HCV and HCV-RNA. These assays have no role in the assessment of disease severity. After acute exposure, HCV-RNA can be identified as early as 2 weeks following exposure whereas anti-HCV is generally not detectable before 8 to 12 weeks. Careful analysis of both these markers helps in diagnosis of acute or chronic HCV infection or resolved HCV infection (**Table 2**).

Table 2: Serology in the Diagnosis of HCV Infection

Anti-HCV	HCV-RNA	Analysis
Yes	Yes	Active infection (acute or chronic)
Yes	No	Resolved HCV infection
No	Yes	Early acute infection, false positive serology
No	No	No HCV infection

The pattern of LFT abnormality, use of imaging modalities and assessment of liver histology in chronic hepatitis C is similar to that in chronic hepatitis B (CHB).

Treatment

All anti-HCV positive patients with detectable HCV-RNA are potential candidates for treatment. Patients suspected of having acute or chronic HCV infection should first be tested for anti-HCV. HCV-RNA testing should be performed in patients with a positive anti-HCV test especially in whom, antiviral treatment is being considered. HCV genotyping should be performed in all HCV-infected persons prior to treatment. This helps to plan for the dose and duration of therapy and to estimate the likelihood of response. Treatment decisions should be individualized based on the severity of liver disease (decompensated liver disease is a contraindication to treatment), the potential for serious side effects and the presence of co-morbid conditions (like HIV co-infection).

The optimal therapy for chronic HCV infection is the combination of peginterferon alfa and ribavirin. Peginterferon alfa 2a is given as a fixed dose and alfa 2b is given according to body weight. Genotype 1 and 4 patients are treated with 48 weeks of treatment while genotype 2 and 3 patients are treated with 24 weeks of treatment. The finding of undetectable levels of HCV-RNA levels at 24 weeks after completion of treatment (sustained virological response) ensures that the treatment can be considered curative. The expected response rate is lower with genotype 1 and 4 patients (55 to 60%) compared to genotype 2 and 3 (75 to 80%).

In view of the poor response rate, especially in genotype 1 and 4, a number of drugs, such as telaprevir, are being currently tried in combination with pegylated interferon and ribavirin with encouraging results.

Hepatitis D Virus

This is uncommon in India but is more commonly seen in West Africa, Mediterranean and in parts of South America.

HDV (hepatitis delta virus) is a RNA virus discovered in 1977 and causes infection which requires HBV particles to infect the liver. The viral transmission is similar to HBV (blood borne and sexual). HDV infection may either be co-infection with HBV (simultaneous infection) or superinfection (HDV in chronic HBV carrier).

Chronic hepatitis D occurs in less than 5% of co-infected patients and in 80% of superinfected patients. The clinical features are similar to chronic HBV or HCV. The disease is progressive and 60 to 70% develops cirrhosis over 5 to 10 years. HCC also occurs with same frequency as in HBV or HCV infection.

The diagnosis is confirmed with a positive test for anti-HDV and HDV-RNA by RT-PCR. No specific treatment is available

14.7 Chronic Non-Viral Hepatitis

CE Eapen

When hepatic inflammation when continued for more than 6 months duration, the disease process is termed as chronic hepatitis. Progression of chronic hepatitis can lead onto cirrhosis and, less commonly, hepatocellular carcinoma. This section presents an overview of chronic non-viral hepatitis and discusses auto-immune hepatitis (AIH) in detail.

CHRONIC NON-VIRAL HEPATITIS

Aetiology

Hepatitis viruses B, C and D are important causes of chronic hepatitis, which are discussed separately in chapter 6, section 14. The important non-viral causes of chronic hepatitis are Wilson's disease, AIH, non-alcoholic steatohepatitis (NASH), drug-induced hepatitis, iron overload and unexplained/cryptogenic chronic hepatitis.

Clinical Features

Chronic hepatitis may be asymptomatic, with the disease being detected on routine blood tests. Patients may also present with non-specific symptoms, like fatigue or joint pains. Some patients may present with features of portal hypertension (like oesophageal variceal bleed) or liver cell failure. Physical examination may be normal. Some patients have jaundice, peripheral stigmata of liver cell failure, like spider nevi and splenomegaly.

Clinical clues may suggest the aetiology of chronic hepatitis. Acne may be a prominent feature of AIH, however it may also occur in other causes of chronic hepatitis (like Wilson's disease). Other autoimmune diseases like Hashimoto's thyroiditis, pernicious anaemia, insulin dependent diabetes mellitus or coeliac disease may be seen in AIH.

Kayser-Fleischer rings in eyes, neurological features (extra-pyramidal involvement: tremors, drooling of saliva, pseudo-Parkinsonian features) or psychiatric illness point to a diagnosis of Wilson's disease. Family history of liver or neurological illness also favours a diagnosis of Wilson's disease. Being an autosomal recessive disorder, Wilson's disease is more often seen in children born to parents of consanguineous marriage.

Chronic hepatitis in a patient with metabolic syndrome (obesity, diabetes mellitus, hypertension) is likely to be due to NASH.

A detailed drug history should be obtained in a patient with chronic hepatitis. Hepatotoxicity is a well recognised side-effect of some drugs, for example, anti-tuberculosis drugs like isoniazid, rifamipicin and pyrazinamide are a common cause of drug-induced hepatitis in India. In patients with drug-induced hepatitis, inadvertent continued use of the drug or repeated exposure to the drug may lead to more severe liver injury.

Hepatic iron overload may either be due to genetic haemochromatosis (clinical clues: family history of similar illness, presence of hyperpigmentation, diabetes mellitus, cardio-myopathy or hypogonadism) or haemosiderosis (example: a patient with thalassaemia who has been multi-transfused).

It is also possible that more than one hepatotoxic factor may be operant in an individual with chronic hepatitis (for example, a patient with metabolic syndrome and NASH, who develops alcoholic hepatitis).

Investigations

Persistent elevation of serum transaminases for more than 6 months raises the possibility of chronic hepatitis. Serum (AST to ALT) ratio is useful to distinguish NASH (AST: ALT ratio < 1) from alcoholic liver disease (ratio >/= 2). Viral markers (serology, molecular tests) are used to rule out hepatitis viral infections. Specific tests are done to look for the different causes of chronic non-viral hepatitis. For example, serum caeruloplasmin, urine copper and slit lamp examination of the eye for Kayser-Fleischer rings are done to look for Wilson's disease.

Liver Biopsy

The liver histology shows hepatic necro-inflammation with infiltration of portal tracts by chronic inflammatory cells—lymphocytes, plasma cells and varying degrees of fibrosis. Histological changes in chronic viral hepatitis are scored by 'grading' (degree of necro-inflammation) and 'staging' (degree of fibrosis).

Mallory hyaline bodies can be seen in a variety of conditions (for example, Wilson's disease, alcoholic hepatitis, NASH). Eosinophilic infiltrate may suggest drug-induced hepatitis. Special stains for copper (Rhodanine stain) and copper associated protein (orcein stain) help diagnose copper overload. Iron deposits are detected on Perl's Prussian blue stain.

Treatment

If an aetiological factor for chronic hepatitis is identified, specific treatment can be given. With effective treatment of Wilson's disease, the affected patients (often children or young adults) can be expected to outlive their doctors! Medications to reduce the copper overload state (for Wilson's disease), immuno-suppressive treatment (for AIH), stopping the offending drug (in drug-induced hepatitis), measures to reduce insulin resistance (for NASH) and iron chelation (in iron overload states) are examples of specific treatment when the cause for chronic non-viral hepatitis is identified.

AUTOIMMUNE HEPATITIS

This is an uncommon type of chronic hepatitis that improves after treatment with corticosteroids and other immuno-suppressive drugs. The other autoimmune liver diseases are primary sclerosing cholangitis, primary biliary cirrhosis and overlap syndrome. In a series of patients with autoimmune liver

disease from Delhi, AIH was seen in 78%, primary sclerosing cholangitis (10%), primary biliary cirrhosis (8%) and overlap syndrome (4%).

Epidemiology

AIH comprised 2% to 6% of the causes of acute and chronic liver diseases in reports from North and Western India. The disorder can occur at any age but has a predilection for girls and young women. The mean age of presentation of adults with AIH in India is between 31 and 36 years with female preponderance (male: female ratio is 1:3).

Pathogenesis of Autoimmune Hepatitis

A young lady on minocycline for treatment of acne who presents with chronic hepatitis could be having AIH. What predisposes an individual to develop AIH? One explanation is an interaction between human leukocyte antigens (HLA), hepatocyte antigens and receptors on T-lymphocytes (**Figure 1**). Candidate self-antigens are asialoglycoprotein receptor (located on hepatocyte surface) in AIH type 1 and cytochrome P450 2D6 (in hepatocyte microsomes) in AIH type 2. HLA-DR3 and DR-4 increase the risk of AIH type 1. In Western India, AIH type 1 is associated with HLA DRB1*0301, DRB1*1301, DRB1*14 and DRB1*1501.

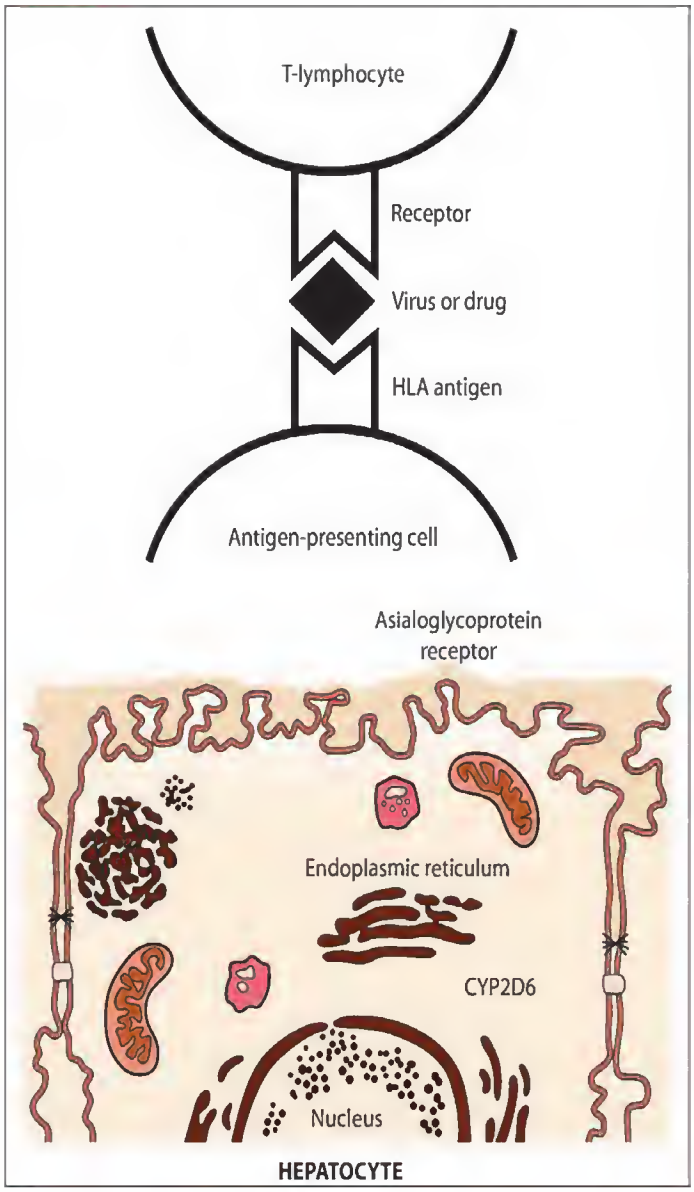

Figure 1: Pathogenesis of autoimmune hepatitis.

Molecular mimicry between viruses (hepatitis A, B, C, Epstein-Barr, measles virus) or drugs (minocycline, atorvastatin, methyldopa, nitrofurantoin) and hepatocyte antigens is a possible mechanism of pathogenesis. In genetically predisposed individuals this may result in an inappropriate immune response against the hepatocyte, even after elimination of the virus or cessation of the drug.

Clinical Features

The majority of patients present insidiously with malaise, anorexia and arthralgia while some may have features similar to acute hepatitis. Some patients may be asymptomatic. Fulminant hepatic failure is an uncommon presentation. In a report from Lucknow, patients with AIH presented with chronic hepatitis (50%), cirrhosis (34%), acute hepatitis (13%) and cholestatic hepatitis (3%).

Associated Autoimmune Diseases

About 40% of Indian patients with AIH have other autoimmune disorders. It is important to look for these disorders in patients with AIH. Fatigue in a patient with AIH may be attributed to the liver disease, while undiagnosed coeliac disease, hypothyroidism or vitamin B12 deficiency may be the cause of fatigue. In a report of 38 patients with AIH from Lucknow, other autoimmune diseases seen were diabetes mellitus (4 patients), hypothyroidism (3 patients), vitiligo (2 patients), thrombocytopaenia (2 patients), rheumatoid arthritis (2 patients), Sjögren's syndrome (1 patients) and autoimmune polyglandular syndrome III (1 patients).

Diagnosis

The diagnosis is based on clinical features and laboratory abnormalities. Elevation of serum transaminases is more than the elevation of alkaline phosphatase. Hyper-globulinaemia, increased serum immunoglobulin (Ig)G levels, positive autoantibodies: anti-nuclear antibody (ANA), anti-smooth muscle antibody (ASMA), anti-liver kidney microsomal antibody (anti-LKM), or anti-liver cytosol-1 (anti-LC1) and interface hepatitis on biopsy are the key tests to confirm the diagnosis. The levels of elevation of serum transaminases or serum globulins do not reflect severity of changes seen on liver biopsy. Making a confident diagnosis of AIH is difficult at times. A composite score to make the diagnosis of AIH has been proposed and presented in **Table 1**.

Types of Autoimmune Hepatitis

Autoantibody profiles are used to classify AIH into two types; however, these antibodies may not be involved in pathogenesis of AIH. Type 1 or classic AIH is characterised by the presence of ANA and/or ASMA. Anti-LKM-1 and anti-LC1 are found in type 2 AIH. Classic (type 1) AIH occurs predominantly in women in all age groups, while type 2 AIH is generally a disease of girls and young women.

Table 1: International Diagnostic Criteria for Diagnosis of AIH

	Parameter	Score
Female sex		+2
Ratio of elevation of serum alkaline phosphatase *vs* transaminase	>3.0	−2
	1.5 to 3	0
	<1.5	+2
Serum globulin or IgG (times upper limit normal)	>2.0	+3
	1.5 to 2.0	+2
	1.0 to 1.5	+1
	<1.0	0
ANA, SMA or LKM-1	>1:80	+3
	1:80	+2
	1:40	+1
	<1:40	0
AMA positive		-4
Hepatitis viral markers	Negative	+3
	Positive	−3
Drug history	Yes	−4
	No	+1
Alcohol	<25 g/day	+2
	>60 g/day	−2
HLA DR3 or DR4		+1
Other autoimmune diseases		+2
Response to therapy	Complete	+2
	Relapse	+3
Liver histology	Interface hepatitis	+3
	Predominant lympho-plasmacytic infiltrate	+1
	Rosetting of liver cells	+1
	None of above	−5
	Biliary changes	−3
	Other changes	−3
Seropositivity for other defined autoantibodies		+2

Definite AIH: totol score >15 before treotment ond >17 ofter treatment; Probable AIH: totol score 10-15 before treotment and 12-17 ofter treotment.
AIH = Autoimmune hepotitis; IgG = Immunoglobulin G; ANA = Anti-nuclear ontibody; SMA = Smooth muscle ontibody; LKM-1 = Liver kidney microsomol-1; AMA = Anti-mitochondrial ontibody; HLA = Humon leucocyte ontigen.

Differential Diagnosis

The other viral and non-viral causes of chronic hepatitis need to be ruled out before diagnosing AIH.

Treatment

Appropriate treatment for AIH can improve the quality of life, prolong survival and delay the need for liver transplantation. The benefits of achieving control of disease activity with immunosuppression has to be weighed against the potential side-effects of immunosuppression. Treatment decisions are thus individualised. Asymptomatic patients with minimal disease activity on liver biopsy or inactive cirrhosis may not need immunosuppression.

Corticosteroids are the mainstay of treatment. Prednisolone only regimen (1 mg/kg/day or 60 mg once daily) or combination of Prednisolone (0.5 mg/kg/day or 30 mg once daily) along with Azathioprine at 50 mg once daily are standard regimens to start treatment. In patients with uncontrolled disease despite steroids and azathioprine, treatment with cyclosporine, mycophenolate, tacrolimus and methotrexate have been tried.

Immunosuppression is tapered down once control of liver disease is achieved and low dose prednisolone and/or azathioprine is given as maintanence treatment for prolonged time periods. The end point of immunosuppressive treatment is sustained remission without need for medications, however this may be possible in only 10% to 40% of patients.

Patients with decompensated autoimmune cirrhosis do well after liver transplantation.

14.8 Alcoholic Liver Disease

Rajesh Upadhyay

INTRODUCTION

World Health Organization (WHO) estimates that about 2 billion people worldwide consume alcoholic beverages and 76.3 million have diagnosable alcohol-use disorders. India has also, unfortunately, witnessed a steadily increasing consumption of alcohol in the last 2 decades, attributable to socio-economic and demographic changes in population. The per capita consumption of alcohol in India has risen to 4 litres per year although it is still less than in US (16.2 litres per year). The National Family Health Survey (NFHS) 2007 reported that 30% of adult Indians have been consuming alcohol and of which 4% to 13% are daily users. **Table 1** shows some recent trends in alcohol consumption in India.

Table 1: Recent Changes in Alcohol Consumption Patterns

Emergence of wine and beer drinking
Increased drinking among women
Decreasing age of initiation
Shift from urban to rural areas
More 'binge drinking'
Greater social acceptability

PREVALENCE AND RISK FACTORS

There is a high prevalence of alcoholic liver disease (ALD) in India and about 50% cases of cirrhosis in India may be due to alcohol abuse. The quantity and duration of alcohol intake are the most important risk factors for the development of ALD. Different alcoholic beverages contain varying quantities of alcohol (**Table 2**) and the quantity is expressed as units (1 unit = 10 g alcohol). A high daily intake of alcohol (>60 g in males and 20 g in females) taken for more than 6 to 8 years significantly increases risk of ALD. Indians develop cirrhosis with smaller quantity and duration of alcohol intake. Other risk factors also influence the development of ALD in different individuals given the same dose or duration of alcohol intake (**Table 3**).

Table 2: Content and Quantity of Alcohol in Different Alcoholic Beverages

Beverage	Alcohol Content (per cent)	Serving Size (in mL)	Quantity of Alcohol (in grams)
Beer	5	350	13.85
Wine	12	120	10.7
Hard liquor	40	30	10.0

PATHOPHYSIOLOGY

A simple model explaining alcohol related hepatic injury is the three hit explanation: 1. lipogenic hit, 2. inflammatory hit and 3. fibrogenic hit.

Liver and gastrointestinal (GI) tract are the main sites of alcohol metabolism. Within the liver, there are two main pathways of alcohol metabolism, alcohol dehydrogenase and cytochrome P-450 (CYP) 2E1. Alcohol dehydrogenase is an enzyme that converts alcohol to acetaldehyde. Acetaldehyde is subsequently metabolised to acetate via the acetaldehyde dehydrogenase. CYP 2E1 also converts alcohol to acetaldehyde.

Table 3: Factors Increasing Risk of Alcoholic Liver Disease

Quantity of alcohol (>60 g in male and >20 g in female)
Duration of intake (High risk cirrhosis with >10 years intake)
Sex (Females susceptibility twice as males)
Hepatitis C co-infection (in up to 20% case)
Genetic factors
Malnutrition
Obesity
Smoking
Iron overload

Lipogenic Hit

Alcohol dehydrogenase and acetaldehyde dehydrogenase leads to reduction of nicotinamide adenine dinucleotide (NAD) to NADH. The altered ratio of NAD/NADH promotes fatty acid accumulation through the inhibition of gluconeogenesis and fatty acid oxidation.

Inflammatory Hit

The CYP 2E1, which is up-regulated in chronic alcohol use, generates free radicals through the oxidation of NADPH to NADP. Chronic alcohol exposure also activates hepatic macrophages, which produce tumour necrosis factor-alpha (TNF-α). TNF-α increases the production of reactive oxygen species. This oxidative stress promotes hepatocyte necrosis and apoptosis, which is exaggerated in the alcoholic, who are deficient in antioxidants, such as glutathione and vitamin E. Free radicals initiate lipid peroxidation, which causes inflammation and fibrosis. Inflammation is also incited by acetaldehyde that, when bound covalently to cellular proteins, forms adducts that are antigenic. Alcohol also increases permeability of intestine thereby releasing endotoxins which ignites Kupffer cells to initiate inflammatory cascade.

Fibrogenic Hit

The stellate cell is the major source of collagen production which leads to fibrosis. It is normally in a quiescent state and serves as a storehouse for vitamin A. The cytokine tumour growth factor-beta (TGF-β) is a major stimulus for stellate cell activation and collagen production. Other cytokines, such as platelet derived growth factor; connective tissue growth factor and oxidative stress also stimulate stellate cells to produce fibrosis.

A simplified pathogenic mechanism for ALD is shown in **Figure 1**.

SPECTRUM OF LIVER DISEASE

Chronic alcohol abuse leads to a spectrum of liver disease ranging from fatty liver, alcoholic hepatitis to cirrhosis and hepato-cellular carcinoma. Fatty liver is the earliest change and is almost universally present in heavy alcoholics. It is generally

a benign condition and usually reverses with abstinence. Alcoholic hepatitis (AH) occurs in 10% to 35% of heavy drinkers who develop necro-inflammation with or without fat infiltration and fibrosis. AH is a precursor of cirrhosis (9 times higher than patients with fatty liver alone) and patients with severe AH have extremely high short-term mortality. Cirrhosis occurs in 8% to 20% of heavy drinkers. It is advanced, irreversible stage of the disease characterised by hepatic fibrosis and regenerating nodules (micro- or macro-nodular). Hepato-cellular carcinoma may develop in this setting. The spectrum of alcoholic liver disease and the inter-relationship is shown in **Figure 2**.

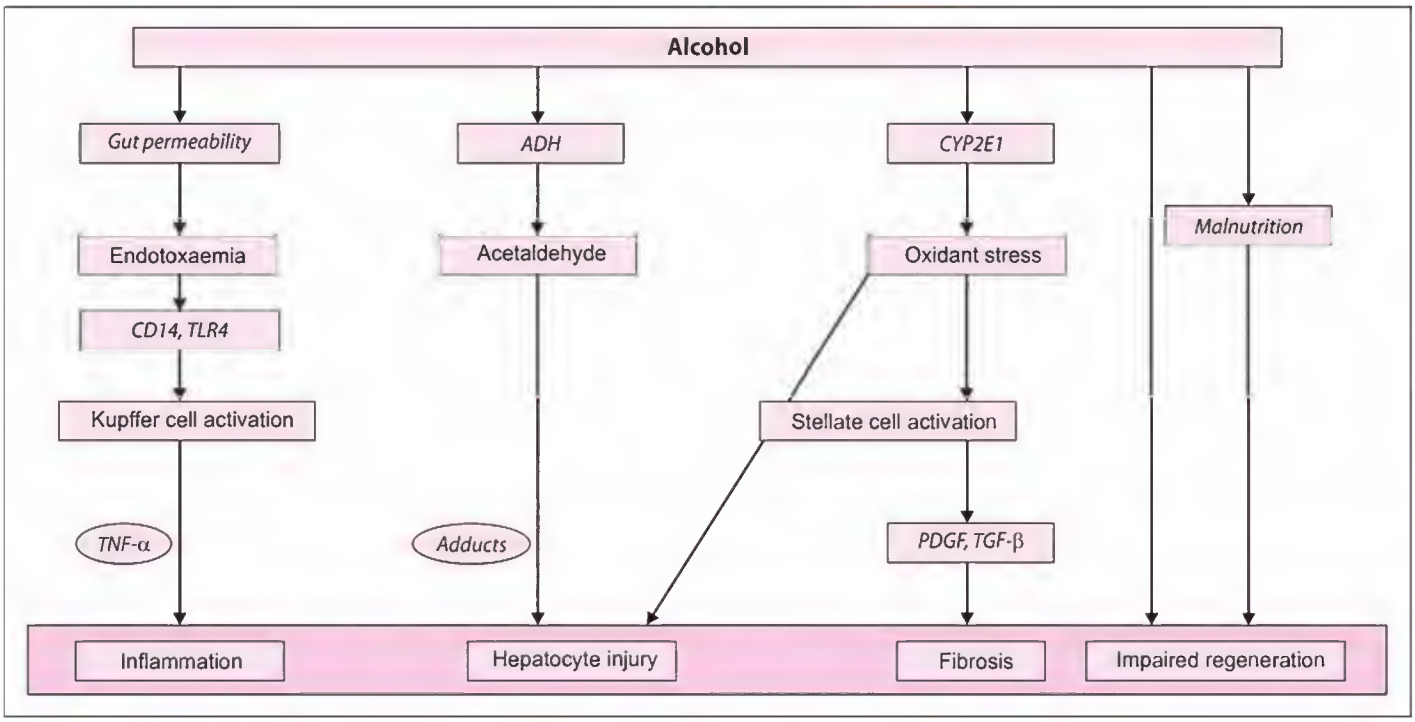

Figure 1: Pathogenic mechanisms of alcoholic liver disease.

ADH = Alcohol dehydrogenase; CYP2EJ = Cytochrome P2EJ; TNF-α = Tumour necrosis factor-α; PDGF = Platelet-derived growth factor; TGF-β = Tumour growth factor-beta.

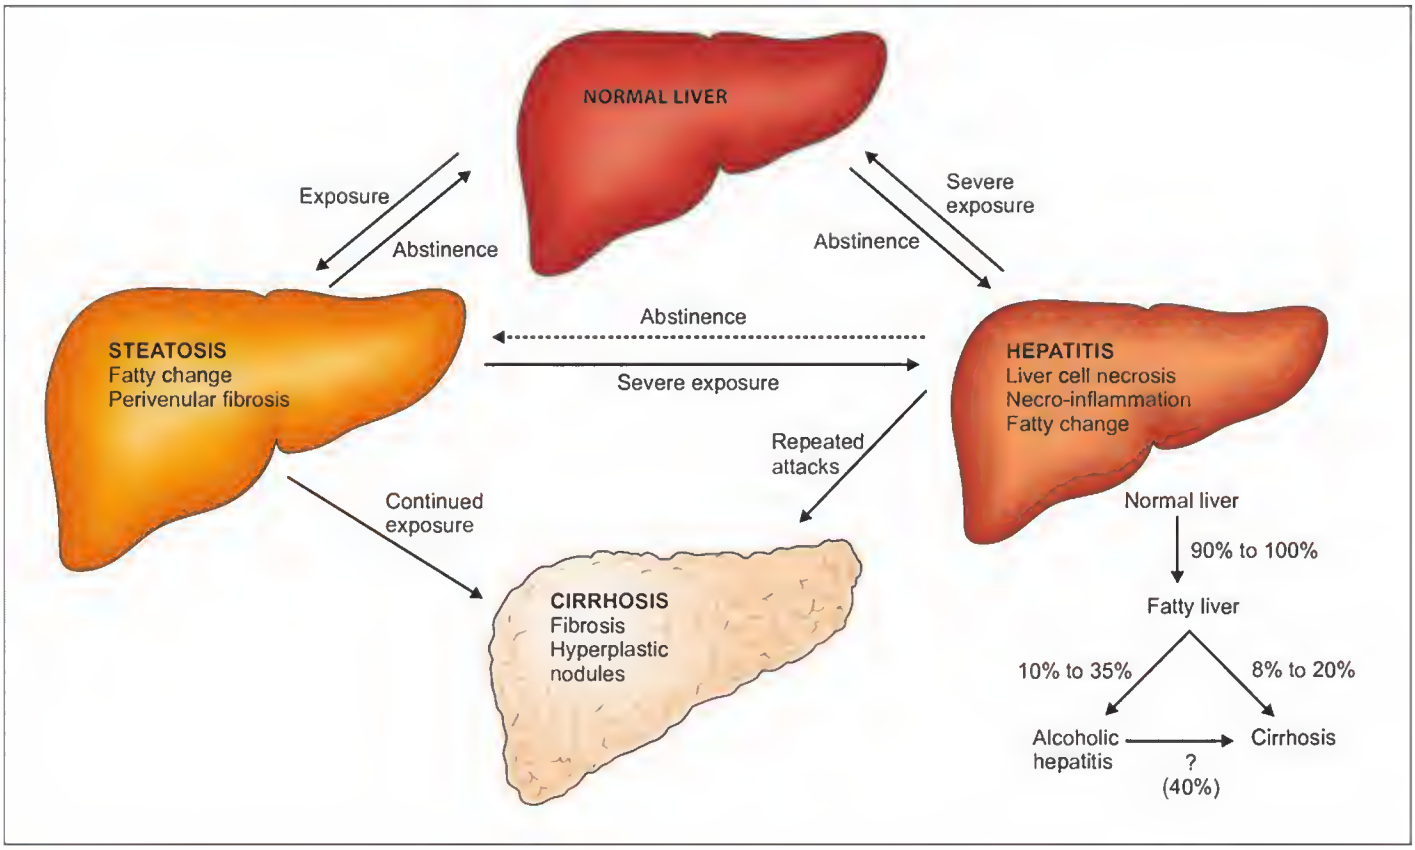

Figure 2: The spectrum and inter-relationship of alcoholic liver disease.

Prognosis and Assessment of Severity

The prognosis is dependent on the many factors such as severity of liver disease, nutritional status, continued alcohol ingestion, presence of co-morbid conditions, e.g. hepatitis B or C, hepatotoxic drugs, development of complications of cirrhosis (e.g., *ascites*, encephalopathy, variceal bleed), increasing age and acute severe AH.

Survival rate at 5 years is as follows: fatty liver – 70% to 80%, AH or cirrhosis – 50% to 75% and cirrhosis with AH – 30% to 50%. Overall one year survival rate is 80% which drops down to 50% at 5 years.

Clinical and laboratory features are powerful prognostic indicators for short-term mortality in acute AH. The Maddrey's score or discriminant, function [DF = 4.6 (patient's prothrombin time – control time) + serum bilirubin (mg/dL)]. Patients with DF > 32 (severe AH) have a one-month mortality of approximately 50%. AH patients with hepatic encephalopathy and hepato-renal syndrome have a mortality of 50% and 75%, respectively. Other prognostic indicators used to predict outcome are model for end stage liver disease (MELD) and Glasgow alcoholic hepatitis score (GAHS). The MELD score is calculated based on a patient's prothrombin time, serum creatinine and bilirubin and is equally sensitive and specific as DF but is more difficult to calculate at bedside.

The Childs Pugh score and MELD remain the most widely used systems for the assessment of outcome in patients with alcoholic cirrhosis.

CLINICAL FEATURES AND DIAGNOSIS

The key to diagnosis is a history of excessive alcohol intake along with features of liver disease (symptoms, physical signs, laboratory data and imaging). Patients frequently deny or understate alcohol abuse, and hence, a clinical suspicion should be confirmed by thorough questioning of family members and close friends as well.

Patients with fatty liver and most patients with mild/moderate AH are usually asymptomatic. Some patients have vague symptoms such as anorexia, malaise, nausea or right hypochondrial discomfort/pain. Physical examination in these patients is unremarkable although a mild smooth, non-tender hepatomegaly without any signs of chronic liver disease (CLD) may be present. Patients with more severe AH usually present with fever and signs of hepato-cellular failure, such as jaundice, ascites and encephalopathy. Patients with cirrhosis may remain asymptomatic and others have vague symptoms, such as tiredness, malaise or features of hepato-cellular failure, such as jaundice, *ascites*, peripheral oedema, etc. Physical signs of CLD is usually present in patients with cirrhosis and can broadly be divided into the following:

1. Signs of portal hypertension, i.e. *ascites*, splenomegaly and prominent abdominal wall veins.
2. Signs of alcoholism and liver disease, such as jaundice, telangiectasia, palmar erythema, parotid enlargement, clubbing, Dupuytren's contracture, neuropathy, etc.
3. Signs of hormonal dysfunction (feminisation), such as hypogonadism and gynaecomastia.

None of these signs are specific for ALD but parotid enlargement, feminisation and Dupuytren's contracture are seen more commonly in ALD. Other signs of extra-hepatic involvement in ALD, such as cardiomyopathy, muscular wasting, pancreatic dysfunction and neuropathy may also be present.

LABORATORY TEST

Liver Function Test (LFT)

The ratio of SGOT: SGPT >2:1 or higher is suggestive of ALD (present in >70% of the cases). Characteristically the SGOT is <400 and SGPT <200 u/l and higher levels should suggest an alternative diagnosis or a superimposed hepatic insult, such as viral infection or drug effect. Gamma GT is neither specific nor sensitive for the diagnosis of ALD. Macrocytosis is common and the combination of macrocytosis with high GGT may have a higher sensitivity for diagnosis. Leucocytosis is a common finding in acute AH and may be difficult to differentiate from associated infection. Laboratory tests which are useful in diagnosis are shown in **Table 4**.

Table 4: Typical Laboratory Abnormalities in Alcoholic Liver Disease

Liver Function Test	
	AST >ALT (AST usually <400 IU and ALT <200 IU)
	Serum albumin, prothrombin time, and serum bilirubin may be normal until significant liver injury is present
	Alkaline phosphatase, GGT levels usually elevated to a variable degree
Haematologic Abnormalities	
	Mild anaemia common (usually macrocytic)
	Platelets (normal to markedly decreased)
	Elevated white blood cell count
	Leukemoid reactions associated with alcoholic hepatitis
Metabolic Alterations	
	Hyperglycaemia
	Hypertriglyceridaemia
	Electrolyte abnormalities
	Low levels of potassium, magnesium and phosphorus

Liver Biopsy in Alcoholic Liver Disease

The overall clinical diagnosis of ALD, using a combination of physical findings, laboratory values, and clinical acumen is fairly accurate. However, liver biopsy may be required in select cases of ALD in order to confirm or exclude other diagnosis when in doubt. In addition, liver biopsy is also useful for the assessment of the disease severity, prognostication and guiding therapeutics. There are no pathognomonic histological features of ALD and the biopsy findings have to be corroborated with other evidences of ALD. The histological features on liver biopsy in different phases are shown in **Table 5**.

Imaging in Alcoholic Liver Disease

Imaging does not have a specific role in establishing alcohol as the cause of liver disease. The major role of imaging is to exclude other causes of abnormal LFT such as biliary obstruction, infiltrative and neoplastic conditions in an alcohol abuser.

Abdominal ultrasound is the first-line and the most cost-effective imaging modality. An increased echogenicity of liver is sensitive for fatty liver but does not help in diagnosing steatohepatitis. The presence of splenomegaly, *ascites*, dilated portal vein and collaterals suggest portal hypertension. Computed

Table 5: Histological Features of Alcoholic Liver Disease	
Fatty liver	Accumulation of microvesicular lipid droplets in hepatocytes, chronic intake leads to macrovesicular globules Perivenular fibrosis Macroscopically large, heavy (4 to 6 kg), soft, yellow and greasy liver
Alcoholic hepatitis	Hepatocyte swelling and necrosis Mallory bodies Neutrophilic reaction Fibrosis
Cirrhosis	Macroscopically the liver is brown and shrunken Regenerative activity of entrapped parenchymal cells with fibrous bands generate uniform micronodules With time nodules become more prominent and gives 'Hob nail' appearance (macronodular cirrhosis with higher risk of hepato-cellular carcinoma)

tomography (CT) and magnetic resonance imaging (MRI) are more sensitive in diagnosis of cirrhosis and demonstrate liver surface nodularity and altered density of the liver. Ultrasound elastography (Fibroscan) has recently been used as a non-invasive method to establish the presence of hepatic fibrosis (by assessing the elasticity of the liver).

Endoscopy in Alcoholic Liver Disease

Upper GI endoscopy is useful in the diagnosis of portal hypertension in patients with ALD. It can demonstrate oesophageal, gastric or duodenal varices and portal congestive gastropathy suggestive of portal hypertension. It also has a diagnostic and therapeutic role in alcoholic patients with upper GI bleed which is usually due to varices but may be due to a variety of causes, such as Mallory-Weiss tear, peptic ulcer, erosive mucosal disease or congestive gastropathy.

TREATMENT

The treatment depends on the stage of the disease and presence of complications of hepatic cirrhosis, such as GI bleed, *ascites* or encephalopathy. It includes certain general measures and specific treatment.

General Measures

Abstinence

This is the cornerstone of management. Abstinence improves survival, improves hepatic histology, reduces portal pressure and progression to cirrhosis. Patients should be encouraged to abstain but they are often unable to achieve complete and durable alcohol abstinence and psychiatric help is often required. Drugs which may help to sustain abstinence are naltrexone and acamprosate.

Nutritional support

There is a high prevalence of protein-calorie malnutrition in patients with ALD. The degree of malnutrition correlates directly with mortality. At one year from the time of diagnosis of AH, patients with mild malnutrition have a 14% mortality rate, compared with a 76% in those with severe malnutrition. In general, enteral nutrition is preferable over parenteral supplementation, and protein should be supplied (1 to 1.5 g/kg body weight/day) to provide positive nitrogen balance. Branched-chain amino-acids are useful as a supplement to maintain positive nitrogen balance in patients who do not tolerate liberal protein intake because of the development of encephalopathy. Nutritional supplementation may improve LFT, but mortality remains unaffected. Patients may also have depletion of potassium, magnesium and phosphates which may require replacement.

Alcohol withdrawal

This is commonly seen and needs aggressive management with intravenous glucose and thiamine supplementation (to prevent Wernicke's encephalopathy). Drugs, such as chlordiazepoxide, benzodiazepines may be required.

Specific Therapies

Fatty liver

Abstinence is the key intervention in management of fatty liver and leads to normalisation of LFT and imaging/histology. Overweight patients should lose weight with diet and exercise. Any associated metabolic abnormalities, such as diabetes or hyperlipidaemia, should also be treated aggressively.

Alcoholic hepatitis

Most patients with AH are associated with fatty liver and have a mild form of the disease requiring no specific treatment except the general measures. Other patients with more severe acute AH require specific treatment with anti-inflammatory agents, e.g. steroids and anti-cytokine therapy, e.g. pentoxifylline, infliximab, etc.

Corticosteroids

Steroids suppress inflammatory and immune responses in AH and has been the most extensively studied drug. Its efficacy remains controversial but overall evidence suggests that it reduces short-term mortality (although about 7 to 8 patients are required to be treated to prevent 1 death). The beneficial effect is limited to patients with severe disease (DF > 32 ± enceph-alopathy). Steroids, however, have a high rate of side-effects particularly infections, and hence should be used only in patients with no evidence of infection or GI bleed and where the diagnosis is definite (ideally biopsy proven). Predinosolone is given at 40 mg for 4 weeks, followed by tapering over the next 4 weeks.

Pentoxifylline

Pentoxifylline is a phophodiesterase inhibitor and also reduces the production of TNF-α and other pro-inflammatory cytokines. At a dose of 400 mg thrice daily, it significantly reduces mortality in patients with acute AH as compared to placebo (24% *versus* 46%, respectively). The drug is inexpensive and fairly well tolerated and is therefore preferred in management.

Infliximab and etanercept

These anti-TNF-α therapy have been used but remain controversial. Small trials with these anti-TNF-α drugs have shown beneficial effect but the cost and side-effects, especially a high incidence of infections, remains a concern for routine clinical use.

Other drugs

A large number of other drugs have also been studied in the management of ALD with variable levels of evidence for efficacy. Some are effective and others are still under evaluation stage (**Table 6**).

An algorithm for the management of acute AH is shown in **Figure 3**.

Table 6: Drugs Used in Alcoholic Liver Disease (Evidence based)

Beneficial	Likely to be Beneficial	Unlikely to be Beneficial
Corticosteroids Pentoxifylline	Infliximab Etanercept Antioxidants S-Adenosyl L-Methionine Silymarin	Colchicine Propylthiouracil Anabolic steroids Polyenylphosphatidylcholine

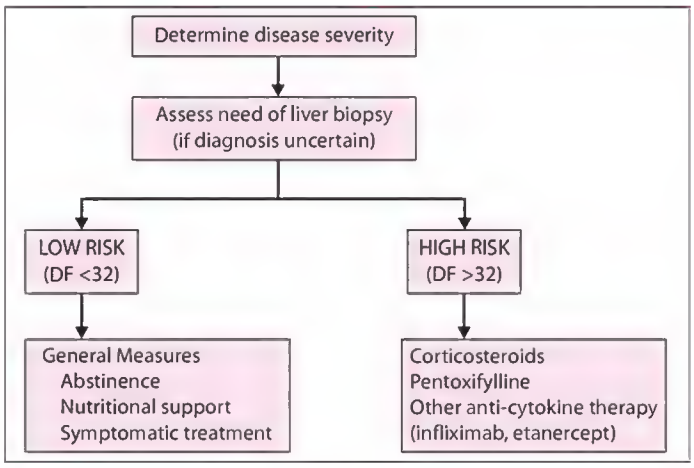

Figure 3: Therapeutic algorithm for alcoholic hepatitis.

Alcoholic cirrhosis

No specific treatment is available for alcoholic cirrhosis. Abstinence and correction of nutritional deficiencies are the major components of management to prevent disease progression. Management of alcoholic cirrhosis and its complication is same as with other forms of cirrhosis and is discussed in another chapter.

Liver Transplantation in Alcoholic Liver Disease

Acute AH, no matter how severe, is a contraindication for liver transplantation. Patients with end-stage ALD should be considered for liver transplant. Generally 6 months of abstinence is considered necessary as eligibility for liver transplantation. This requirement theoretically has a dual advantage of predicting long-term sobriety and allowing recovery of liver function from acute AH. Survival of patients post-transplant is similar to those with non-alcoholic cirrhosis (70% 5-year survival). However, alcohol use after transplantation for alcohol-related liver disease approaches 50% during the first 5 years, and abuse occurs in up to 15% of the patients.

CONCLUSIONS

Although 90% to 100% of heavy drinkers show evidence of fatty livers, only 10% to 35% develop AH and 5% to 15% develop cirrhosis. The daily intake of alcohol that results in liver injury varies and depends on a number of factors. ALD develops at lower doses in South Asians, women and patients with hepatitis C infection. Abstinence and correction of nutritional deficiencies are major components in the long-term management of ALD. Anti-inflammatory therapy with corticosteroids and anti-cytokine therapy with pentoxifylline are effective in patients with severe AH. Liver biopsy may be required when diagnosis is in doubt and is of importance when corticosteroids are being considered for treating AH. Patients with end-stage ALD should be considered for liver transplantation.

14.9 Cirrhosis of the Liver

Philip Abraham

DEFINITION

Cirrhosis is a diffuse process of fibrosis that converts the liver architecture into structurally abnormal nodules. In most if not all cases, the process follows or is accompanied by hepato-cellular necrosis.

Hepato-cellular necrosis can heal in one of two ways: complete regeneration and restitution of normal architecture (as occurs after recovery from fulminant hepatitis); or replacement by collagen, leading to fibrosis, as in cirrhosis. By this stage, evidence of the initial insult and necrosis may have disappeared.

Focal conditions like focal nodular hyperplasia need to be differentiated from the diffuse nodular process in cirrhosis. Fibrosis without nodularity (as in non-cirrhotic portal fibrosis and schistosomiasis) and nodularity without fibrosis (nodular regenerative hyperplasia) are also known to occur and should be differentiated from cirrhosis. Congenital hepatic fibrosis includes fibrosis and nodules, but the lobular architecture is maintained within the nodules.

CLASSIFICATION

Morphologically, cirrhosis is classified as:

1. *Micronodular*, in which all or nearly all the nodules are <3 mm in diameter and are surrounded by thick fibrous septa. This is often an early stage in the development of the disease. The liver is usually normal in size or enlarged.
2. *Macronodular*, where the nodules are more variable in size, with many being >3 mm in diameter, some up to several centimetres. Some nodules may contain normal lobules. The liver size is usually reduced.
3. *Mixed nodular*, in which micro- and macronodules are present in almost equal numbers.

AETIOLOGY

The commonest causes of cirrhosis worldwide are alcohol abuse and viral hepatitis (B and C). In urban centres in India, alcohol abuse accounts for more than 50% of cases. Hepatitis B accounts for 30% to 70% of cases, with hepatitis C following in frequency. About 30% of alcoholics also have markers of hepatitis virus infection; the relative contribution of viral infection and alcohol in such patients is variable.

An average daily intake of 80 gm of alcohol for 10 to 20 years is required for the development of cirrhosis in Western populations. It appears that Indians develop cirrhosis with smaller quantities of alcohol and over shorter durations; possible reasons include their smaller build, poor nutrition, adulterants in the illicit country liquor commonly consumed and higher frequency of concurrent hepatitis virus infection.

The other causes of cirrhosis are listed in **Table 1**. Malnutrition and mycotoxins (especially aflatoxin) may initiate or aggravate cirrhosis but are not recognised as independent causes of the disease.

Table 1: Causes of Cirrhosis

Alcohol*
Viral hepatitis (B and C)*
Metabolic disorders
Wilson's disease*
Haemochromatosis
Alpha-1 antitrypsin deficiency
Cystic fibrosis
Glycogen storage diseases
Galactosaemia
Autoimmune hepatitis*
Venous outflow obstruction
Budd-Chiari syndrome*
Veno-occlusive disease
Cardiac failure
Biliary obstruction
Primary sclerosing cholangitis
Primary biliary cirrhosis
Extrahepatic biliary obstruction (unrelieved obstruction for 3 months or more)
Unknown causes
Cryptogenic cirrhosis* (increasingly attributed to non-alcoholic steatohepatitis)
Indian childhood cirrhosis (infrequently reported now)
Sarcoidosis, Sjögren's syndrome, scleroderma, psoriasis, sickle cell disease
Drugs
Methotrexate, oxyphenisatin

**Common causes.*

PATHOLOGY AND PATHOGENESIS

The major pathways leading to cirrhosis are:

Hepatitis

Lobular hepato-cellular necrosis and central-portal bridging necrosis with fibrosis are important routes; piecemeal necrosis of hepatocytes may also be important. These changes of chronic hepatitis occur in viral hepatitis and in several other causes of cirrhosis.

Fatty liver

Ballooned hepatocytes containing Mallory bodies and macrovesicular fat deposits, surrounded by neutrophils and lymphocytes and collagen deposits, is the predominant route in alcoholics. Severe steatohepatitis may lead to fibrous septa, which contract and accentuate the architectural distortion caused by necrosis. A similar picture is seen in non-alcoholic steatohepatitis, which, as a part of the metabolic syndrome, is being increasingly incriminated as a major cause of 'cryptogenic' cirrhosis.

Portal and centrilobular fibrosis

Bile duct disease causes cirrhosis by initiating fibrosis in the portal tracts, with linking of these tracts ultimately. A similar process of fibrosis sets in the centrilobular area in patients with venous outflow obstruction.

The end-result of all these pathways is fibrosis and scarring with distortion of the architecture (**Figure 1**). Regeneration of hepatocytes may proceed simultaneously with the necrosis. Intrahepatic portal-systemic shunting of blood is a consequence of the necrotic bridges. Portal hypertension follows collagen deposition in the space of Disse and compression of the vasculature by regenerative nodules, fibrosis and hepatocyte enlargement.

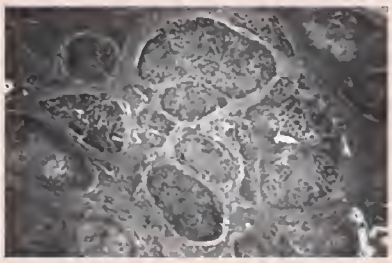

Figure 1: Histology of liver showing cirrhosis.
Courtesy: Dr. IM Vora

CLINICAL FEATURES

About one-third of patients with cirrhosis are *asymptomatic* because just 10% of the liver cell mass is adequate to maintain metabolic functions, and because the liver has a unique regenerative capability. *Weakness* and *fatigability* are common in decompensated cirrhosis, which carries a poorer prognosis; muscle wasting is evident. Overall *weight loss* may be masked by fluid retention. The clinical features associated with hepatocellular failure are depicted in **Table 2**.

Table 2: Clinical Features of Hepatocellular Failure

Jaundice
Foetor hepaticus
Parotid enlargement
Spider naevi, bruises and purpura
Loss of axillary and pubic hairs
Breast atrophy, gynaecomastia/testicular atrophy
Dupuytren's contracture, flaps, white nails with clubbing
Pedal oedema

Spider angiomas (naevi) and *palmar erythema* are seen in alcoholics. The naevi consist of a central arteriole with radiating capillaries; pressure on the arteriole with a pinhead obliterates the naevus. Such naevi vary in size from a few millimetres to a centimetre, are found commonly on the face, chest and upper limbs, and can rarely spurt blood. They can also be found uncommonly in normal subjects, especially in pregnancy, in rheumatoid arthritis and in patients on oestrogen therapy. Palmar erythema appears as reddening of the thenar and hypothenar eminences and finger pulp, with sparing of the rest of the palm.

Gynaecomastia in men is believed to be due to increased conversion of androgens into oestrogens in the peripheral tissues; spironolactone therapy can also induce gynaecomastia. *Hypogonadism* manifests in men by testicular atrophy and loss of libido, especially in alcoholics, and in women by oligomenorrhoea or amenorrhoea. *Infertility* is common in both sexes.

Anaemia in cirrhosis is due to several factors: nutritional iron or folate deficiency, blood loss, bone marrow hypofunction, hypersplenism, and haemolysis. *Impaired coagulation* due to decrease in the synthesis of coagulation factors in the liver, disseminated intravascular coagulopathy, and thrombocytopaenia secondary to hypersplenism may manifest with ecchymosis, purpura or gingival haemorrhage.

Low-grade fever, white opaque nails, clubbing of nails, Dupuytren's contracture (in alcoholics), *cyanosis* (central and peripheral), and *foetor hepaticus* (ammonical smell of breath in hepatic encephalopathy) are infrequent manifestations. The *Kayser-Fleischer corneal ring* should be looked for in all young cirrhotics, in whom Wilson's disease should be suspected.

The other major manifestations in decompensated cirrhosis are features of hepatocellular failure and portal hypertension, viz. jaundice, ascites and hepatic hydrothorax, gastrointestinal (GI) bleeding, and encephalopathy. *Jaundice* is usually due to failure of hepatocytes to excrete bilirubin, with resulting conjugated hyperbilirubinaemia. Except in the presence of ongoing histologic activity, jaundice is absent or mild; severe jaundice is a poor prognostic feature.

Ascites is frequently associated with oedema of the feet. Distension of abdomen, anorexia and fullness after small meals are the presenting symptoms. Occasionally, umbilical or inguinal hernia may be the presenting feature. Ascites is a sequel of portal hypertension (high hydrostatic pressure), along with decreased serum albumin levels (low osmotic pressure) due to low functional hepatocyte mass. Both hepatic and splanchnic lymph spillover may contribute to its formation.

On examination, the abdomen is distended with bulging of the flanks. The abdominal wall is thin due to loss of subcutaneous fat and muscle mass. Veins in the wall may therefore appear prominent and should be distinguished from the dilated veins of intrahepatic portal hypertension and inferior vena cava block. *Dilated veins* radiating from the umbilicus (caput medusa), when present, help to differentiate patients with intrahepatic causes of portal hypertension (in whom they may be present) from those with prehepatic causes (where they do not occur).

The puddle sign around the umbilicus can detect small amounts of fluid, but is inconvenient to elicit and unreliable. Flank dullness (indicating at least 1500 mL of fluid) and shifting dullness are other signs in ascites. A fluid thrill can be elicited when the abdomen is tense. Tense ascites is diagnosed when organomegaly cannot be detected despite deep palpation. About 5% to 10% of patients with ascites have pleural effusion ('hepatic hydrothorax'), on the right side in about 70% of them. The fluid is drawn up through defects in the diaphragm by the negative intrathoracic pressure.

The most common source of *upper GI haemorrhage* in cirrhosis is oesophageal varices, which are collateral vessels decompressing the portal hypertension. Less commonly, varices in the gastric fundus or body may bleed. Portal hypertensive ('congestive') gastropathy, gastric antral vascular ectasias, gastric erosions and peptic ulcers are other potential sites of bleed in cirrhosis. Ectopic varices may be found elsewhere in the alimentary tract, especially in the anorectum, but these seldom bleed.

Hepatic (portal-systemic) encephalopathy may occur spontaneously due to poor hepatocyte function and portal-

systemic shunting, or may be precipitated by various factors (**Table 3**). Ammonia is the best-characterised neurotoxin in the spontaneous cases; mercaptans and phenolic compounds are others. Synergism may exist between these factors. Gamma aminobutyric acid (GABA), the most important inhibitory neurotransmitter, is activated. Hyperammonaemia is associated with depletion of glutamate, the most important excitatory neurotransmitter. Decrease in concentrations of the branched-chain amino acids (valine, leucine and isoleucine) as a consequence of increased levels of aromatic amino acids has also been implicated as a mechanism.

Table 3: Precipitating Factors for Hepatic Encephalopathy

High-protein diet
Constipation
GI bleeding
Infection, including spontaneous bacterial peritonitis
Excessive diuretics causing hyponatraemia, hypokalaemia, renal failure
Sedatives and hypnotics
Interventional procedures
Surgical porto-systemic shunts

An entity of minimal hepatic encephalopathy is now being increasingly recognised on psychometric tests in 30% to 65% of patients with cirrhosis who do not have overt encephalopathy. Its clinical importance is still under evaluation, although recent data suggest that it impairs quality of life and the individual's ability to perform skilled work.

Recent evidence suggests that *cirrhotic cardiomyopathy* and *osteodystrophy* may be subclinical in most cases but are important determinants of mortality and morbidity.

INVESTIGATIONS

Among biochemical investigations, decreased serum albumin level and increased serum globulin may be the only abnormalities. Serum bilirubin and aminotransferases may be elevated in the presence of histologic activity. An AST:ALT ratio >1 in patients with chronic viral hepatitis and non-alcoholic fatty liver disease may suggest the presence of cirrhosis, particularly if associated with low platelet count. In alcoholic liver disease, the ratio is >2 even in the absence of cirrhosis. Elevated gamma-glutamyl transferase is suggestive of alcohol abuse. Serum alkaline phosphatase is elevated markedly in patients with biliary cirrhosis or sclerosing cholangitis.

Tests for hepatitis B and C viruses; autoantibodies; serum copper and caeruloplasmin and urinary copper; serum iron and transferrin; and alpha-1 antitrypsin levels should be undertaken based on the clinical suspicion of aetiology of the disease.

Psychometric tests in early cases, electroencephalography and evoked potentials may be required for the evaluation of hepatic encephalopathy. Tests for serum or cerebrospinal ammonia and glutamate are not routinely done and may be of more relevance when studied sequentially.

Imaging techniques useful in the diagnosis and evaluation of cirrhosis include ultrasonography, computed tomography (CT scan), radionuclide scan and MRI. Of these, ultrasonography is the most informative and is the least costly: apart from assessing liver size and shape, it can detect fatty infiltration, hepato-cellular carcinoma, ascites, portal hypertension and collateral circulation. Radionuclide scan can reliably differentiate cirrhosis from non-cirrhotic portal hypertension.

Endoscopy is performed to detect oesophageal varices (a reliable sign of portal hypertension) and other potential sites of bleeding. When indicated, endoscopic therapeutic measures can be instituted.

Ascitic fluid paracentesis is done to determine the characteristics of the fluid. In most of the uncomplicated cases, the fluid has low protein concentration (<2.5 g/dL) and few cells. However, in up to one-third of uncomplicated cases the protein content may be higher. A high protein level may be seen in patients on diuretics. Serum ascites albumin gradient (SAAG) of >1.1 g/dL is highly specific for ascites due to portal hypertension, even in the presence of complicating factors. Rarely (in <2% of cases), the fluid may be bloody.

A high ascitic fluid polymorphonuclear cell count (>250/mm^3) suggests spontaneous bacterial peritonitis, a complication seen more frequently in patients with low fluid protein level (<1 g/dL). Fluid adenosine deaminase levels (in tuberculous peritonitis), amylase levels (in pancreatic ascites), and cytology (in malignant ascites) should be tested when clinical suspicion exists.

Liver biopsy is the most reliable test for the diagnosis of cirrhosis but is not required if other evidence is available. It is done by the percutaneous route, usually with a biopsy gun or Tru-cut needle (suction techniques, as with the Menghini needle, are not used now). In patients with coagulopathy or ascites, transjugular biopsy is preferred. Laparoscopy with biopsy is an alternative choice. If an additional focal lesion, like hepato-cellular carcinoma, is suspected, imaging-guided biopsy is indicated.

The tissue obtained at biopsy is often fragmented. Microscopic features to be looked for include:

1. *Fibrosis*, resulting from collapse of the reticulin framework as well as replacement of the necrosed hepatocytes by collagen. The normal relationship between the vascular channels is disrupted and these may lie randomly in the fibrous septa or enclosed nodules.
2. *Activity*, manifest by parenchymal inflammatory cell infiltration and necrosis. This is considered as a sign of ongoing liver injury and hence may represent one of the indications for therapeutic intervention to arrest progression of the disease. Simultaneous regeneration may result in large binucleated cells and two-cell-thick hepatocyte plates (versus the normal one-cell-thick plates in adults). The regenerating nodules aggravate the architectural distortion caused by fibrosis.
3. *Fatty infiltration*, which when associated with Mallory hyaline bodies, neutrophilic infiltration and pericellular fibrosis, is evidence of alcohol aetiology and, in non-alcoholics, of non-alcoholic steatohepatitis. Mallory bodies are also seen in chronic cholestasis and Wilson's disease.

Positive staining with orcein occurs with hepatitis B surface antigen (HBsAg) or copper-associated protein. The latter is seen in Wilson's disease, Indian childhood cirrhosis and

chronic cholestasis. Special stains are used to detect iron (in haemochromatosis) and alpha-1 antitrypsin bodies. Bile duct damage and progressive bile duct loss are seen in primary biliary cirrhosis and sclerosing cholangitis.

Markers that have been used as surrogate for biopsy include: indirect markers (AST:ALT ratio, AST to platelet ratio index [APRI], FibroTest, and ActiTest), direct markers of extracellular matrix turnover (hyaluronic acid), and ultrasonographic evaluation of liver stiffness (Fibroscan).

MANAGEMENT

There is as yet no specific treatment for cirrhosis. Increasing evidence suggests though that the fibrosis in cirrhosis may be reversible, especially when specific therapy is available for the aetiology. Liver transplantation is the only definitive treatment for advanced disease.

A balanced diet with 1 gram protein and 30 kcal per kg body-weight per day must be ensured; malnourished patients may need more protein. Institution of adequate nutritional support actually improves morbidity and survival. The addition of choline, methionine or the other dietary 'hepatoprotective agents' has not shown any benefit. No item of diet (except salt in the salt-retaining state) needs to be restricted. Alcohol should be avoided even in non-alcoholic cirrhosis.

Hepatoprotective agents like ursodeoxycholic acid (UDCA), silymarin, and phosphatidyl choline have given variable results; theoretically, these drugs are more likely to benefit patients with precirrhotic liver disease, although UDCA has shown beneficial effects on the fibrosis in primary biliary cirrhosis. Colchicine has been used with some benefit in primary biliary cirrhosis and as an anti-fibrotic agent; however, more data are required.

Some causes of cirrhosis have specific therapy available; for example, antiviral agents in cirrhosis with activity due to hepatitis B and C, D-penicillamine or zinc therapy in Wilson's disease, iron chelation and phlebotomy in haemochromatosis, and corticosteroids and immunosuppressants in autoimmune disease.

Ascites

Bed rest and sodium restriction are of benefit in the management of ascites but are seldom adequate alone. The supine posture improves glomerular filtration rate and so is advisable especially for a few hours after a diuretic dose. Restriction of sodium intake in diet to 2-3 grams (40-60 mEq) per day helps reduce diuretic requirement; any further reduction makes food unpalatable. Fluid intake is restricted only in those with hyponatraemia.

The aldosterone antagonist spironolactone has a weaker natriuretic effect than loop diuretics but counters the secondary hyperaldosteronism in these patients. Low doses (100 to 150 mg per day) are effective in most cases but higher doses may be required in those with marked hyperaldosteronism. Amiloride is a cheaper alternative and is free of the risk of gynaecomastia that sometimes accompanies spironolactone therapy. Simultaneous administration of the loop diuretics frusemide or torsamide increases the natriuretic effect of both drugs and reduces the risk of potassium imbalance. The goal of diuretic therapy should generally be to achieve a weight loss of 0.5 kg a day in patients without peripheral oedema and up to 1 kg a day in those with oedema.

Hyponatraemia is a common complication of diuretic therapy. Approximately 20% of patients develop azotaemia due to intravascular volume depletion. These, along with the hypokalaemia complicating frusemide therapy, contribute to the precipitation of hepatic encephalopathy.

Ascites refractory to diuretics can be managed by one of the following modalities: therapeutic paracentesis (large-volume or total paracentesis with intravenous infusion of plasma expanders like human albumin or colloids); placement of transjugular intrahepatic porto-systemic stent (TIPSS); insertion of a peritoneovenous shunt (LeVeen shunt or equivalent); or portacaval shunt. The last two methods are not in favour now.

Portal Hypertension

Portal hypertension is the most common and lethal complication of cirrhosis. It is defined as clinically significant by an increase in the portal pressure gradient above 10 mm Hg (for formation of varices) or 12 mm Hg (for variceal bleeding, ascites). Varices develop in most patients during long-term follow-up.

The Sengstaken-Blakemore triple-lumen tube and its variations have been used for emergency control of variceal bleed when endoscopic therapy is not immediately available. Endoscopic band ligation is the preferred mode of treatment for bleeding oesophageal varices; injection sclerotherapy is done if band ligation is technically difficult.

Drugs used to treat portal hypertension are usually vasoconstrictors, and include vasopressin, terlipressin, somatostatin, propranolol and other beta-blockers. Vasodilators including isosorbide 5-mononitrate cause arterial hypotension, which in turn may enhance sodium retention and aggravate renal dysfunction. Failure of medical and endoscopic treatment can be managed by surgery (which is now rarely performed) or placement of a TIPSS.

Hepatic Encephalopathy

Most precipitating events for encephalopathy are correctable with appropriate therapy. Thus, fluid, electrolyte and glucose levels must be monitored and corrected where indicated; diuretic therapy may have to be discontinued, if it contributes to the imbalance. A search should be made for a focus of infection, which in most cases is either spontaneous bacterial peritonitis or urinary or lower respiratory infection. If GI haemorrhage is present, appropriate therapy should be instituted, as this will also reduce the intestinal protein load. All medication with sedative effect should be discontinued.

Dietary protein can be started as soon as the patient is able to eat, but should be restricted initially to 0.5 g per kg body weight. Vegetable proteins are safer than animal proteins. The protein intake is increased gradually with improvement, with an aim of maintaining positive nitrogen balance. Protein overload should be avoided. Addition of the branched-chain amino acids may be beneficial especially in the protein-intolerant patient.

To reduce intestinal ammonia load, the colon should be cleansed with acidifying solutions like lactulose; tap water enema is ineffective. Ammoniagenic bacteria should be eliminated with

antibiotics; rifaximin is the current choice. The non-digestible disaccharide (lactulose) can be given orally to acidify the colon; its dose should be titrated (usually 15 g 3-6 times daily) to obtain 2 to 3 soft stools a day. Lactitol is used as an alternative.

The benzodiazepine antagonist flumazenil has been tried with some benefit in hepatic encephalopathy. Results with L-dopa and bromocriptine are less promising. Extracorporeal liver assist devices and bioartificial livers are under evaluation.

COMPLICATIONS

Functional renal failure is estimated to exist in about 15% of patients admitted to hospital with ascites and in about 50% of cirrhotics who die. The risk of developing this complication in patients with ascites is estimated at 30% and 40% at 2 and 5 years, respectively. The renal failure is secondary to alterations in systemic haemodynamics and renal perfusion; the kidneys themselves are otherwise normal. The most serious clinical type ('hepatorenal syndrome') is characterised by a rapid rise in blood urea and serum creatinine, progressive oliguria, dilutional hyponatraemia and hyperkalaemia. Most patients have tense ascites. Early institution of terlipressin and albumin infusion may help arrest this otherwise fatal development.

Spontaneous bacterial peritonitis is an infection of low-protein ascitic fluid by organisms translocated from the alimentary tract. The infection is usually monomicrobial, unlike in secondary bacterial peritonitis.

Portal vein thrombosis can complicate cirrhosis. Hepatocellular carcinoma develops in 10% to 25% of patients with liver cirrhosis depending on the cause and survival duration. The risk is much higher in patients with hepatitis B or C infection; haemochromatosis, alpha-1 antitrypsin deficiency and alcoholic cirrhosis are the other at-risk groups.

The hepatopulmonary syndrome and portopulmonary hypertension are two dreaded complications of cirrhosis for which therapy (short of liver transplantation) is presently unsatisfactory.

PROGNOSIS

It is estimated that patients with compensated cirrhosis become decompensated at the rate of approximately 10% per year. Five-year survival in compensated and decompensated cirrhosis is about 50% and 20%, respectively. Ascites is usually the first sign of decompensation. Among those with ascites, presence of tense ascites or functional renal failure carries a grave prognosis, with death usually occurring within weeks or months.

The original Child-Turcotte grading of severity of liver disease into A, B and C classes considered bilirubin and albumin levels, ascites, encephalopathy and nutrition. Pugh's modification replaced prothrombin time for nutritional status, and allocated points according to severity (**Table 4**). These systems have proved useful in determining prognosis, but consideration must also be given to other factors like age, presence of viral markers, renal function, nutritional status, continued alcohol consumption, size of varices or risk of haemorrhage, and hepatocellular carcinoma. Recently, a more accurate model for end-stage liver disease (MELD) score has been used to predict survival as well as to determine priority for liver transplantation. The MELD score is calculated using the equation: 3.8 x log (e) (bilirubin mg/dL) + 11.2 x log (e) (INR) + 9.6 log (e) (creatinine mg/dL) [INR: international normalised ratio], which is easier done by logging on to dedicated websites and entering the relevant figures. Scores range from 6 (least ill patient) to 40 (sickest patient).

Table 4: Child-Turcotte-Pugh Grading of Severity of Liver Disease

Parameters	Points		
	1	2	3
Encephalopathy (grade)	None	1 and 2	3 and 4
Ascites	Absent	Slight	Moderate
Serum bilirubin (mg/dL)	1 to 2	2 to 3	>3
Serum albumin (g/dL)	>3.5	2.8 to 3.5	<2.8
Prothrombin time (seconds prolonged)	1 to 4	4 to 6	>6
Total score	CTP class		
5 to 6	A		
7 to 9	B		
10 to 15	C
